Therefore, the CGH can be designed as just a one-dimensional line grating with periodicity only along the *y*-direction. The gratings have to create 15 spots instead of lines. As a consequence, the problem of creating a 2-D output field has been separated into two one-dimensional (1-D) tasks:

- The diffractive CGH (i. e., the line grating) generates 15 spots.
- The refractive lens spreads each spot into a horizontal line.

For the second (refractive) design problem, a preliminary numerical simulation in Zemax (i. e., a ray-tracing software program) was performed. Because ray-tracing

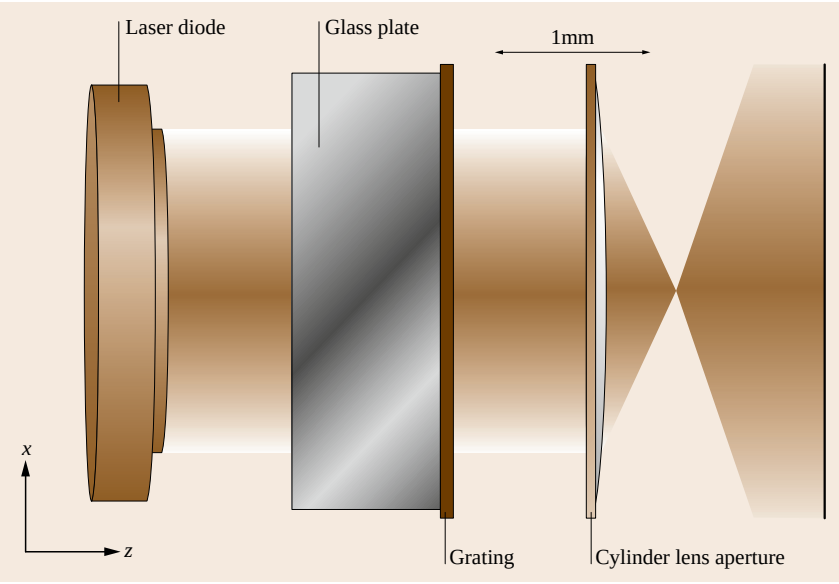

Fig. 8.23 Optical setup (*xz*-plane) of the hybrid design consisting of the DOE on the back-side of the glass plate and a cylindrical lens of radius 0.7 mm behind the DOE. The DOE is a line grating with periodicity along the *y*-direction (not visible)

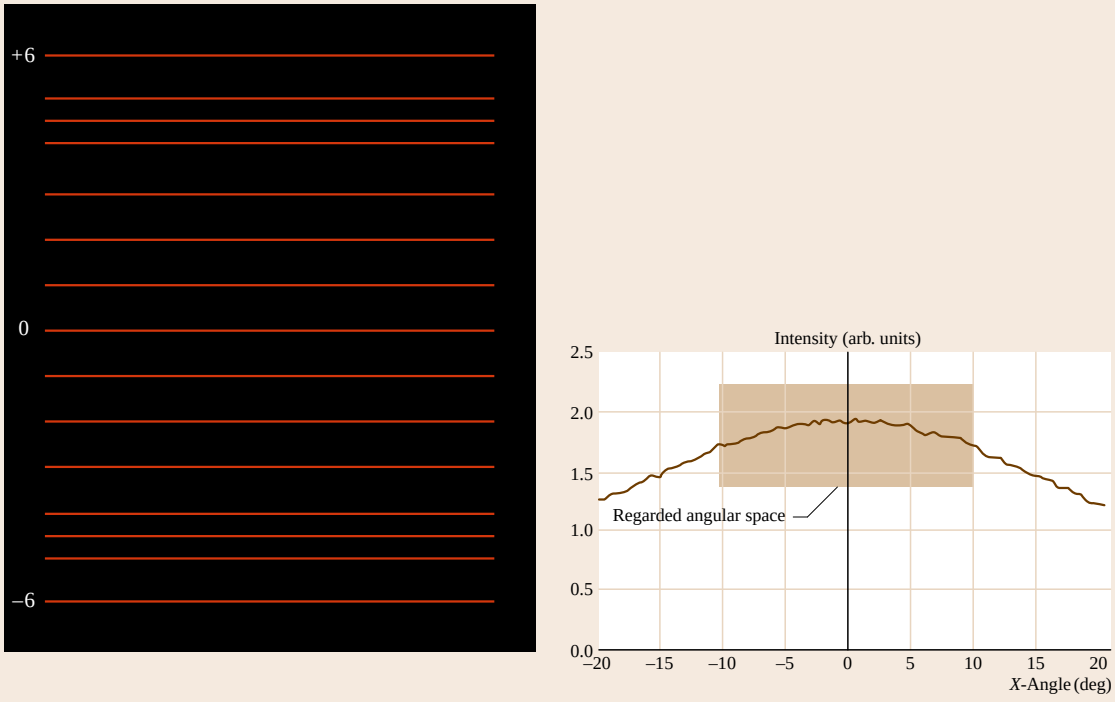

Fig. 8.24 Simulation results for the hybrid design of Fig. 8.23. The diagram shows a horizontal intensity profile for line 0. The simulation was performed with Zemax. Here, an idealized line grating has been used, which does not generate stray light

codes cannot handle wave-optical diffraction, an idealized line grating was used. Figure 8.24 displays the results. The most important conclusion is that a cylindrical lens of radius 0.7 mm (focal length ≈ 1 mm) reforms the spots into horizontal lines with Gaussian-like angular intensity distributions. Regarding only the angular space from −10° to +10° the uniformity error along one line is about 6% (see inset of Fig. 8.24). Additionally one gets slight distortion of less than 0.5% (see image corners in Fig. 8.24). To generate the 15 spots by a DOE without any stray light in between, we applied another *trick*. The complete desired DOE aperture of 3 mm × 3 mm is divided vertically into two parts of 3 mm height (see inset of Fig. 8.25). For each part a separate line grating is designed: The left CGH (called the −4B/0/+4B grating) generates the lines −4B, 0, and +4B. The right one (denoted as the −6 to +6 grating) creates the 13 lines from −6 to +6. Note that line 0 is intentionally generated twice (as discussed later).

Figure 8.25 shows the two calculated grating phase profiles. Both CGHs were designed using VirtualLab4 and its beam-splitter optimization algorithms. The corresponding grating periods $D_y^{\max}$ were chosen as $34 \times 750\,\text{nm} = 25.5\,\mu\text{m}$ (−6 to +6 grating) and $7 \times 750\,\text{nm} = 5.25\,\mu\text{m}$ (−4B/0/+4B grating). These val-

Table 8.5 Calculated key figures for the optical performance of the hybrid design

Parameter	Value	Min.	Max.	Target
Linewidth	0.05	0.05	0.2	0.1
Conversion efficiency	≈ 20%	70%	–	80%
Rel. zeroth-order intensity	0%	–	5%	1%

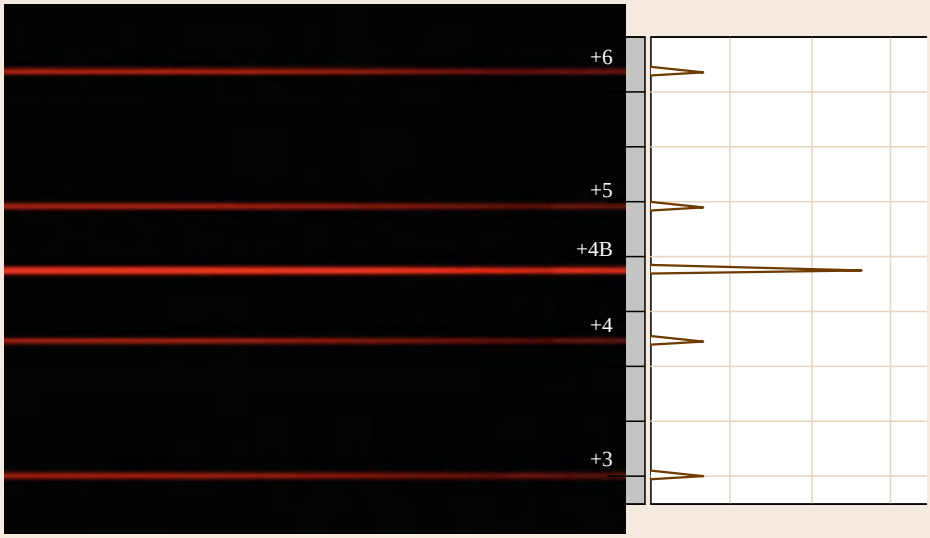

Fig. 8.27 Numerical design results for the hybrid design. The shown detail exhibits the total field size of H6°, V5.5° and is centered at the angular position H8°, V + 6.75°. The simulation was performed with VirtualLab4, a wave-optical software

ues correspond to angular resolutions $\Delta\alpha_y^{\min}$ of 1.48° and 7.22°, respectively, and are close to the specified line spacings of 1.5° and 6.75° (between line 0 and ±4B). These choices for $\Delta\alpha_y^{\min}$ guarantee a negligible amount of stray light (and no ghost lines) in between the lines.

Figure 8.26 displays the optical performance for both gratings. From the variation of the relative spot intensities, an *interline* uniformity error of about 10% can be extracted. This is slightly more than the above-discussed *intraline* uniformity error of about 6%.

It is important to note that the hybrid design possesses a *mechanical* degree of freedom concerning the horizontal adjustment of the DOE with respect to the laser beam position (inset of Fig. 8.25). The −6 to +6 grating distributes the incident laser power into 13 lines, i. e., about 8% per line. The −4B/0/+4B grating spreads the incident power into three lines, i. e., about 33% per line. In order to give lines −4B and +4B the same power as the other lines, about 85% of the input power has to hit the −6 to +6 grating while 15% should illuminate the −4B/0/+4B grating. This can be adjusted by moving the DOE horizontally (inset of Fig. 8.25). Through such adjustment, it is also possible to increase or decrease the power in line −4B and +4B relative to lines −6 to +6.

However, for the present design the power portion in line 0 is two times higher than the other lines, because line 0 is (in order to further decrease stray light) part of both the −6 to +6 grating and the −4B/0/+4B grating. However, if this is not allowed, one of the two gratings has to be modified to exclude line 0.

Finally, the complete hybrid design was simulated by wave optics in VirtualLab4, which accounts for granularity and diffractive stray-light effects. Figure 8.27 displays a detail of the calculated output field between line +3 and +6. In this simulation we intentionally enhanced the power of line +4 (using the *mechanical* adjustment described above) by a factor of 4.

The most important feature of the hybrid design is that neither granularity effects nor stray light (especially ghost lines) can be detected. However, the expected intensity decrease towards higher horizontal angles can also be seen (see the discussion relating to Fig. 8.24). For the sake of completeness, Table 8.5 summarizes the key optical figures of the hybrid design.

For the given example problem we have presented and discussed three DOE design strategies which aim to optimize different key optical performance figures. For most practical design problems, it is not possible to meet all of the challenging optical specifications. Therefore, it is crucial for the designer to have different design options and strategies. This chapter intends to give the reader some guidance for the choice of an appropriate layout.

8.4 Subwavelength Structured Elements

When light is incident on a surface-relief grating with period Λ the angles of the transmitted diffraction waves $\theta_{t,m}$ in the m-th diffraction order are given by the grating equation

$$\sin\theta_{t,m} = \frac{m\lambda}{\Lambda n_2} + \frac{n_1}{n_2}\sin\theta_i \,. \tag{8.55}$$

Here n_1 and n_2 are the refraction indices of the incident and the transmitting medium, respectively, θ_i is the incidence angle as measured from the grating's surface normal, and λ is the incident free-space wavelength.

If the period of the diffraction grating becomes much smaller than the optical wavelength λ, we find that only the zeroth order is allowed to propagate and all the other orders are evanescent

$$\Lambda \ll \lambda \rightarrow m = 0 \,. \tag{8.56}$$

The subwavelength-structured interface is optically equivalent to an unstructured film whose optical properties vary with profile depth. The substitution of an effective material for a high-frequency grating allows its description by effective medium theory (EMT). The effective index of refraction can be tailored to a chosen quantity by adjusting the fill factor of the grating structure. Figure 8.28 shows selected geometries of subwavelength structures and the corresponding index of refraction profiles resulting from EMT. A simple binary subwavelength grating translates into a single layer with a refractive index n_{eff} between n_1 and n_2 which is dependent on the fill factor. In the case of a multilevel surface relief profile the effective medium is a film stack where each layer corresponds to a distinct level of the surface relief profile. A triangular subwavelength grating is equivalent to a graded index-modulated surface in which the refractive index is converted from the incident medium to the substrate.

These effective media are also discussed in terms of artificial dielectrics because the subwavelength structures allow access to material properties that normally do not exist in inorganic glasses or optical polymers. The characteristics of the effective media offer a wide variety of applications and the realization of different components such as wave plates [8.65–67], antireflection surfaces [8.68–72], polarization sensitive elements [8.73–77] or blazed gratings and lenses [8.78–82].

8.4.1 Wave Plates

Wave plates are optical components to control the polarization of the electric field vector. For example a $\lambda/4$ wave plate is often used to convert linearly polarized light into circularly polarized light or vice versa and a $\lambda/2$ wave plate is commonly introduced to cause a rotation of linearly polarized light by 90°. The control mechanism of the wave plates is based on the different phase velocities for corresponding polarization directions in an anisotropic medium. Conventional wave plates are made of anisotropic birefringent materials such as calcite, quartz or mica.

An alternative type of wave plate can be realized by the form birefringence of subwavelength structures [8.83]. Here different indices of refraction for orthogonal polarization directions are correlated to the variation of the fill factors with the direction. In the following the basic principal of that kind of form birefringence will be discussed by analyzing the binary and lamellar relief structure of Fig. 8.28. Let ε_1 be the dielectric constant of the covering medium (spaces) and ε_2 the dielectric constant of the lamella material (lines). Further, consider a plane monochromatic wave which is incident on the zeroth-order grating and assume an electric field vector which is perpendicular to the lamellas.

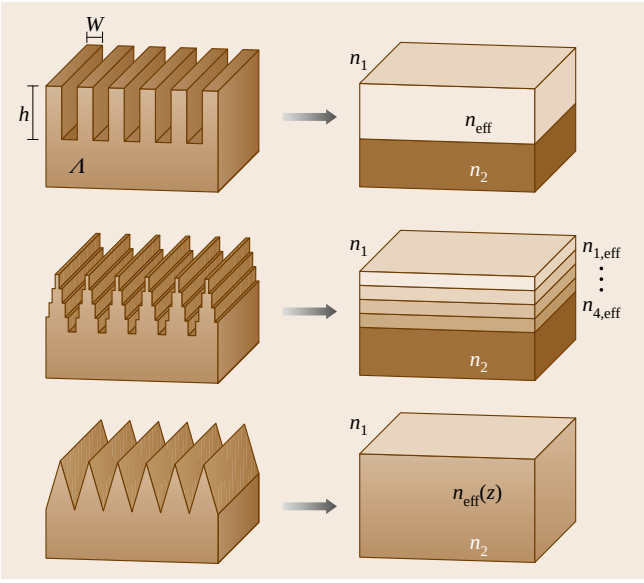

Fig. 8.28 Illustration of different diffractive subwavelength structures and their thin-film equivalents from effective medium theory

Following the boundary conditions of Maxwell's equations the normal component of the electric displacement $\boldsymbol{D}$ must be continuous across the interface between the lines and spaces so that for the corresponding electric fields $\boldsymbol{E}_1$ and $\boldsymbol{E}_2$ follows

$$\boldsymbol{E}_1 = \frac{\boldsymbol{D}}{\varepsilon_1}, \quad \boldsymbol{E}_2 = \frac{\boldsymbol{D}}{\varepsilon_2} . \tag{8.57}$$

A volume averaging of the electric field $\boldsymbol{E}$ leads to the effective dielectric constant $\varepsilon_{\perp}^{(0)} (= \boldsymbol{D}/\boldsymbol{E})$

$$\varepsilon_{\perp}^{(0)} = \frac{\varepsilon_1 \varepsilon_2}{\varepsilon_1 f + \varepsilon_2 (1-f)} , \tag{8.58}$$

where the ratio $f = W/\Lambda$ represents the volume fraction or fill factor of the grating (W is the width of a single grating bar).

On the other hand, when the incident field has its electric field vector parallel to the lamellas then the tangential component of the electric vector is continuous across the discontinuity and for the electric displacements in the two regions it follows that

$$\boldsymbol{D}_1 = \boldsymbol{E}\,\varepsilon_1, \quad \boldsymbol{D}_2 = \boldsymbol{E}\,\varepsilon_2 . \tag{8.59}$$

The averaging of the electric displacement $\boldsymbol{D}$ now leads to an effective dielectric constant $\varepsilon_{\parallel}^{(0)}$

$$\varepsilon_{\parallel}^{(0)} = \varepsilon_2 f + \varepsilon_1 (1-f) . \tag{8.60}$$

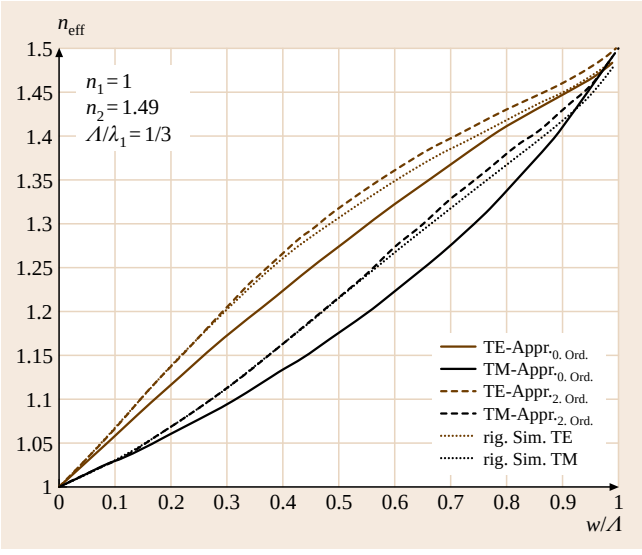

Fig. 8.29 Effective index of refraction as a function of the fill factor for different polarization directions calculated with the zero- and second-order EMT. Additionally RCWA was applied

With the refractive index $n = \sqrt{\varepsilon}$ we find a form birefringence of the subwavelength grating

$$\Delta n = \sqrt{\varepsilon_{\parallel}^{(0)}} - \sqrt{\varepsilon_{\perp}^{(0)}} . \tag{8.61}$$

For an incident wave normal to the grating and polarized at 45° with respect to the grating orientation, the phase retardation ϕ caused by a grating with relief depth h is

$$\phi = \frac{2\pi}{\lambda} \Delta n h . \tag{8.62}$$

The subscript (0) in the presented formulas for $\varepsilon_{\perp}^{(0)}$ and $\varepsilon_{\parallel}^{(0)}$ indicates a zeroth-order approximation with respect to the profile period-to-wavelength ratio Λ/λ. To obtain higher-order approximations in Λ/λ for the effective optical properties, it is necessary to analyze the field distributions in a nonstatic manner [8.84]. Following this approach the second-order expression in terms of the ratio Λ/λ for the effective dielectric constants are represented for both polarization directions by

$$\varepsilon_{\parallel}^{(2)} = \varepsilon_{\parallel}^{(0)} \left[1 + \frac{\pi^2}{3} \left(\frac{\Lambda}{\lambda} \right)^2 f^2 (1-f)^2 \frac{(\varepsilon_2 - \varepsilon_1)^2}{\varepsilon_0 \varepsilon_{\parallel}^{(0)}} \right] , \tag{8.63}$$

$$\varepsilon_{\perp}^{(2)} = \varepsilon_{\perp}^{(0)} \left[1 + \frac{\pi^2}{3} \left(\frac{\Lambda}{\lambda} \right)^2 f^2 (1-f)^2 \times (\varepsilon_2 - \varepsilon_1)^2 \frac{\varepsilon_{\parallel}^{(0)}}{\varepsilon_0} \left(\frac{\varepsilon_{\perp}^{(0)}}{\varepsilon_1 \varepsilon_2} \right)^2 \right] . \tag{8.64}$$

Figure 8.29 shows the effective index of refraction as a function of the fill factor for different polarization directions calculated with both the zeroth- and second-order approach. Additionally, as an exact but time-consuming benchmark, the fully vector electromagnetic method of rigorous coupled wave analysis (RCWA) has also been applied to investigate the accuracy of both approaches. For this diagram the incident medium was taken to be air ($n_1 = 1$), the substrate medium has a refractive index of $n_2 = 1.49$ and the period-to-wavelength ratio was set to be $\Lambda/\lambda = 1/3$.

In all three cases the deviation between the orthogonal polarization directions becomes significant in the central region where the dimensions of lines and spaces are similar. In the peripheral regions, where either the lamellas or the spaces become small compared to the grating period, the effective refractive indices reach the limiting values of the homogeneous substrate or air.

Within the three methods, the second-order approximation and the RCWA results are broadly correspondent, while the values calculated with the zeroth-order approximation are too small and therefore less suitable for accurate predictions.

Subwavelength structures which are periodic in two dimensions (2-D) show a polarization sensitivity that is dependent on the fill factor (L_x/Λ_x, L_y/Λ_y) and periodicity (Λ_x, Λ_y) in the orthogonal directions. A schematic view of such a 2-D structure is depicted in Fig. 8.30. It consists of an array of dielectric homogeneous pillars with a rectangular cross section periodically immersed in a second dielectric medium. In the totally symmetric case the periods and the widths of the pillars are identical in both dimensions which results in polarization insensitivity and a symmetry in the effective permittivity.

Instead of a corresponding EMT for the 2-D structures, several different approximations have been developed and compared to RCWA calculations [8.71, 72, 85]. The various approximations are based on different averaging procedures assuming that the effective permittivity of a 2-D structure is somewhere between the values for the orthogonal one-dimensional (1-D) structures. It has to be mentioned that a simple volume averaging is insufficient, but to get a more accurate result a complex consideration has to be carried out. In an exemplary extended averaging procedure the periodic binary rectangular structure is replaced by two different orthogonal one-dimensional structures. Here the permittivities of the two corresponding one-dimensional grating bars are set to be $\varepsilon_\perp$ and $\varepsilon_\parallel$, as calculated from the permittivity of the pillars [8.72].

Although 2-D effective-medium approximations show an acceptable validity especially in the long-wavelength limit, today increasingly rigorous design methods are applied. Here the further development in computing hardware and software reduces time and storage issues.

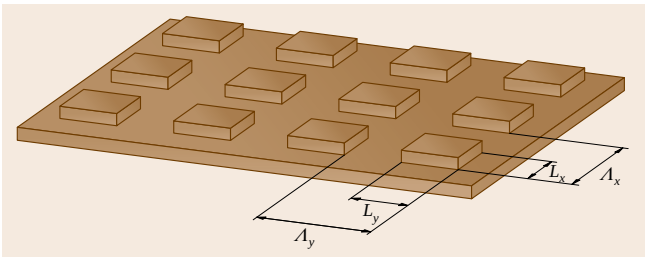

Fig. 8.30 Schematic view of a binary 2-D effective medium

8.4.2 Antireflection Gratings

The reduction of Fresnel reflections at optical interfaces is an issue of enormous interest in a wide range of optical applications. Today antireflection (AR) coatings are most frequently based on multilayer interference structures with alternating high and low refractive indices. An alternative to the multilayer films are subwavelength structured antireflection surfaces, which provide a graded transition between the refractive indices of the two interfacing media. Such antireflective structures are also found in nature on the corneal surfaces of night-active insects [8.68, 86]. For example Fig. 8.31 shows scanning electron microscope images of a typical moth eye. In the upper image the hexagonal array of the facets of the compound eye is clearly visible. With increasing magnification (lower part) an area covered with conical and uniform protuberances is observable. The diameter of each protuberance is about 100 nm and the spatial periodicity is approximately 170 nm, well below the wavelength of the visible spectrum.

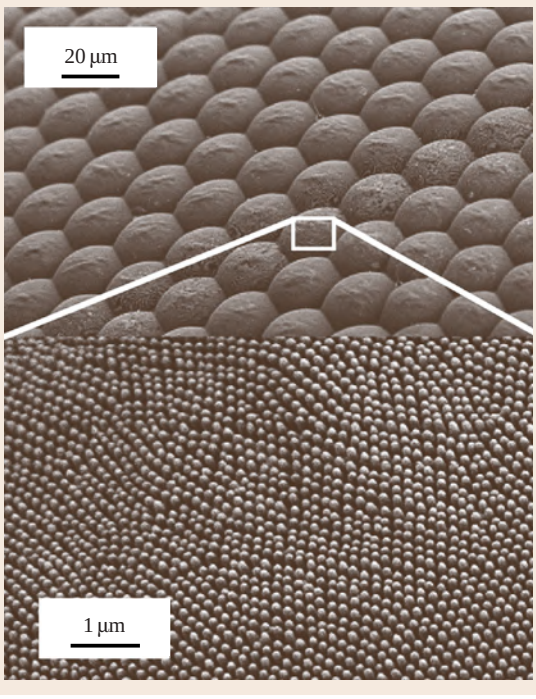

Fig. 8.31 Scanning electron microscopy images of a night-active insect. The *upper part* shows the hexagonal structure of the compound eye. With increased magnification (*bottom*) a subwavelength periodic surface corrugation becomes visible (courtesy of Prof. J. Spatz)

Different characteristics of subwavelength AR structures are advantageous compared to stacks of thin dielectric films, e.g., thin-film coatings may suffer from adhesion problems especially when the thermal expansion coefficients of substrate and layer material are different and the optical devices are used over a broad thermal range. Additionally, due to the restrictions in thin-film coating materials, the available number of discrete refractive indices is also limited. A further aspect concerns the sensitivity of the reflectance to incident angle or wavelength. Here, in general, a subwavelength AR structure tolerates more variations compared to simple layer configurations.

A binary pillar subwavelength structure (Fig. 8.28 top) shows an antireflection performance comparable to that achieved by an elementary single-layer dielectric coating. Following thin-film theory a single layer will exhibit minimum reflectivity at normal incidence when the reflectance from the air–film interface interferes destructively with the reflection at the film–substrate interface. This phase condition is fulfilled when the depth of the profile h satisfies

$$h = \frac{\lambda_0}{4n_{\text{Layer}}} \,. \tag{8.65}$$

Additionally, complete destruction will only occur if the amplitudes of both reflecting waves are identical, which implies an amplitude condition for the refractive index of the layer n_{Layer}

$$n_{\text{Layer}} = \sqrt{n_1 \cdot n_2} \,. \tag{8.66}$$

Exemplary, to fulfill the last equation for the interface between air ($n_{\text{air}} = 1$) and a typical inorganic glass (assumption $n_{\text{g}} = 1.5$) the refractive index of the layer has to be $n_{\text{Layer}} \approx 1.22$ which is not available for thin-film materials. On the other hand, subwavelength structured effective media have the ability to control the effective index of refraction by simply adjusting the fill factor so that in principal each value is possible.

An extension to the single-layer equivalent binary subwavelength grating with improved optical performance is offered by the introduction of a multilevel stair-step surface relief (Fig. 8.28 center). A stair-step multilevel grating consisting of N steps shows similar optical characteristics compared to a traditional thin-film coating of N homogeneous layers. The optical properties of each individual layer are mainly dependent on the particular fill factor. In comparison to simple binary subwavelength gratings, the multilevel stair-step grating permits a large wavelength bandpass and is more tolerant against variations in the angle of incidence [8.87]. For triangular structured surface profiles (Fig. 8.28 bottom) the effective medium has gradient optical properties. By proper design of such surfaces extremely low reflectances can result [8.88].

Different techniques such as e-beam writing and mask-lithography [8.89] have been applied to realize master structures of subwavelength gratings. Among them, interference lithography (IL) has the advantage of allowing the realization of the complete array in a single exposure step over a large area. In the IL process, a photoresist-coated substrate is exposed with an interference fringe pattern generated by coherent beams [8.69, 90], where the grating period Λ is given by

$$\Lambda = \frac{\lambda}{2n \sin\theta} \,. \tag{8.67}$$

Here λ is the exposure wavelength, n is the refractive index, and θ is the half-angle between the interfering light waves under the condition of symmetric incidence. In air, the minimal obtainable grating period using counter-propagating waves ($\theta = 90°$) is therefore $\lambda/2$. To realize a periodic 2-D structure double- or multiple-exposure techniques are necessary with a defined rotation of the sample between the single exposure steps. During the recording process, a latent structure is created in the resist, which is transformed into a continuous surface phase profile in the subsequent development process. After the development process a stabilization of the pattern structure and an adjustment of the profile depth can be realized by selective reactive ion beam etching.

At the top of Fig. 8.32 a scanning electron microscope image of a linear photoresist grating is presented in side view. The sinusoidal corrugation shows a period of 140 nm and a depth of 70 nm. The identical spatial period in a two-dimensional pattern is obtained by double exposure and rotation of the sample by 90° (atomic force microscope (AFM) scan at the bottom of Fig. 8.32).

The structures were realized by the use of a frequency-quadrupled Nd-YAG laser with 266 nm wavelength. Deep-UV interference lithography requires additional process steps including pre- or soft-bake and post-exposure bake. Soft bake is necessary for solvent removal, stress reduction and resist planarization. The process of post-exposure bake is an essential, critical and indispensable step to guarantee solubility of the optical exposed areas of these chemical amplified photoresists. These technological procedures have to be

performed very carefully to ensure constant conditions and to obtain reproducible and defined profile parameters.

Figure 8.33 shows the measured transmission as a function of the wavelength of three samples of subwavelength crossed gratings. The profile was transferred into fused silica by a reactive-ion etching process. Here the depth of the etched structure is 300 nm and the diameter of the pillars is about 85 nm. In comparison to an unstructured surface, the transmission is increased significantly across a broad spectral range in the visible spectrum.

Using immersion configurations in the IL process allows a further reduction of feature sizes. In the accompanying exposure setup the photoresist-coated substrate is typically sandwiched between UV-transparent prisms using an immersion liquid with a matched refractive index. The minimal period is decreased by a factor given by the refractive index of the immersion medium. The scanning electron microscope images presented in Fig. 8.34 show patterns with a grating period of 93 nm (10 800 lines/mm) which were obtained by single (Fig. 8.34a) or double (Fig. 8.34b) exposure using 266 nm immersion lithography. This structures are developed to serve as AR coatings for deep-UV applications.

Fast and cheap alternative methods to create subwavelength structures are offered by bottom-up technologies which are based on self assembly processes. Here of special interest is the block copolymer micelle nanolithography (BCML) [8.91–93] which allows to fabricate antireflective moth-eye structures not only on flat substrates, but also on optical elements with even small radius of curvature and on the surfaces of microoptical elements.

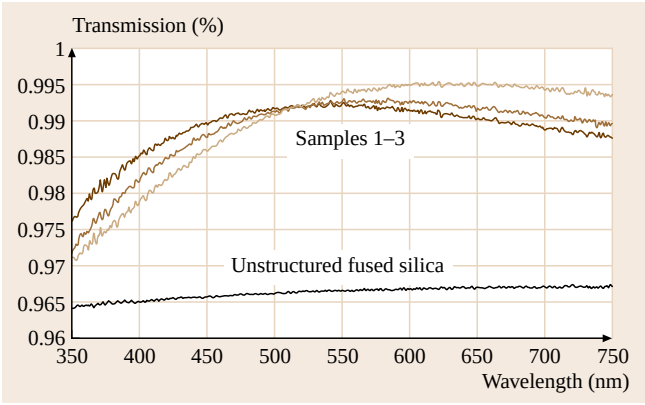

Fig. 8.33 Measured transmission in dependence on the wavelength for three samples of subwavelength crossed gratings in fused silica. The depth of the structure is 300 nm and the diameter of the pillars is about 85 nm. In comparison to an unstructured surface, the transmission is increased significantly across a broad spectral range in the VIS

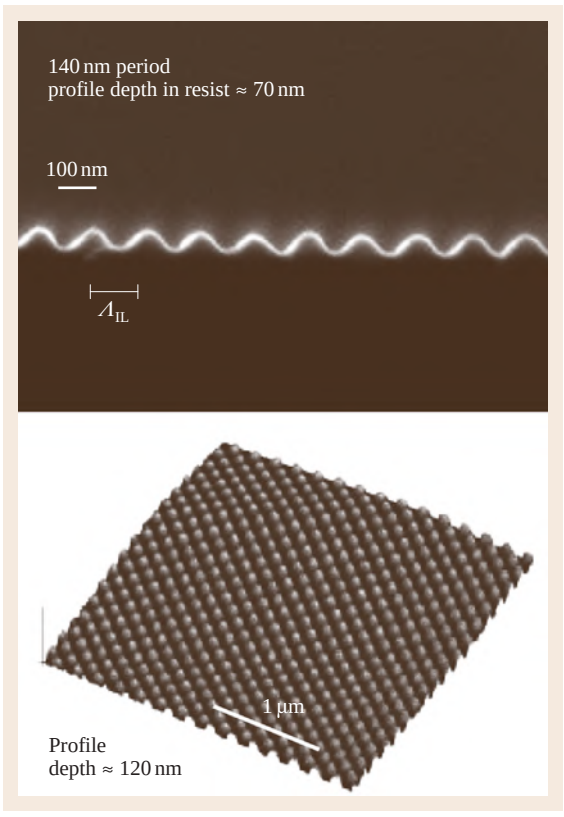

Fig. 8.32 *Moth eye* surfaces generated by interference lithography (IL)

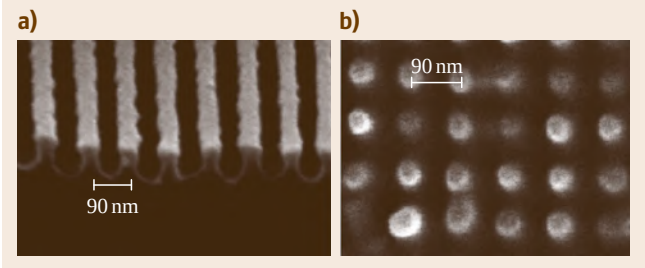

Fig. 8.34a,b Scanning electron microscope images of gratings with periods of 93 nm (10 800 l/mm). The gratings were obtained by single **(a)** and double **(b)** exposure technique using 266 nm immersion lithography

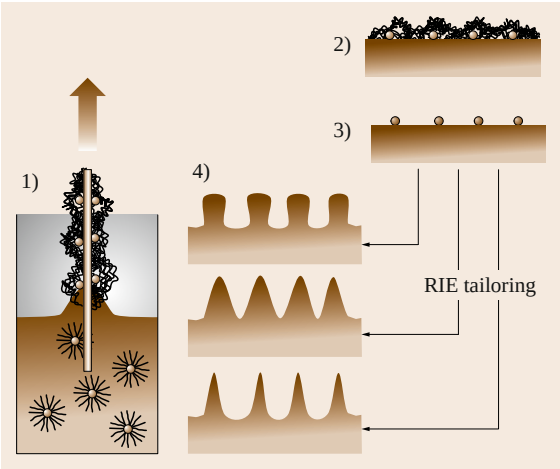

Fig. 8.35 Schematic illustration of the BCML process to create subwavelength antireflective structures

In the BCML process a hexagonal mask of gold nanoparticles can be prepared by simply dipping the substrates in a solution of special diblock copolymers in toluene with tetrachloroaurate ($HAuCl_4$).

In the solution uniform spherical micelles are formed with gold mainly representing the micellar core. By controlling the speed of the retraction of the substrates the distance of the nanoparticles can be adjusted precisely. Typical distances are in the range between 20 and 150 nm and therefore the technique is well-suited for generating subwavelength structures even for the UV and DUV range. Finally, the polymer shell is removed by subsequent plasma treatment. Dip-coating has a substantial advantage over other methods since it enables a fast and homogeneous coating of plane and curved substrates. Lenses of several square centimeters in diameter can be coated within minutes with high accuracy and reproducibility. A schematic of the sample processing is depicted in Fig. 8.35.

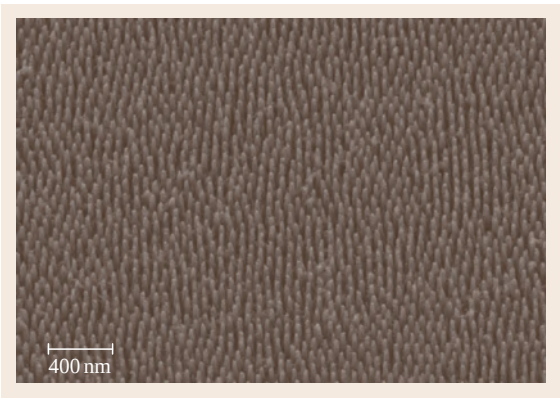

Fig. 8.36 Scanning electron microscope images of moth eye structures manufactured by BCML (courtesy of Prof. J. Spatz)

In a subsequent reactive ion etching (RIE) process the mask structure is transferred into the substrate material. Depending on the adjusted multistep RIE process parameters nanostructured surfaces with tailored antireflective properties can easily be fabricated that show optimum performance for specific applications. With this method subwavelength structured surfaces of arbitrary heights between 150 and 250 nm and adjustable lattice spacing are obtainable (Fig. 8.36).

8.4.3 Polarization-Sensitive Elements

Historically, the wire-grid polarizer (WGP) was perhaps the first component to make use of the properties of subwavelength structured gratings as it was applied by Heinrich Hertz to investigate the properties of the newly discovered radio waves at the end of the 19-th century. Meanwhile, with constant progress in manufacturing technologies, the wire-grid polarizer is also available for the infrared and the optical wavelength region as well.

The classical WGP consists of a subwavelength periodic grid of parallel, self-supporting and perfectly conducting wires. This structure is characterized by a high reflectivity of transverse electric (TE) polarization and simultaneously a high transmittance of the transverse magnetic (TM) polarization of the incident electromagnetic radiation.

For applications in the visible spectral range WGPs are realized as subwavelength-period metal gratings deposited on a dielectric substrate. The introduction of additional dielectric layers sandwiched between the metal grid and the supporting substrate allows the adjustment of the spectral operation bandwidth and to relax the tolerances of the acceptance angle [8.94]. A further extension to control the polarization properties of the WGP is possible when the subwavelength-period grating is already formed in the dielectric medium and the metal stripes are supported on the dielectric bars.

Due to their specific optical characteristics and the compactness, WGPs became of particular interest in projection display applications especially when combined with liquid crystal on silicon (LCoS) imager systems [8.95, 96]. In these setups, the WGP acts as a beam splitter, separating the incoming illumination radiation and the back-reflected and polarization-rotated light coming from the LCoS panel.

Commonly the working principal of the WGP is explained by the dissimilar electron mobility parallel and perpendicular to the metal wires. If the incident wave is polarized along the wire direction, a corresponding electron oscillation is induced. The reradiated wave cancels the incident wave in the forward direction, so that the wave is totally reflected. In contrast, if the incident wave is polarized perpendicular to the wire grid, and if the wire spacing is wider than the wavelength, then the oscillation of the electrons is restricted and the incident wave transmits the structure.

The approach of effective-medium theory (EMT) to describe the characteristics of subwavelength structured devices is also applicable to WGPs [8.97]. Hereby, the transmission and reflection properties of the wire grid polarizers can be estimated by inserting a complex value for the refractive index n_1 of the metal.

$$n_1 = n + \mathrm{i}\kappa \tag{8.68}$$

For a highly conducting metal $\kappa \gg n$ and spacers made of perfect insulators (n_2) the refractive indices for both polarization directions become:

$$n_{\parallel} = \mathrm{i}\kappa\sqrt{f}\,, \tag{8.69}$$

$$n_{\perp} = n_2/\sqrt{1-f}\,. \tag{8.70}$$

In the case when the wire grids are made of perfect conductors and the dielectric spacers are made of perfect insulators, the incident radiation with a polarization parallel to the wire grids interacts with the medium equivalent to a metallic layer and is reflected. In contrast, for incident radiation polarized perpendicular to the wire grids, the element behaves as a perfect dielectric layer and the radiation is mainly transmitted.

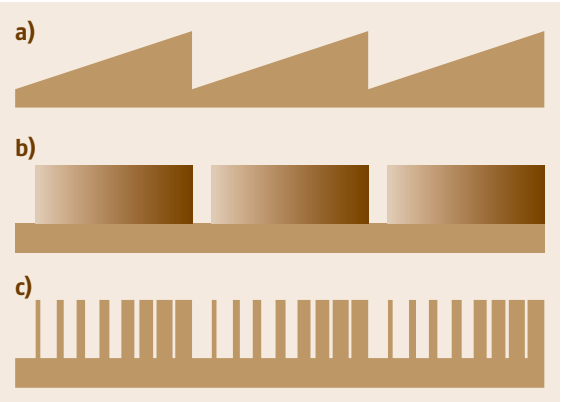

Fig. 8.37a–c Illustration of (**a**) blazed sawtooth profile, (**b**) blazed index and (**c**) blazed binary gratings

In more-realistic scenarios the assumption of perfect conductivity is not suitable and therefore rigorous calculations become necessary to calculate the polarizing properties of the structures.

A different type of polarization-sensitive elements that provides a high polarization extinction ratio is based on a subwavelength structured multilayer system of alternating layers of dielectric materials with high and low refraction indices [8.73, 74]. In this approach the properties of anisotropic spectral reflectivity is realized by combining the effects of form birefringence of a high-spatial-frequency grating with the resonant reflectivity of a multilayer structure.

8.4.4 Subwavelength Blazed Gratings and Lenses

In the previous discussions on wave plates, antireflection coatings and polarizers based on subwavelength structures the properties of this artificial effective media were treated similarly to homogeneous thin films. Additionally, high-spatial-frequency structures can also be used to realize high-efficiency diffractive elements such as gratings and diffractive lenses.

The basic idea is a lateral tailoring of the local effective index of refraction by controlling the feature size of the subwavelength structures. Each individual period of a diffractive element which is larger than the wavelength is composed of a sublattice with variable width

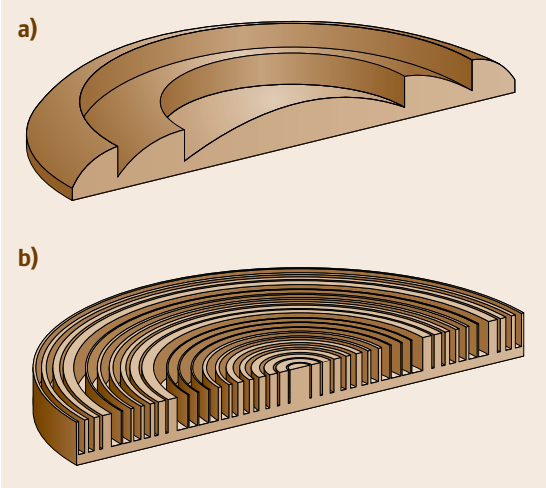

Fig. 8.38a,b Schematic comparison of diffractive lenses: (**a**) surface relief profile; (**b**) blazed binary approach

of lines and spaces forming a subwavelength binary surface profile.

The principal concept is illustrated in Fig. 8.37. A classic sawtooth blazed profile guarantees a continuous linear phase shift along each individual period by varying the depth of the structure in a material of constant refractive index and shows a phase step of 2π at the end of each period (Fig. 8.37a). The analog phase distribution can be modeled by a gradient index material with constant height (Fig. 8.37b). In this so-called blazed index grating, the refractive index is varying linearly and continuously from 1 to a maximum value within the period. In a blazed binary grating (Fig. 8.37c), the continuous gradient material is approximated by the variation of the structural dimensions of the binary subwavelength features.

For the first time the physical principle of this artificial distributed-index media was verified by the use of water waves [8.78, 98]. The concept was transferred to the infrared spectral range at 10.6 μm [8.99] and was also applied to near-infrared and optical wavelengths [8.97, 98].

Blazed binary gratings allow a highly efficient coupling of light into the first diffraction order [8.79] which may even exceed the properties of a conventional blazed grating [8.81]. This enhanced performance has been interpreted as a pillar waveguiding effect responsible for a drastic reduction of the shadowing zone [8.99].

As an illustration, Fig. 8.38 shows a schematic comparison of a conventional diffractive lens based on a sawtooth surface profile and a subwavelength diffractive lens.

8.5 Electrooptic Modulators

An electrooptic modulator (EOM) can be used to control the amplitude, phase, frequency, polarization or propagation direction of a light wave electrically. EOMs are typically used for external modulation of light sources, thus avoiding amplitude, frequency and linewidth stability issues associated with direct modulation.

EOMs in general consist of an electrooptic material embedded between a pair of plated electrodes. A voltage applied to these electrodes generates an electric field oriented mostly perpendicularly to the electrode surfaces. The field induces changes in the material structure or orientation and thus the refractive index or birefringence of the material is modulated by the electric field.

Two fundamental setups of EOMs can be differentiated: the *longitudinal-oriented modulation* where the light wave propagates parallel (Fig. 8.39a) to the electric field direction and *transverse-oriented modulation* with the light wave propagating perpendicularly (Fig. 8.39b) to the electric field. In the case of the longitudinal configuration the electrodes must be transparent to the light to be modulated or a small aperture in each electrode must allow the light to propagate through the modulator.

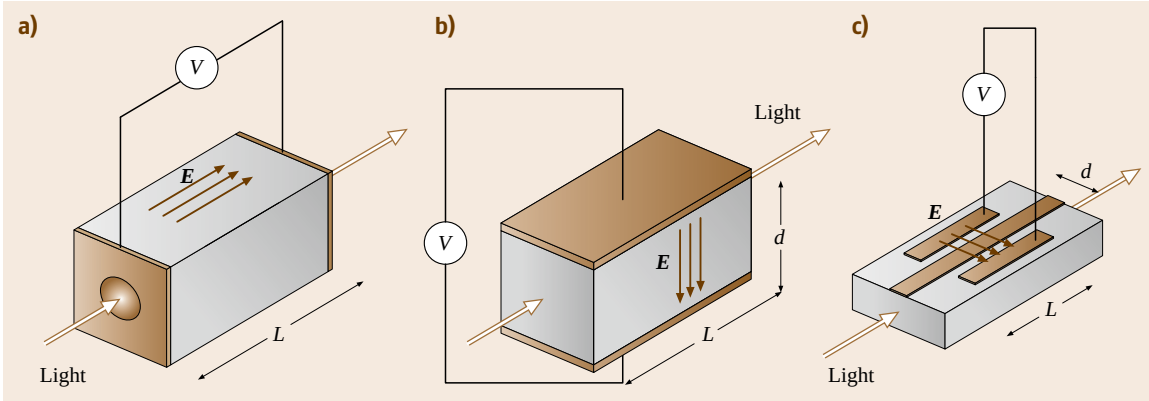

Fig. 8.39 **(a)** A longitudinal-oriented EOM has the ***E*** field applied parallel to the light-propagation direction, **(b)** whereas in the transverse oriented EOM the light wave is propagating perpendicularly to the ***E*** field. **(c)** An integrated optical modulator of transverse type

EOM devices can be constructed as bulk or as integrated optical devices (Fig. 8.39c). *Bulk modulators* are made out of discrete pieces of electrooptical materials such as lithium niobate $LiNbO_3$, and lithium tantalate $LiTaO_3$. These materials have high electrooptical coefficients and can be used over a wide range of wavelengths.

Integrated optical modulators are wavelength-specific due to the waveguide technology used. They are used in transverse modulation schemes that allow the width of the waveguide to be much smaller than its length. Thus, the half-wave voltage (8.76) is very small (typically a few volts) compared to the high voltage requirements of bulk modulators (up to tens of kV). In [8.100] a $BaTiO_3$-based modulator is reported with broadband modulation up to 40 GHz and a half-wave voltage of 3.9 V.

Some applications of electrooptic modulators are Q-switching, all optical switching, active mode locking and laser-disc recording.

Pockels and Kerr Effects

Electrooptic material change their optical properties when affected by an external electric field due to the altered position, orientation or shape of the material's structure. When an electric field E is applied the refractive index as a function of E (Fig. 8.40) can be expressed as

$$n(E) = n - \tfrac{1}{2} k_{\text{Pockels}} n^3 E - \tfrac{1}{2} k_{\text{Kerr}} n^3 E^2 \,. \qquad (8.71)$$

If the change in refractive index is mostly linearly proportional to the applied field strength then the effect is known as the linear electrooptic effect or Pockels effect, with

$$n(E) = n - \tfrac{1}{2} r_{\text{Pockels}} n^3 E \,, \qquad (8.72)$$

where r_{Pockels} is the linear electrooptic coefficient or Pockels coefficient.

The value of the electrooptic coefficient r depends on the directions of the light and the orientation of the applied electric field since the crystal is anisotropic.

In isotropic materials such as gases, liquids or centrosymmetric crystals the linear coefficient is zero and the change in the index of refraction depends on the square of the applied electric field. This is known as the quadratic electrooptic effect or Kerr effect, with

$$n(E) = n - \tfrac{1}{2} r_{\text{Kerr}} n^3 E^2 \,, \qquad (8.73)$$

where r_{Kerr} is the quadratic electrooptic coefficient or Kerr coefficient.

Considering an average value for $r_{\text{Pockels}} = 10\,\text{pm/V}$ and a modulation voltage of $V = 10\,\text{kV}$ (which results in an electrical field strength of $E = 10^6\,\text{V/m}$ in a 1 cm-thick medium), the electrically induced change in refraction index is approximately 10^{-5}. The same range is achieved when using the Kerr effect with an average value of $r_{\text{Kerr}} = 10\,\text{am}^2/\text{V}^2$. Although this change in refractive index is very small it will result in a significant phase shift for a wave propagation distance that is much greater than a wavelength of the light. For the given example the phase shift will be approximately $\pi/2$ for a wavelength of 600 nm.

An anisotropic electrooptical crystal with Pockels characteristic (with the electrooptic coefficient k_{Pockels}) will be considered in the following compilation of modulation techniques.

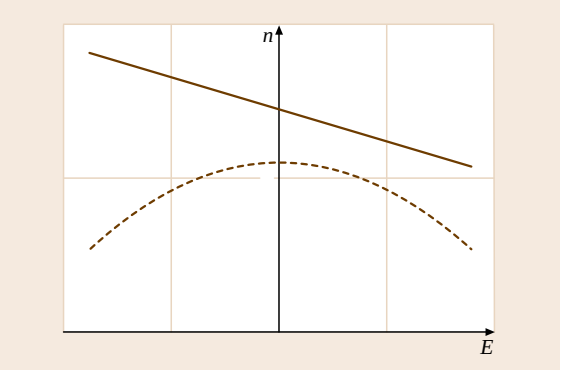

Fig. 8.40 The refraction index as a function of the applied electrical field strength E: (*solid line*) Pockels medium; (*dashed line*) Kerr medium

8.5.1 Phase Modulation

In analogy to the definition of the electric field strength between the electrodes of a parallel-plate capacitor, the field strength in a Pockels modulator can be expressed as

$$E = \frac{V}{d} \,, \qquad (8.74)$$

where V is the applied quasistatic voltage on the electrodes of the modulator, and d is the distance between them (in the case of the longitudinal modulator it is equal to the length L).

In a *transversal Pockels modulator* (Fig. 8.39b) the phase shift is a function of the electric field strength E

$$\varphi = \varphi_0 - \pi \frac{n^3 L}{\lambda_0} k_{\text{Pockels}} E \,, \qquad (8.75)$$

where $\varphi_0 = 2\pi\, n_{(V=0)} L/\lambda_0$ is the natural phase shift and λ_0 is the free-space wavelength.

By reducing the electrode distance d the voltage necessary for a given phase shift will be also reduced. This applies particularly in integrated optical devices.

The required voltage to achieve a phase shift $\varphi = \pi$ is called the *half-wave voltage* and can be expressed as

$$V_\pi = \frac{\lambda_0 d}{n^3 k_{\text{Pockels}} L} \,. \tag{8.76}$$

It is convenient to express the phase shift by using V_π as

$$\varphi = \varphi_0 - \pi \frac{V}{V_\pi} \,. \tag{8.77}$$

In a longitutional Pockels modulator (Fig. 8.39a) the distance between the electrodes is equal to the distance of light modulation $d = L$ and thus φ is independent of d and L:

$$\varphi = \varphi_0 - \pi \frac{n^3}{\lambda_0} k_{\text{Pockels}} V \tag{8.78}$$

and the corresponding half-wave voltage is

$$V_\pi = \frac{\lambda_0}{n^3 k_{\text{Pockels}}} \,. \tag{8.79}$$

Frequency modulation can be achieved by applying a sinusoidal phase modulation. This is due to the fundamental interrelation between these two kinds of modulation, where the frequency modulation can be seen as phase modulation with integrated modulation signal [8.101]. Thus sinusoidal phase modulation results in sinusoidal frequency modulation [8.102].

Another approach is to apply a circular electric modulation field of frequency ω_m to cause the principle axes to rotate with angular velocity $\omega_\text{m}/2$. A setup is used where two circular polarizers (inverted with respect to each other) at both ends of the modulator convert linearly polarized light to circularly polarized and vice versa.

The circularly polarized optical wave with frequency ω at the input will be shifted to $\omega \pm \omega_\text{m}$ at the output, depending on the direction of rotation and field strength of the applied electric field [8.103].

8.5.2 Polarization Modulation

A polarization state converter or dynamic wave plate allows the controlled change of an input polarization at the output of the modulator. This is achieved by coherent addition of two orthogonal waves (portions of the input wave) within the modulator.

The orientation of the electrooptic medium and the direction of the electric field are configured to have control of the fast and slow axis in the cross section normal to the light path. The corresponding refractive indices for this axis are

$$n_{x'} \approx n_x - \tfrac{1}{2} n_x^3 k_{x\,\text{Pockels}} E \,, \tag{8.80}$$

$$n_{y'} \approx n_y - \tfrac{1}{2} n_y^3 k_{y\,\text{Pockels}} E \,, \tag{8.81}$$

where n_x and n_y are the refractive indices in the absence of an electric field, and k_x and k_y are the appropriate electrooptic coefficients under the specific spatial and electric field conditions (for a detailed description see to [8.104] Chap. 18.2).

Light portions (the ordinary and extraordinary wave) propagate at different speeds through the system resulting in a relative phase difference Γ between them. This phase difference depends on the length of the system L and is also known as the retardation

$$\Gamma = \Gamma_0 + \frac{2\pi}{\lambda_0}(n_{x'} - n_{y'})L \,, \tag{8.82}$$

where Γ_0 is the natural phase retardation with no voltage applied.

In the absence of natural birefringence ($n_x - n_y = 0$) the induced retardation in a transverse modulator is

$$\Gamma_i = \frac{\pi}{\lambda_0} \left(k_{\text{Pockels}\,y} n_y^3 - k_{\text{Pockels}]\,x} n_x^3 \right) \frac{VL}{d} \,. \tag{8.83}$$

The voltage required to achieve a retardation of $\Gamma_i = \pi$, which shifts a vertical polarized input wave to a horizontal polarized output wave, is the half-wave voltage V_π for the polarization modulator

$$V_\pi = \frac{\lambda_0}{k_{\text{Pockels}\,y} n_y^3 - k_{\text{Pockels}\,x} n_x^3} \frac{d}{L} \,. \tag{8.84}$$

The corresponding formulas for a longitudional modulator are equal to (8.81) without the d/L term due to the modulator's independence of d and L.

8.5.3 Intensity Modulation

Intensity modulation is achieved by altering the transmission of light, which is the ratio of output to input intensity, $T = I_\text{o}/I_\text{i}$. As phase or retardation modulation does not affect the intensity of the output light an additional element or setup is needed.

One approach is to add a polarizing analyzer to a dynamic wave plate as described in [8.103] in such a way that the analyzer's axis is orthogonal to the input polarization (crossed polarizer setup). With no voltage applied the output intensity is zero (point A in

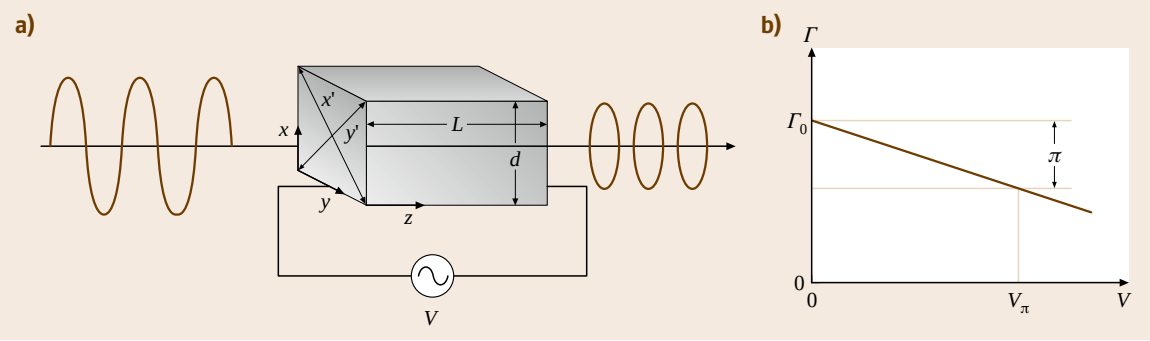

Fig. 8.41 **(a)** When linearly polarized light (parallel to the x-axis) enters the crystal, the output polarization state is in general elliptical. For $V = V_\pi$ the polarization is again linear, but turned 90° with respect to the input polarization. **(b)** The phase retardation is linearly related to the applied voltage. In the absence of an applied voltage only Γ_0 is present

Fig. 8.41b) and with $V = V_\pi$ (point C in Fig. 8.41b) the output intensity reaches the level of the input intensity. The transmittance T is a periodic function of V

$$T(V) = \sin^2\left(\frac{\Gamma_0}{2} - \frac{\pi}{2}\frac{V}{V_\pi}\right). \qquad (8.85)$$

By operating the modulation voltage near $V_\pi/2$ (point B in Fig. 8.41b) the output intensity is nearly linearly related to the voltage.

Figure 8.42a shows a typical setup. The light entering the modulator after passing the input polarizer is linearly polarized. Its polarization direction is tilted 45° with respect to the direction of the electric field. With a voltage applied the light will be split into two orthogonal components that will have a relative phase difference Γ_i between them after passing through the modulator. The superposition of these two components results in elliptically polarized light that will be analyzed by the output polarizer. With $V = V_\pi$ the superposition again results in linearly polarized light oriented at 90° with respect to the incoming light's polarization, and thus it will be fully transmitted by the analyzer.

It is also possible to use parallel polarizers, in which case the transmission behavior is inverted: full transmission at $V = 0$ and no transmission with $V = V_\pi$.

Another approach to modulate the intensity of light is to superpose the waves of the two branches of a Mach–Zehnder interferometer in which at least one branch contains a phase modulator (Fig. 8.43a). Assuming that the beam splitters divide the optical intensity equally, the intensity at the output I_o depends on the

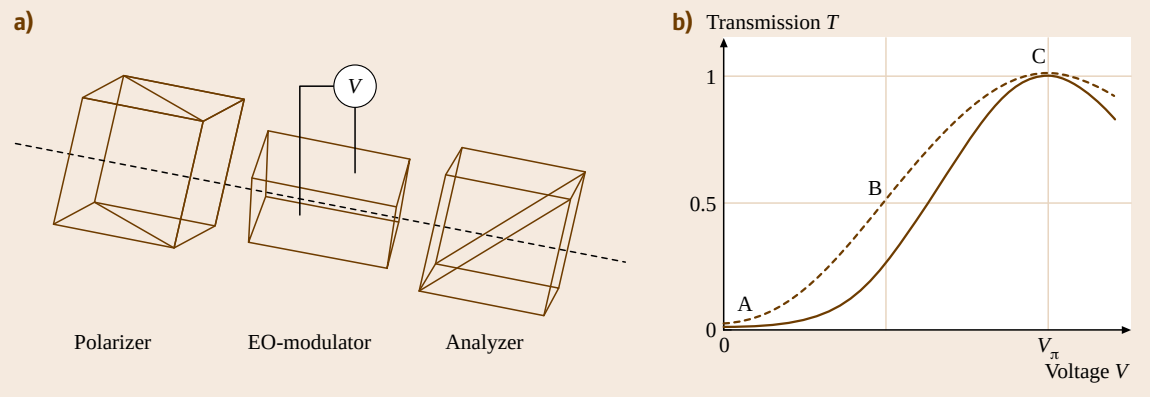

Fig. 8.42 **(a)** An intensity modulator setup implementing a dynamic wave plate between two crossed polarizers, placed at 45° with respect to the retarder's axes. **(b)** The transmittance T varies with the applied voltage V, following the *dashed line* for a Pockels characteristic modulator and the *solid line* for Kerr characteristic, both for $\Gamma_0 = 0$

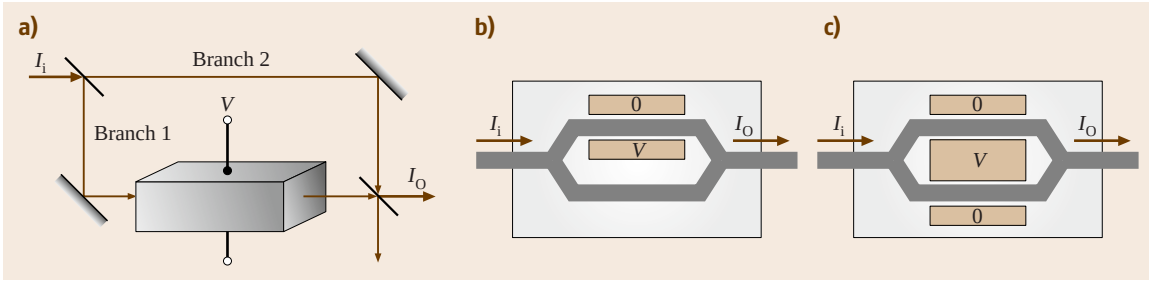

Fig. 8.43 (**a**) Mach–Zehnder interferometer where one branch contains a phase modulator. The transmittance of the interferometer T varies with the applied voltage V. The same setup can be used in an integrated optical device (**b**) where the input light is split into the two branches by a waveguide. With an additional electrode a push–pull configuration can be constructed (**c**) where the light in the two branches are modulated by the same voltage

phase difference φ in the two branches:

$$I_o = \frac{1}{2} I_i + \frac{1}{2} I_i \cos\varphi = I_i \cos^2 \frac{\varphi}{2} \,. \tag{8.86}$$

Considering the half-wave voltage expression for the phase shift (8.76), the transmittance $T = I_o/I_i$ is again a periodic function of V

$$T(V) = \cos^2\left(\frac{\varphi_0}{2} - \frac{\pi}{2}\frac{V}{V_\pi}\right) . \tag{8.87}$$

Here the value of φ_0 depends on the optical path difference when no voltage is applied. A value of $\pi/2$ is used to operate the modulator in the nearly linear region around $T = 1/2$ (point B in Fig. 8.42b). If the modulator is switched between full transmission and total extinction, φ_0 can be used to select whether $V = 0$ or $V = V_\pi$ corresponds to $T = 0$ and $T = 1$ (points A and C in Fig. 8.42b).

A Mach–Zehnder-based modulator can also be constructed as an integrated optical device. The input optical waveguide is split into the two branches of the interferometer and recombined at the output (Fig. 8.43b). In addition to the setup where a phase modulator is added to one of the branches there is a configuration called push–pull, which adds an additional modulator to the second branch (Fig. 8.43c). Full transmission occurs at 0° net phase difference while total extinction occurs at 180°. This configuration requires lower drive voltages to achieve a required phase shift.

Due to the small electrically induced changes in the refractive index, thermal influences and stress-induced double refraction as well as birefringence can be rather disturbing. Therefore, electrooptic modulators often contain two equal Pockels cells in a configuration where the temperature dependence of the relative phase shift is largely canceled [8.105].

8.6 Acoustooptic Modulator

Devices that apply an acoustic wave to a medium guiding optical waves are called acoustooptic modulators (AOM). They consist of at least one acoustic wave generator (usually a piezoelectric transducer) attached to an optical material such as tellurium dioxide, crystalline quartz or fused silica. The applied acoustic wave influences the spatial density distribution of the optical material (by compression and rarefaction) and thus a corresponding change in the index of refraction is generated. Due to the periodic structure of the acoustic wave the variation in the index of refraction is also periodic and acts as a diffraction grating for an optical wave present in the medium (Fig. 8.44).

The distance of the periodically repeated planes of equal density is given by

$$\Lambda = \frac{v_s}{f_s} \,, \tag{8.88}$$

where v_s is the velocity of sound in the medium and f_s is the frequency of sound. In analogy to the formula for Bragg diffraction, the angles θ can be calculated for light diffracted from this periodic structure as (Fig. 8.41):

$$\sin\theta = \pm\frac{\lambda}{2\Lambda} \,, \tag{8.89}$$

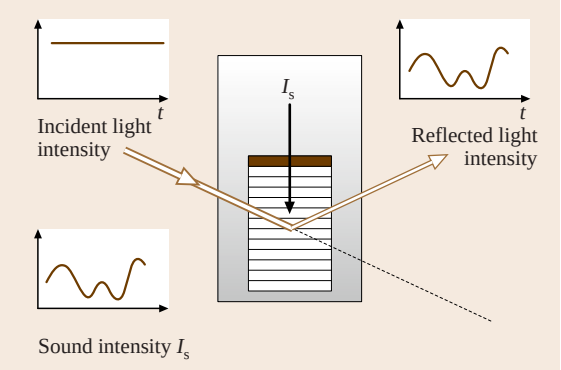

Fig. 8.44 AOM controlled by the sound intensity with a proportional modulated output intensity of the light

where λ is the wavelength of light in the medium. For these angles the criteria for constructive interference is satisfied; θ represents both the angle of reflection as well as the angle of incidence. The intensity drops sharply for angles that differ slightly from θ.

Depending on the application there are many criteria for the choice of the material, including the transparency range, the optical damage threshold, and required size.

The characteristics of AOMs are given in Table 8.6.

8.6.1 Intensity Modulator

The intensity of the reflected light is proportional to the intensity of the modulating sound wave for sufficiently weak sound intensity. At higher sound intensities nonlinear effects have a negative impact on the modulator.

The achievable bandwidth B is limited either by the size of the light beam waist (with the transit time $T = D/v_s$ of sound across the waist width D) to $B = 1/T$ (as shown in [8.104] Chap. 20.2) or by the transducer impedance mismatch, which can be overcome by inserting a quarter-wave plate.

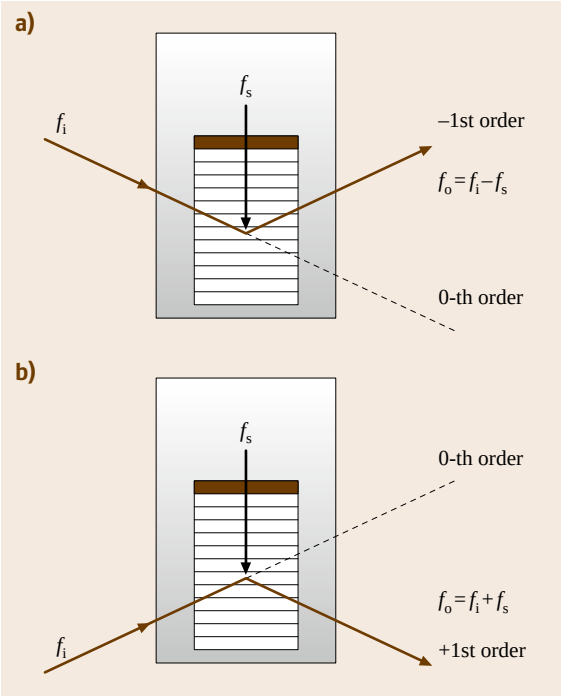

Fig. 8.45a,b Frequency shifter for (a) downshift and (b) upshift of the input light frequency

8.6.2 Frequency Shifter

Partially reflected optical waves are Doppler-shifted by the refractive-index variations created by an acoustic plane wave that moves with a velocity v_s. While the angular frequency of the incident optical wave is $\omega = 2\pi f$ the reflected light is upshifted to an angu-

Table 8.6 Characteristics of acoustooptic modulators

Material	Bandwidth (MHz)	Rise time (ns)	Acoustic input power (W) saturation	Material wavelength range (μm)	Efficiency at maximum bandwidth (633 nm)
Glass	5–10	50	1–6	0.4–25	> 70%
$PbMoO_4$	> 80	4–6	0.5–1.5	0.42–5.5	> 70%
TeO_2	> 80	4–6	0.5–1.5	0.35–5	> 70%
Ge	10	70	20–30	2–20	> 50% at 10.6 μm
GaP	100–1500	0.7–10	0.02–2	0.6–1	> 80%
GaAs	50–200	5–20	0.02–2	1–1.6	> 30% at 1.5 μm

lar frequency $\omega + \Omega$ with $\Omega = 2\pi f_s$. This is achieved using a setup such as that shown in Fig. 8.45b where the acoustic wave propagates in the opposite direction to the incoming optical wave. In a geometry where light and sound waves travel in the same direction (Fig. 8.45a) the frequency of the reflected light is downshifted to $\omega - \Omega$.

Frequency shift over a range wider than the modulators range can be achieved by placing two modulators in series. When the first modulator applies an upshift and the second a downshift then the resulting output frequency will be shifted by the difference of the two frequencies. The sum of both frequencies will be achieved if both modulators apply an upshift. The overall efficiency is given by the combined diffraction efficiencies.

8.6.3 Deflector

By applying a wide acoustic frequency range with bandwidth Δf to an AOM the deflection (separation) angle 2θ can be made to vary proportionally to f_s. As θ is not only the reflected but also the required incidence angle a setup is needed where the incidence angle can be decoupled. This can be achieved by varying the direction of the acoustic wave corresponding to the applied acoustic frequency, for example by using multielectrode transducers.

As the optical wave has a limited angular width the number of resolvable spots is limited to the ratio of the maximum scan angle variation $\Delta\theta = (\lambda/v_s)B$ to the angular width λ/D of the beam

$$N = \frac{D}{v_s} B \,. \tag{8.90}$$

Here, D/v_s is the transit time of sound through the light beam's width and B is the bandwidth of the sound wave.

Some applications of AOMs applying the modulation technics described above are:

- Cavity dumping in a laser resonator (deflection)
- Active mode locking
- Laser printing, where the AOM modulates the power of the laser beam
- High-frequency (HF) spectrum analyzer, where the AOM deflects the length depending on the (to analyze) modulation signal to a charge-coupled device (CCD) line detector
- Laser projector, where AOMs modulate the intensity of the RGB components of light according to the video signal to be displayed
- Laser scanning microscopy.

8.7 Gradient Index Optical Components

The local variation of the refractive index $n(x, y, z)$ in the optical material of an optical component additionally implies several possibilities to generate new functions of the component. In contrast to conventional refractive optics where light is refracted at the abrupt change from one homogeneous medium with index n_1 to a second one with index n_2, the direction of the propagating light changes continuously in gradient index (GRIN) media, depending on the distribution of the refractive index $n(x, y, z)$. The propagation in terms of geometrical optics is governed by the rules of Fermat's principle. This will be described in more detail in Sect. 8.7.1.

Usually, four gradient index types are distinguished. For axial gradients the index varies only in the direction of the optical axis z, whereas in planes perpendicular to the optical axis the index is constant. For radial gradients, which nowadays is the most important type, the index is solely a function of the radial coordinate r, which is perpendicular to the optical axis z. In one-dimensional or lateral GRIN media, the index depends only on one coordinate, y, which is perpendicular to the optical axis. Spherical gradients exhibit a variation of the index with a spherical radius R,

$$\begin{aligned} &n = n(z) && \text{axial gradient} \\ &n = n(r = x^2 + y^2) && \text{radial gradient} \\ &n = n(y) && \text{one-dimensional gradient} \\ &n = n(R = x^2 + y^2 + z^2) && \text{spherical gradient} \,. \end{aligned} \tag{8.91}$$

For all types of gradients described in (8.91), there are defined index profile functions that generate effects on incoming light beams similar to those of conventional optical components as, e.g., lenses. A radial (or one-dimensional) gradient with an almost parabolic secant-hyperbolic index profile,

$$n(r) = n_0 \,\mathrm{sech}(gr) \,, \tag{8.92}$$

with a maximum index n_0 on the optical axis creates a focusing lens (Fig. 8.46) with a periodic sinusoidal ray trace [8.106, 107] for meridional rays. Period P solely depends on the gradient parameter g,

$$P = 2\pi/g \,. \tag{8.93}$$

A radial gradient with a parabolic index profile bending outwards

$$n^2(r) = n_0^2[1+(gr)^2] \tag{8.94}$$

has the effect of a diverging lens [8.108] (Fig. 8.46). Both types (8.92) and (8.94) result in a lens function with plane optical surfaces, which is a tremendous advantage for the production and application of miniaturized gradient index lenses.

A unique spherical gradient is Maxwell's fisheye [8.109]

$$n(r) = \frac{n_0}{1+(R/R_0)^2} \,, \tag{8.95}$$

as it images all points of the surface ($R = R_0$) of a sphere on its opposite side; n_0 is the index in the center of the sphere. A modified version of the spherical or semi-spherical gradients is used for planar microlens arrays [8.110].

A so-called Luneburg lens [8.111] uses a spherical gradient

$$n(r) = n_0\sqrt{2-(R/R_0)^2} \tag{8.96}$$

to collimate light from a point source on the surface of the sphere. A generalized type of similar profiles is employed for 1 producing fiber-based cylindrical collimating lenses of small focal lengths [8.112].

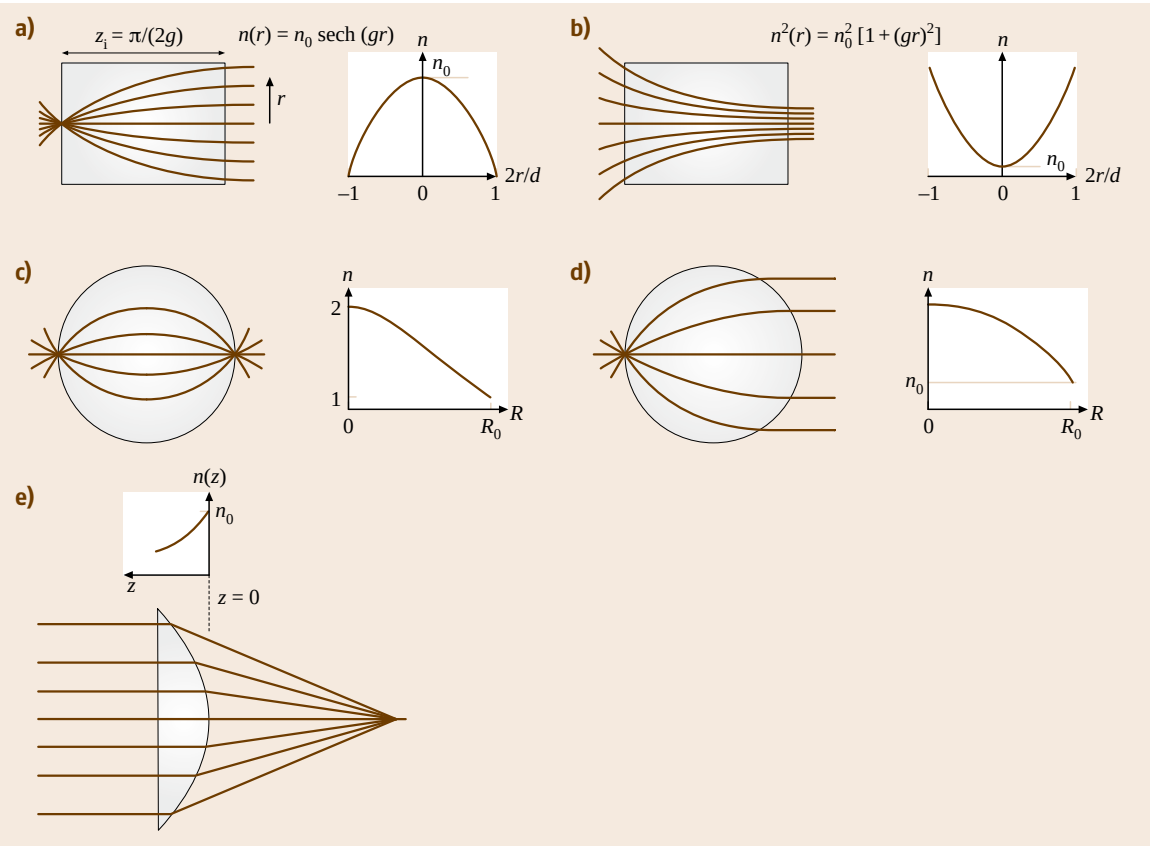

Fig. 8.46a–e Various types of gradient-index components with different lens performance **(a)** radial focusing lens, **(b)** radial diverging lens, **(c)** spherical lens – Maxwell's fisheye ($n_0 = 2$) and **(d)** Luneburg lens, **(e)** plano-convex lens with axial gradient

Axial gradients are most commonly used to correct the spherical aberration of lenses if made of a homogeneous medium with spherical surfaces. An axial index profile that eliminates the spherical aberration of parallel light rays striking the spherical surface of a plano-convex lens on the gradient side (Fig. 8.46) was derived analytically by *Murty* [8.113],

$$n(z) = \frac{n_0}{\sqrt{1+2n_0(n_0-1)z/r_c}}\,, \tag{8.97}$$

with n_0 the index at the vertex ($z = 0$) of the spherical surface with r_c the radius of curvature.

Most of these gradient examples represent analytical solutions of the ray equations (Sect. 8.7.1) but their conversion into practice/fabrication is difficult because of their exotic index value ranges. Gradient index materials used to produce optical components for the visible and near-infrared domain are mostly silicate glasses and sometimes plastics, with indices between 1.4 and 1.9, allowing a limited index variation because of the chemistry, and mechanical and optical properties of the materials. Furthermore, applications often require the integration of GRIN components into a configuration that deviates from the ideal and analytical examples presented in this chapter. Hence, the index profiles are formulated in model functions, normally as a polynomial expression, introducing an appropriate number of design parameters. Numerical ray tracing is then performed to determine optimum index profile parameters for a specific configuration or application, also considering the technological feasibility. Section 8.7.1 will outline some fundamentals of ray tracing in gradient index media. A more-detailed introduction to the fundamentals of gradient index optics is given in [8.106, 111, 114–116].

8.7.1 Ray Tracing in Gradient Index Media

Light propagation in gradient index media can be described by different physical models, i. e., by ray tracing in the sense of geometrical optics, by scalar wave propagation [8.117], or by solving the vector wave equations [8.116]. The suitability of the models depends on the size of the gradients with respect to the wavelength and the effects under investigation. Besides gradient index waveguide optics, favoring wave propagation [8.118], ray tracing is the most common method to describe, simulate and optimize gradient index components, because its calculations are comparably fast and compatible with the principles of the optical design software. Hence, this method will be treated in more detail in this section.

In the geometric-optical sense, ray propagation in media with a nonuniform index distribution $n(x, y, z)$ is described by the vector ray equation, which is derived from Fermat's principle [8.119]

$$\frac{\mathrm{d}}{\mathrm{d}s}\left[n(x,\ y,\ z)\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}s}\right] = \nabla n(x,\ y,\ z)\,, \tag{8.98}$$

with $\boldsymbol{r}$ the position vector and $\mathrm{d}s$ the path element along the ray trace (Fig. 8.47).

The vector equation (8.98) can also be represented as a system of differential equations of second order for the coordinates x, y and z,

$$\frac{\mathrm{d}^2x}{\mathrm{d}\tau^2} = \frac{\partial}{\partial x}\left(\frac{1}{2}n^2\right)\,; \quad \frac{\mathrm{d}^2y}{\mathrm{d}\tau^2} = \frac{\partial}{\partial y}\left(\frac{1}{2}n^2\right)\,;$$
$$\frac{\mathrm{d}^2z}{\mathrm{d}\tau^2} = \frac{\partial}{\partial z}\left(\frac{1}{2}n^2\right)\,. \tag{8.99}$$

Element $\mathrm{d}\tau$ results from the path element $\mathrm{d}s = n\,\mathrm{d}\tau$.

There are analytical solutions of (8.99) for many index distributions, some well-known ones have been introduced above. Detailed descriptions are given in [8.106, 107, 111, 115].

In routine cases, where the index distributions have to be optimized and adapted to a specific design configuration of an optical system and to profile shapes that can be fabricated by applying an appropriate technology, the ray equations (8.99) are solved numerically via the Runge–Kutta method [8.120]. This procedure is mostly used for the commercially available optical design software. The index profiles are usually formulated as polynomial expansions in r, R, x, y, and z. The computation of wavefront aberrations and point-spread functions (PSF) considering the diffraction furthermore requires the calculation of the optical path length OPL of rays tracing in gradient index media,

$$\mathrm{OPL} = \int n(x,\ y,\ z)\,\mathrm{d}s\,;$$
$$\mathrm{d}s = \sqrt{\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2}\,, \tag{8.100}$$

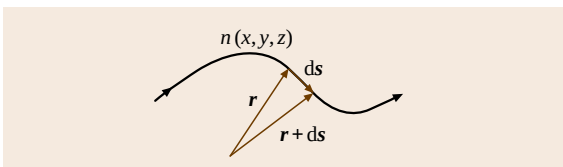

Fig. 8.47 Ray trace in a inhomogeneous medium

where ds is the geometrical path element. The described Runge–Kutta method uses $d\tau$ as the numerical step parameter. Hence, the calculation of the optical path length (OPL) can easily be included in the numerical procedure [8.121] by

$$\mathrm{OPL} = \int n^2(x,\ y,\ z)\,\mathrm{d}\tau\ . \tag{8.101}$$

8.7.2 Fabrication Techniques

Gradient index materials for visible light and near-infrared applications are usually based on transparent silicate glasses and sometimes on organic polymer materials. The refractive index can be changed by locally varying the chemical composition and structure and related optical and mechanical properties. Early models [8.122] relate the optical properties of homogeneous silicate glasses to their composition. More recent studies [8.123, 124] also consider aspects of the index gradient fabrication and chromatic properties of the gradient glasses. The appropriateness of a GRIN fabrication technology depends on the following optical aspects:

- The desired index change Δn
- The profile shape and symmetry
- The depth of the gradient, which determines the size of the GRIN element
- The chromatic variation of the index profile.

Although several techniques such as the sol-gel [8.125] and the chemical vapor deposition (CVD) [8.126] processes have been described in the literature, ion exchange or diffusion technology in glasses and plastics are of most practical importance for the production of gradient index lenses [8.127–130] and will therefore be treated here in more detail. However, CVD processes are of great industrial relevance for the production of graded index fibers for optical data transmission as well as for the fabrication of Luneburg-type cylindrical lenses (Sect. 8.7.3). Sol-gel techniques have been investigated in more detail because of their potential of facilitating the fabrication of large radial-gradient lenses of diameters larger than 5 mm to open up new applications to camera lenses or eyepieces in optical instruments [8.131]. To produce even larger GRIN lens elements, organic or plastic materials have been investigated in detail [8.132]. A combination of the diffusion of different monomers with different refractive indices followed by copolymerization generates the final index gradient.

Ion Exchange and Diffusion Processes in Glass

Diffusion processes in glass are used to produce most of the commercially available GRIN lens types. Large axial gradients [8.133] and radial gradients [8.134] are fabricated by fusion–diffusion between different initially homogeneous glasses of distinguished refractive indices, which are combined into a plate stack for axial gradients or by inserting rods in tubes of different glasses. After joining, the compound is annealed at temperatures well above the transition temperature and the softening point of the glasses, causing the diffusion of many components of the glasses, with the initial step-like index distribution forming a continuous index gradient. In the case of one-dimensional axial gradient with index changes as large as 0.4, blanks are used to grind and polish spherical lenses with corrected spherical and chromatic aberration (Sect. 8.7.3). In the case of radial gradients, a larger preform with the appropriate index profile produced by the described diffusion is afterwards extended to the final lens diameter at lower temperatures.

For producing radial and lateral gradients of smaller diameter, i. e. between 0.1 mm and 3.0 mm, the ion exchange of monovalent cations between molten salt baths and initially homogeneous borosilicate glass rods or slabs is used [8.127, 128, 135] at temperatures between 300 and 600 °C. This is below or in the range of the transition temperature of the glass, where the network of the glass formers is still rigid, but monovalent ions have some mobility and the salts are liquid (Fig. 8.48). Numerous technological aspects affect the feasibility of producing a desired final refractive index profile. The ions to be exchanged determine the possible index change (Table 8.7) and the ion exchange depth after a certain exchange time, which results from different degrees of polarizability and ion radii. Table 8.7 compares the relevant properties of monovalent ions [8.136].

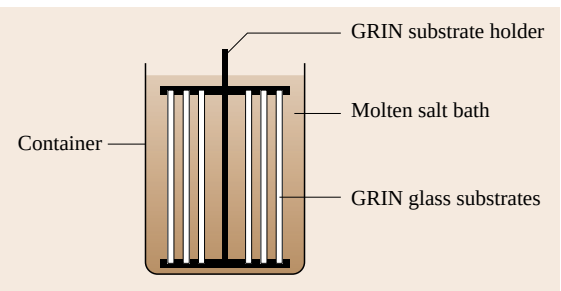

Fig. 8.48 Ion exchange scheme for borosilicate glass rods and slabs in molten salt baths

Table 8.7 Polarizability, ion radius and possible refractive index change of monovalent ions suitable for ion exchange

Ion	Electronic polarizability ($Å^3$)	Ion radius (Å)	Δn
Na^+	0.41	0.95	–
Li^+	0.03	0.65	≤ 0.01
K^+	1.33	1.33	≤ 0.01
Ag^+	2.40	1.26	≤ 0.14
Cs^+	3.34	1.65	≤ 0.03
Tl^+	5.20	1.49	0.1 . . . 0.2

The fabrication time depends on the kinematic properties of the ion exchange, which is described as an interdiffusion process of the ions A and B in the glass and the salt melt,

$$A^+_{Glass} + B^+_{Salt} \leftrightarrow A^+_{Salt} + B^+_{Glass} \,. \tag{8.102}$$

It is modelled by Fick's diffusion equation

$$\frac{\partial c_A(\boldsymbol{r}, t)}{\partial t} = \nabla[D(c_A, T)\nabla c_A(\boldsymbol{r}, t)] \,, \tag{8.103}$$

where c_A is the normalized concentration of cation A, and D is the diffusion coefficient. It generally depends on the concentration and on temperature T. It describes most of the process-relevant properties of the base glass composition and the kinematic behavior of the ions exchanged at different temperatures. Several empirical and physical models have been developed to attain a realistic simulation of the ion-exchange fabrication processes [8.136–139]. A process temperature has to be chosen where the diffusion coefficients are high enough to attain an economic production time, but still below or in the range of the softening point of the glass to avoid deformation of the glass blanks. Besides the temperature and the ion exchange time, the configuration of the initial and boundary conditions appropriate for the diffusion process, which can be controlled by varying the salt-bath composition, is an important tool to optimize the index profiles.

High-numerical-aperture lenses with radial gradients are obtained by large index changes of > 0.1. GRIN lenses are mostly produced by thallium/sodium–potassium ion exchange [8.127] (Fig. 8.49) or by silver–sodium exchange [8.128, 135]. In contrast to silver, thallium is a very toxic material, larger portions of which, however, can initially be contained in the base glass composition of GRIN glass, because thallium oxide does not tend to reduce to metallic thallium during the melting process of glass. Silver is almost nontoxic,

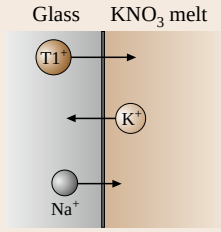

Fig. 8.49 Thallium/sodium–potassium ion exchange for producing high-NA radial GRIN lenses (after [8.127])

but glasses with a content of silver oxide larger than 15 mol% cannot be molten directly, because silver salts and oxides tend to reduce to metallic silver at typical melting temperatures above 1000 °C, which causes a dark color of the glass. The glass can then not be used for the GRIN-lens production, so that a two-step process is generally applied to produce focusing GRIN lenses [8.128, 135], where a sodium-containing base glass is initially immersed in a silver-containing salt melt. This first process is carried out sufficiently long to attain an almost uniform refractive index increase Δn (ion stuffing) (Fig. 8.50). In a second *burying* step, silver ions in the glass are partially removed and replaced by index-lowering sodium ions, where the glass substrates are immersed in a sodium-containing salt melt, yielding the desired parabolic profile.

Many applications require longer ray periods P (8.93) connected with lower numerical apertures and minimized chromatic aberrations. Preferably, the lithium-sodium ion exchange in alumo-borosilicate glass is used to produce these types of radial GRIN lenses with smaller index changes Δn [8.140–143].

This section does not claim to be a complete survey of all the GRIN fabrication techniques available; it rather reflects the author's experience.

8.7.3 Application

Radial and Lateral Gradient Lenses with Plane and Spherical Surfaces

Micro GRIN lenses with almost parabolic radial or lateral index profiles are an interesting alternative to conventional homogeneous glass lenses since the lens performance depends on a continuous change of the refractive index within the lens material. Instead of complicated surface shapes, plane optical surfaces are used. The light rays are continuously bent within the lens until, they are finally focused on a spot. Miniaturized lenses are fabricated with thickness or diameter

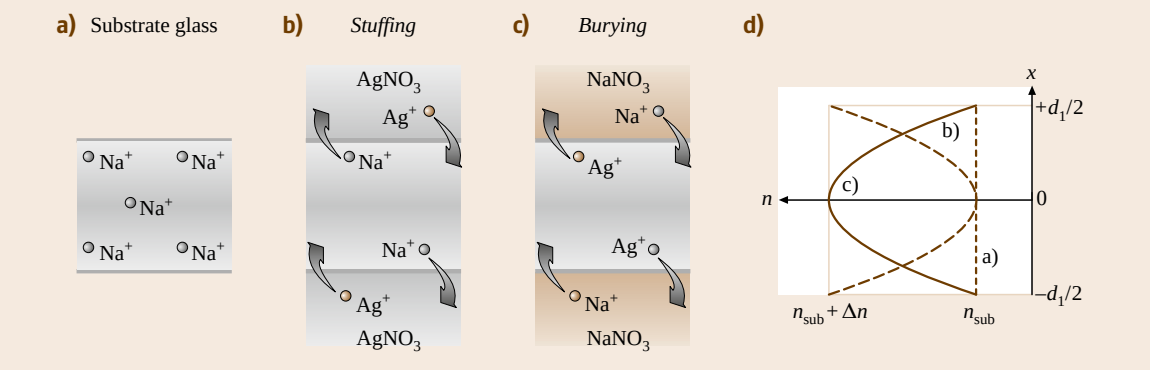

Fig. 8.50a–d Silver–sodium ion exchange for producing high-NA radial and one-dimensional GRIN lenses (after [8.135])

of 3 mm down to 0.2 mm. The simple geometry allows larger volumes of their cost-effective production and essentially simplifies the assembly of rather complex systems, including optical fibers, prisms and beam splitters, as these plane optical components can directly be attached to the GRIN lenses. Varying the lens length yields an enormous flexibility to fit the lens parameters, e.g., the focal length and working distance, to a specific requirement. Preferred fields of application are optical telecommunication components, laser diode-to-fiber couplers, miniaturized endoscopes, and a variety of optical sensors. Novel fields are endomicroscopic probes with high-resolution requirements and miniaturized heads for optical coherence tomography (OCT). Before these applications are presented in more detail, some fundamental aspects will be pointed out.

An almost parabolic radial focusing refractive-index profile (8.92) generates a continuous cosine ray trace within a GRIN focussing lens, the period or pitch length P of which (8.93) does not depend on the entrance height and the entrance angle of the light ray (Fig. 8.51).

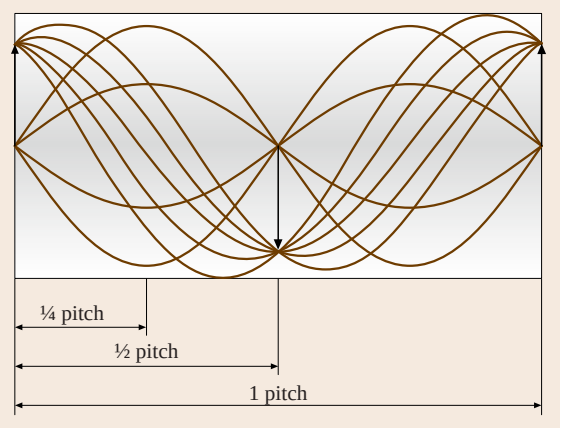

Fig. 8.51 Ray traces within a GRIN focusing lens of different pitch lengths

Various imaging configurations can be designed using the same index profile by choosing different lens lengths:

- The quarter-pitch lens images a point source on the entrance surface of the lens into infinity, or collimates it. This configuration is usually applied to the collimation of single-mode and multimode optical fibers and laser diodes, where the source can be attached directly to the lens. For high-power laser diodes, cylindrical GRIN lenses are used for the fast-axis collimation. Together with other GRIN components they are easily integrated to form compact microoptical systems.
- The half-pitch lens images an object on the entrance surface inverted on the exit surface of the lens (magnification $M = -1$).
- The 1 (2, 3, or more, respectively)-pitch lens images an object on the entrance surface of the lens identical to the exit surface (magnification $M = +1$). In endoscopes, those lenses are used as relay lenses, which transmit the image from the front part of the endoscope to the eyepiece (Fig. 8.51).
- Endoscope objective lenses are somewhat longer than a quarter-pitch lens. They image the object field to be viewed at a working distance on the exit surface of the lens on a reduced scale (Fig. 8.52).

The geometrical gradient constant g of the radial index profile (8.92) characterizes the steepness of the index gradient and, with the lens length z_l, it determines the

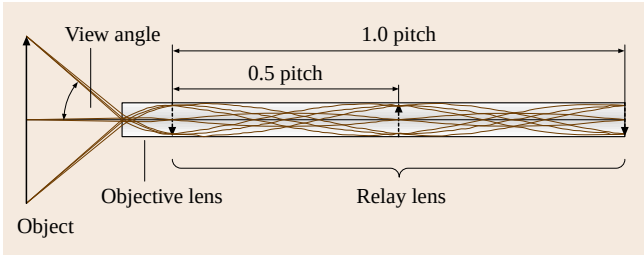

Fig. 8.52 GRIN endoscope without eyepiece function

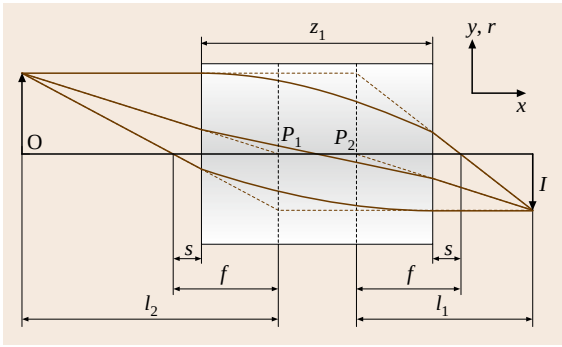

Fig. 8.53 Image formation by a GRIN focussing lens

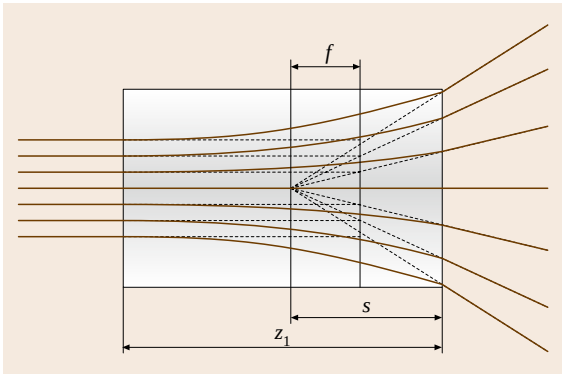

Fig. 8.54 Ray traces in a GRIN diverging lens

focal length f and the working distance s of the lens,

$$f = \frac{1}{n_0 g \sin(g z_1)}\,, \quad s = \frac{1}{n_0 g \tan(g z_1)}\,. \tag{8.104}$$

Figure 8.53 illustrates the procedure of optically designing an imaging GRIN system using these parameters.

The distance between the principal planes P_1 and P_2 indicates that GRIN lenses have to be treated as *thick* lenses. However, this fact does not influence the image quality and isoplanatic property of GRIN lenses.

The maximum acceptance angle of a GRIN collimation lens or the maximum viewing angle of a GRIN objective lens, respectively, ϑ is determined by the numerical aperture (NA). As in fiber optics, it is derived from the maximum index change of the GRIN profile,

$$\begin{aligned}\sin(\vartheta) = \mathrm{NA} &= \sqrt{n_0^2 - n_\mathrm{R}^2} \\ &= n_0 \sqrt{1 - \operatorname{sech}^2(gd/2)}\,,\end{aligned} \tag{8.105}$$

where n_R is the refractive index in the margin of the profile, and d is the diameter or the thickness of the lens.

Diverging lenses with plane optical surfaces are obtained by parabolic-shaped refractive index profiles (8.94), with the minimum of the index n_0 in the center of the profile.

A characteristic ray trace through a diverging lens is shown in Fig. 8.54. The comparably short focal length f of the lens is also determined by the lens length z_l,

$$f = -\frac{1}{n_0 g \sinh(g z_l)}\,, \quad s = -\frac{1}{n_0 g \tanh(g z_l)}\,. \tag{8.106}$$

However, a periodic path of the rays does not occur in this case. Those lenses are applied to the production of microoptical telescopes and scanners.

Optical communication systems use various fiber-optical components, where radial GRIN lenses with plane optical surfaces are successfully used on a large-volume scale, because of their advantageously small size, light weight, easy assembly and adjustment, and short focal length. Well-established basic functions of GRIN lenses with diameters between 1.0 and 1.8 mm are the collimation of a single-mode fiber in the 1310 nm spectral band and in bands between 1500 and 1600 nm and the low-loss coupling of a collimated beam again in a single-mode fiber (Fig. 8.55). The insertion loss can be kept very low (less than 0.5 dB) for distances L between a pair of GRIN lenses up to 25 mm and more, but in general, it is a function of this separation and other alignment factors [8.144, 145].

Optical elements, the function of which is sensitive to the angular orientation of the light, such as filters, op-

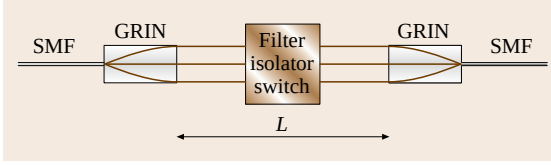

Fig. 8.55 Single-mode fiber coupling by a pair of GRIN lenses

tical crystals, gratings and moveable switching prisms, are placed between the GRIN lenses to build up a fiber-optical device. Most important are dense wavelength division multiplexing (DWDM) devices [8.146], where a multiwavelength signal in an incoming single-mode fiber (SMF) needs to be divided into many wavelength channels (Fig. 8.56).

Fiber-optical attenuators and splitters can be built up similarly to Fig. 8.56 depending on the filter properties of the element between the GRIN lenses. Often, fibers and GRIN lenses with angled facets are used for optical interconnects to minimize back-reflections, which can disturb the performance of precisely wavelength-tuned devices and systems.

Radial GRIN lenses are also fabricated with spherical surfaces to enable the efficient coupling of laser diodes to optical fibers (Fig. 8.57). The spherical surface allows a working distance (WD) of a few hundred microns between the laser facet and the lens surface, while the NA of the lens is somewhat increased with respect to a similar lens with plane surfaces. The working distance is often necessary because of the can-type package of many laser diodes with a window. The lens matches the high NA of the laser diode to the lower NA of the fiber. The spherical aberration introduced by the spherical surface of the lens can be corrected by adapting the radial index profile [8.147].

A one-dimensional or cylindrical GRIN lens with plane surfaces is obtained by a parabolic-like one-dimensional index distribution, which is oriented perpendicular to and not varying along the optical axis (Fig. 8.58). It is produced by ion exchange in glass plates and can be applied to the fast-axis collimation of laser diode bars [8.148], or to the anamorphic shaping of elliptically diverging and often astigmatic beams of laser diodes into the circular focussed beams that are necessary for the efficient coupling into fibers, or for the pumping of solid-state lasers [8.149, 150].

In the field of conventional endoscopy, where an object in a barely accessible hollow space needs to be imaged at a large viewing angle through a small opening, the GRIN lens technology is important if the diameter of the optics has to be smaller than 2.0 mm, especially below 1.0 mm, as conventional lenses are difficult to manufacture and to assemble in long imaging systems. The complete imaging system of an endoscope can be built up with only two GRIN lenses: an objective lens of high numerical aperture (NA > 0.5), which generates a demagnified intermediate image of the object at a large viewing angle, and a relay lens of low numerical aperture (NA ≈ 0.1), which relays the intermediate image of

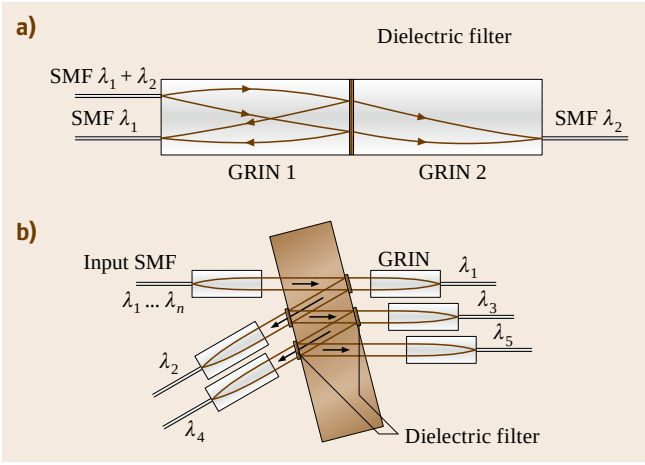

Fig. 8.56a,b Dense wavelength division multiplexing (DWDM) using GRIN lenses and narrow-band interference filters. **(a)** Two-channel multiplexer, **(b)** multichannel multiplexer (after [8.146])

the objective to the outside of the body (Fig. 8.52). Several ray periods or pitches of the GRIN relay with additional intermediate images may be necessary to generate the required length of the endoscope. It is also possible to integrate the eyepiece or ocular function into the same relay lens [8.150] to avoid additional optical elements. These GRIN systems do not cause any internal Fresnel reflection losses as there are no internal optical surfaces within the imaging tube. The aberrations have been analyzed in comparison with those of conventional optical systems in endoscopes, and the possibilities of

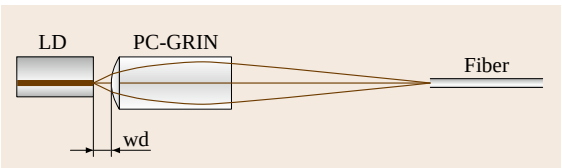

Fig. 8.57 Plano–convex radial GRIN lens with spherical surface for coupling laser diodes (LD) into fibers (after [8.147])

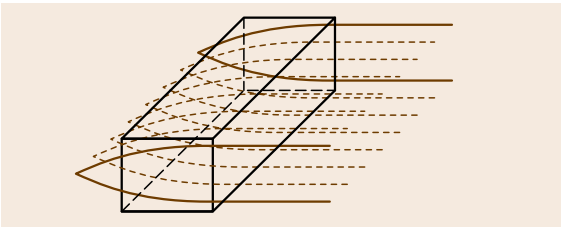

Fig. 8.58 Cylindrical GRIN lens with a one-dimensional lateral index profile

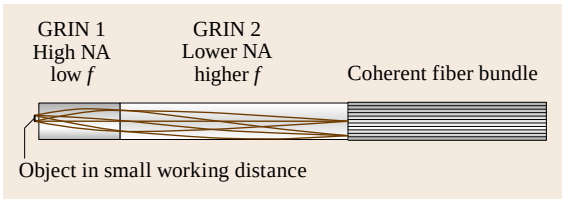

Fig. 8.59 Magnifying telecentric GRIN telescope connected to a coherent fiber bundle for endomicroscopic probes

preventing and correcting the aberrations have been studied in detail [8.141, 142]. Flexible endoscopes use coherent imaging fiber bundles for image transmission over tens of centimeters. If the diameter of the optical channel is less than 1.0 mm, GRIN objective lenses, which can be attached directly to the fiber bundle, are preferably used as they yield a good image quality. They are available in diameters down to 0.20 mm [8.151].

A novel field of applying GRIN lens systems is endomicroscopy, where small optical probes are needed to image biological tissue and corresponding specific functional features at subcellular resolution in the micrometer range. GRIN lens systems have been developed which provide the required lateral and axial resolution below 1 and 10 μm, respectively. They generate magnified telecentric images of the object (Fig. 8.59), which can then be transferred with coherent fiber bundles [8.152], via rigid GRIN relay lenses [8.153], or by scanning an individual probe fiber [8.154]. These endomicroscopic probes are often employed in a confocal or laser scanning scheme, most recently also involving multiphoton excitation [8.154].

Optical coherence tomography (OCT) is another field of the preferred application of radial GRIN optics. The penetration depth of OCT is generally less than 2–3 mm, also requiring miniaturized endoscopic probes for internal medical diagnostics [8.155]. GRIN lenses with plane optical surfaces are relatively easy to combine with the single-mode signal fiber and prisms for the beam deflection to enable the scanning of the tissue

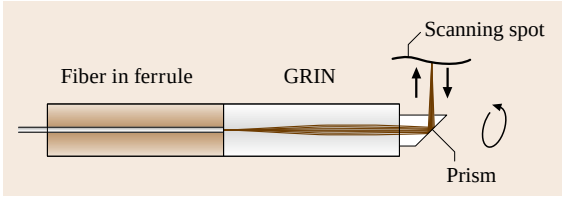

Fig. 8.60 OCT probe design with fiber, GRIN lens and scanning prism

by rotating the optical assembly or by using some other scanning method (Fig. 8.60).

Many optical sensing applications are also based on GRIN focusing rod lenses with radial gradients. A variety of physical parameters such as displacement, pressure, temperature, or fluid flow have been determined by intensity-modulated fiber-optical sensors, where the coupling efficiency between two fibers is varied by lateral and axial displacements of the GRIN lens with respect to the fiber positions, by displacing mirror coatings on membranes, or by changing the reflectivity performance of the coating [8.156]. The problem of a stable intensity reference is overcome by sensor solutions where the phase of coherent Gaussian light beams is analyzed by interferometric setups comparable to those used in optical coherence tomography (Fig. 8.60) [8.157].

Luneburg-Type Cylindrical Lenses

One type of radial index profiles in glass fibers has also successfully been used for the fabrication of cylindrical lenses of a generalized nonfull-aperture Luneburg type [8.112]. Earlier design studies investigated solutions of Luneburg-type lenses with index profiles where the required large index variation or the absolute index range was difficult to fabricate. However, it has been shown that radial index profiles with a peripheral cladding layer of a preform glass tube, which can be fabricated by using the chemical vapor deposition (CVD) technology, result in a cylindrical lens performance with well-corrected spherical aberration. Here, the rod is transversally radiated by a divergent line source of limited numerical aperture up to 0.5 (Fig. 8.61) [8.158].

By tuning the drawing process, diffraction-limited microlenses can be produced having the shape of fibers or rods with precise diameters and polished surface quality. The fused-silica cladding and the gradient index

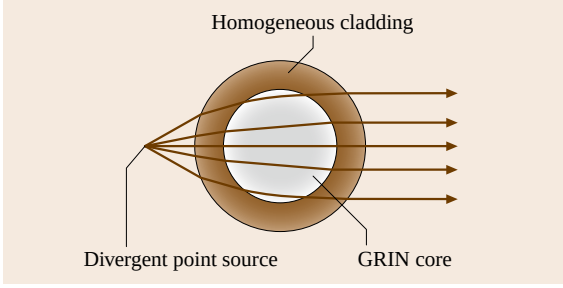

Fig. 8.61 Generalized non-full-aperture Luneburg lens (after [8.112])

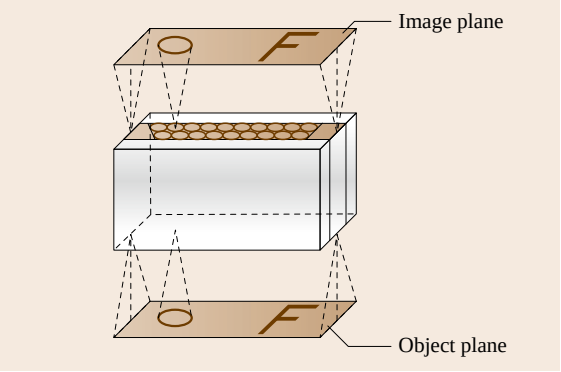

Fig. 8.62 Non-inverted 1 : 1 imaging using a GRIN rod lens array (after [8.160])

core of these lenses can withstand very high temperatures (the transition temperature is ≈ 1100 °C). The lenses can be used in the visible and near-infrared spectrum. The rods or fibers are cut to the desired lengths. These lenses are used either as fast-axis collimators for single laser diodes or for building cylindrical-lens arrays for laser diode bars. In order to accommodate a small emitter pitch, the edge of the lens may be ground to a desired width [8.159]. Typical rod diameters are 0.06–3.0 mm with correspondingly scaled focal widths.

Large GRIN Lenses with Axial Gradients

In an axial-gradient lens, a spherically curved surface usually imparts the basic focusing power, whereas the axial index gradient controls or corrects aberrations, especially the spherical ones introduced by refraction on the spherical surface. Commercially available axial gradients are produced by a bulk glass diffusion process [8.161] in large glass blanks with diameters up to 330 mm. For designing lenses, the index profile is described by

$$n(z, \lambda_{\mathrm{ref}}) = \sum_{k=0}^{11} n_k \left(\frac{z}{z_{\max}} \right)^k , \qquad (8.107)$$

where z is the axial distance from the blank surface and $z_{\max}$ is the blank thickness. In contrast to the simple analytical solution (8.97), which, however, is difficult to realize, plano-convex, biconvex and meniscus-type lenses are fabricated from specially designed Gradium glass blanks of standard diameters between 5 and 80 mm. The correction of spherical and chromatic aberrations by adapting the index profiles is possible, which would reduce the number of surfaces in optical systems and related reflection losses, and besides also the

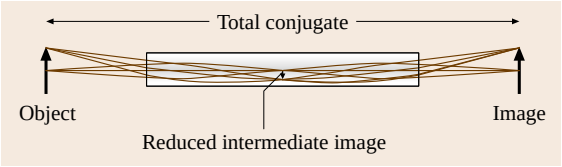

Fig. 8.63 Imaging ray traces of one array lens with reduced intermediate image

mounting complexity. Binocular eyepieces and focus heads for high-power industrial Nd-YAG welding and cutting laser systems have been developed in addition to other applications [8.162].

GRIN Rod Lens Arrays

GRIN lenses, especially with plane optical surfaces, can easily be combined to lens arrays because of their simple geometry and the possibility of simultaneously grinding and polishing the optical surfaces of the individual lenses in the array. A commercially very successful application is the SELFOC lens array [8.160] which generates a noninverted 1 : 1 image (Fig. 8.62). Usually, the arrays are composed of one or more rows of lenses. The images from adjacent lenses overlap and form a continuous erect image. The short total conjugate between the object plane and the image plane, typically 9–80 mm, allows the compact integration of the optical system, even if large plane objects of up to 60 cm width have to be imaged.

The generation of erect images by single lenses, which can overlap to form a uniform large image, is ascribed to the unique property of radial focusing GRIN lenses to generate intermediate images inside the lens rod according to the pitch length of the lenses. In general, the pitch length of rod lens arrays is between 0.5 and 1.0 pitches, resulting in a reduced intermediate image in the middle of the rod (Fig. 8.63).

The resolution, transmission, and homogeneity of the image quality are determined by the rod lens diameter, by the numerical aperture of the lens and the related lens aperture angle (the image cone in Fig. 8.62), by the total conjugate and the working distance between the object and the lens surface, and finally also by adapting the index profile to the imaging conditions. The optimization of these parameters has been investigated in many studies [8.163–165]. Traditionally, these lens arrays have been widely applied to various photocopiers and scanning devices, to large printing machines, to medical imaging devices, and to many production lines requiring the permanent examining of surface quality and defect detection.

8.8 Variable Optical Components

Single-lens optical systems are only used for the least-demanding applications. They suffer from, among other things, severe chromatic and spherical aberration. To solve these problems, corrective lenses have to be inserted into the light path. If additionally the focus needs to be changed, then the lens elements need to be moved relative to one another. This also requires additional lens elements. Therefore, high-quality optical systems with focusing ability need to have many elements, making them complex, heavy, and bulky.

Lenses are not the only optical components with the potential to change from fixed to variable optical properties. Other optical components that can do this include optical filters, polarizers, and attenuators.

Glass is a nearly perfect optical material, but it is static; after grinding and polishing it is fixed in a particular shape, and a change in focal power is impossible. To make an optical zoom system with glass lenses, these fixed elements must be moved back and forth along the optical axis. Glass zoom lenses are big, heavy, and expensive, and suffer from a limited field of view. The whole zoom system also has to incorporate mechanical components, such as stepping motors or piezoelectric drivers, and some kind of gearing mechanism.

Variable optical components try to offer ways around these limitations. Various approaches, such as materials with internal microstructures that can be altered to change their shape and/or refractive index, have been studied. Microfluidic systems can produce such changes of optical interfaces by varying their internal pressure or actively changing liquids. The familiar technology of liquid crystals offers a way to modulate the refractive index. Liquid-crystal-based lenses and other devices are discussed in Sect. 5.10.1.

The goal of developing variable optical components is the integration of new (intrinsic) variable optical properties in such components to make them cheaper, less prone to failure because of mechanical wear, and with a form factor as small as possible for a given purpose.

The focus of this section is on the setup, production, and function of such variable optical components and concepts discussed in research and academia in this field. In spite of the great potential of replacing more complicated optical systems, more work has to be done to develop such components to a higher level before they can become part of the standard catalog of optical components.

Fig. 8.64 Drop of water on a compact disc (CD) acting as a lens with the potential for variable shape. The optical refractive power and the aberrations are obvious. The challenge here is to control the surface shape of the lens and the encapsulation of such a device to avoid influences from the environment such as evaporation or gravity effects

8.8.1 Variable Lenses

The simplest device with the potential to work as a variable lens is a drop of optical transparent liquid, as shown in Fig. 8.64, where it is obvious that liquids can work as lenses.

A major challenge is the control of the shape of the drop and therefore its optical power as well as avoiding environmental influences such as gravity, vibration, evaporation, and centering the drop on the optical axis.

Water Lens

As early as the 17th century, the English scientist *Stephen Gray* built microscopes using water drops as lenses with diameter of about 0.3 mm so that their curvature was not strongly influenced by gravity [8.166]. Due to the smooth surface of the drop, Gray found that the images that these lenses created were quite good. The drops were kept from moving around by placing them in tiny holes drilled in a plate. Different hole diameters led to different lenses with different drop curvatures, and therefore different magnification factors.

Using the same idea of the refractive power of the interface between air and an optical liquid, a variable-focus lens is easily realized. To control the shape of such a liquid interface, pressure can be applied. For this purpose the liquid interface of water contained in small wells is used. A schematic sketch of the lens housing and possible lens types is shown in Fig. 8.65.

A capillary barrier develops at the exit of the well due to the abrupt area expansion. The shape of the air–liquid interface is described by the Young–Laplace equation of capillarity.

An interesting application of an open liquid-based lens is described in [8.168]. A water droplet is held in a hole with diameter of roughly 1.7 mm in a Teflon plate. The contact line between water, air, and Teflon is pinned to the edge of the hole, since Teflon is highly hydrophobic. An audio speaker is then used to change the air pressure on one side of the plate and push or pull the water to either side of the plate. This essentially changes the shape of the optical interfaces, i. e., the lens shape. Using a sinusoidal pressure wave optimized for the resonant frequency of the lens enables the maximal amplitude change of the lens, i. e., maximal changes to the focal length of the liquid lens. The idea is then to synchronize the taking of images of a certain focal distance with the movement of the water in its bore hole of the oscillating lens. This fast movement also allows for rapid capture of focus series, which could be used for 3-D rendering and similar applications.

That such a lens is an open system is an obvious disadvantage. Environmental conditions will easily influence the shape of the air interface, and the optical liquid used will most likely evaporate and therefore the lens will not have the same characteristic over a long period of time.

A way to overcome a couple of the drawbacks mentioned above is the introduction of another liquid that is immiscible with the optical liquid. Ideally, it should have the same density and a different refractive index. By using a second liquid, evaporation can be minimized, since the whole system of both liquids can be encapsulated very tightly. Such an approach is shown in Fig. 8.66. An active optical surface develops at the interface between the water and silicone oil and changes its shape depending on the pressure of the water.

Using liquids of equal density minimizes the influence of gravity, and the optical interface between the two liquids will therefore only be minimally disturbed. This approach is also used in electrowetting-based liquid lenses.

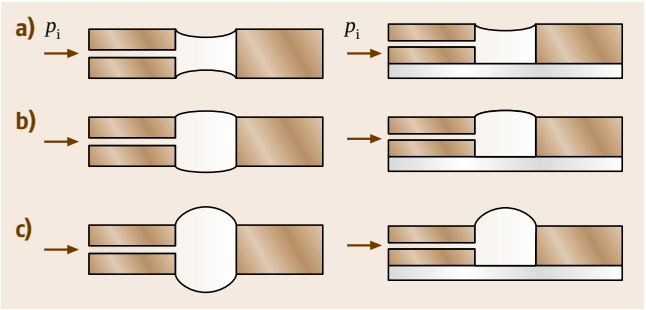

Fig. 8.65a–c Schematic cross-section of bi- and plano-concave **(a)** and convex **(b,c)** water lenses. The shape of the air–liquid interface depends on the inner pressure p_i and the capillary forces (after [8.167])

Electrowetting-Based Lenses

Electrowetting Phenomenon. Electrowetting describes the phenomenon of spreading liquid drops on solid surfaces using an applied voltage across the liquid and a counterelectrode underneath the solid surface.

Lippman [8.169] started the study of this effect by observing the influence of an electrostatic charge distribution on the capillary forces and tension at an interface. The relation between the contact angle of a liquid drop on a solid surface and the interfacial tension at the three-phase point was formulated by *Young* [8.170]. Combining the results of both studies leads to the Young–Lippman equation, which describes the change of the contact angle of a liquid drop on top of a solid surface induced by electrostatic forces when a voltage is applied between the drop and the underlying counterelectrode. In earlier research on electrowetting phenomenon, electrolytic decomposition of water upon applying voltages beyond a few hundred millivolts was a problem.

In the early 1990s, *Berge* [8.171] introduced the idea of using a thin insulating layer to separate the conductive liquid from the metallic electrode in order to

Fig. 8.66 Radius of curvature variation with pressure for liquid–liquid interface-based lenses. The lens was made of water contained in a glass aperture (1 mm diameter) and immersed in low-viscosity silicone oil (after [8.167])

eliminate the problem of electrolysis. This new concept has become known as electrowetting on dielectrics (EWOD).

A detailed theoretical description of the electrowetting effect can be found in [8.172]. Only the basic idea is briefly discussed here. The phenomenon of electrowetting on dielectrics is shown in Fig. 8.67.

An electrically conducting fluid drop on an insulating surface usually forms a drop with a resulting contact angle θ_0 to the surface. The shape of the drop is determined by minimization of the interfacial energies between the insulator and the droplet, the droplet and the surrounding gaseous phase, and the surrounding gaseous phase and the insulator.

If a voltage is applied between the droplet acting as one electrode and a (counter)electrode underneath the insulating film, the droplet spreads over a wider area and the contact angle θ decreases. Additionally, minimization of the interfacial energies leads to a change of the shape of the droplet. Depending on the applied voltage, a wide variety of different droplet shapes are possible.

Using an optical transparent and conductive liquid with a refractive index n_1 on a thin insulating layer on top of a transparent counterelectrode, it becomes obvious how to create a lens. The refracting interface is formed between the optical liquid and the air.

Optical devices based on electrowetting can usually be separated into two subgroups. The first uses the electrowetting on dielectrics effect by moving liquid drops macroscopically on electrodes. A concept for an optical switch based on electrowetting on dielectrics [8.173] is discussed in Sect. 8.8.2. The second group of optical devices employs so-called competitive electrowetting. This is especially used to make lenses.

Competitive Electrowetting. The electrowetting described above has the disadvantage that it usually works best for tiny droplets where the influence of gravity is negligible. Optimization is most likely possible for particular mounting positions and temperatures. For applications requiring larger diameters and which are not limited to one position of use, the influence of gravity on the droplet surface has to taken into account. Additionally, the influence of the electrode structures in the beam path is very often a disadvantage, due to diffraction or the occurrence of stray light.

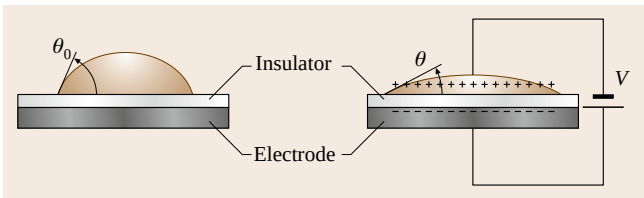

Fig. 8.67 Generic electrowetting setup: conductive liquid droplet at zero voltage (*left*) and with applied voltage (*right*). See text for details

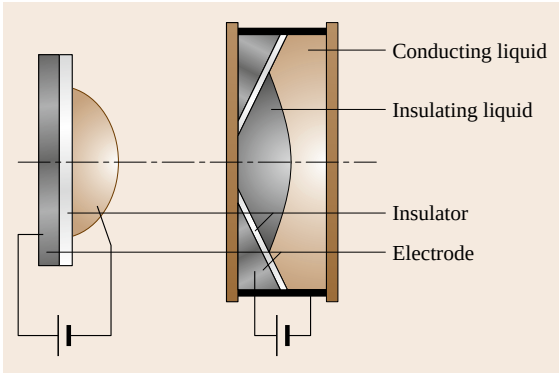

Fig. 8.68 Schematic of the device evolution from electrowetting on dielectrics to competitive electrowetting. The shape of the refractive interface is formed between the conducting liquid and the insulating liquid. Density matching makes the device insensitive to gravity forces. A conducting liquid is used as the electrode

One way to avoid these disadvantages is to introduce another liquid into the system. The requirements for such a liquid are as follows: It has to be an insulating liquid, immiscible with the conducting liquid, and should have the same density as the conducting liquid.

A schematic cross-section through a device is shown in Fig. 8.68. The drop of insulating liquid is covered with the conducting liquid. The device evolution is clearly visible. By applying a voltage between the conducting liquid and the counterelectrode, the contact angles changes and therefore forces the liquid–liquid interface into different shapes. Due to the fact that the refractive indices for the two liquids are not equal, a refracting surface is formed. This setup makes it possible to make a device that is insensitive to gravity forces due to the density match between the liquids. Because the packaging and the conducting liquid are used as electrodes, there are no electrodes to disturb the optical path.

Components Based on Electrowetting.

Liquid Lenses. As mentioned above, competitive electrowetting allows the design of optical components with a refractive interface that can change shape as controlled

by an electrical voltage and that therefore has a variable focal length. Such a lens was first described in [8.174]. The device is a closed cell filled with two immiscible liquids. A device with similar properties was presented in [8.175].

The first (insulating) liquid is a nonpolar oil, while the other is a (conducting) aqueous salt solution. Both liquids were density-matched to within 10^{-3}. Due to this density matching of the two liquids, the lens becomes insensitive to shocks and vibrations. The principal setup of such a liquid lens is shown in Fig. 8.69.

At low voltage, the water contact angle is high, i. e., the oil droplet has a low contact angle, and vice versa. The optical power (or the inverse focal length) of a lens is shown as a function of the applied voltage in Fig. 8.70.

From 0 to ≈ 36 V the lens has a concave and for higher voltages a convex shape. The focal length is therefore in the range -250 mm to infinity and from infinity to 40 mm.

Such electrowetting lenses seem to be very robust. It is reported that they can be switched more than 10^6 times without any sign of degradation. Switching speeds on the order of 10 ms have been achieved for a lens with diameter of 2.5 mm [8.177]. To reach the maximal speed, precise adjustment of the liquids' viscosities is necessary, such that the drop motion is critically damped. Otherwise the droplet either oscillates several times or relaxes only slowly towards the new equilibrium shape.

Competitive electrowetting lenses with aperture smaller than 1 mm can be completely fabricated using microelectromechanical systems (MEMS) technology [8.178]. To produce such lenses or lens arrays, quadratic V-groove-defined holes are etched in a standard silicon wafer. These will later be used as cavities to hold the two liquids. Afterwards, all surfaces are passivated with an insulating layer consisting of silicon dioxide and a hydrophobic layer. To contact the droplet, an ITO (indium tin oxide)-structured Pyrex wafer is anodically bonded to the bottom of the wafer. The lens liquid is deposited in the middle of the V-groove and embedded in the surrounding liquid, and another glass cover closes the system on top. A water-based inorganic salt solution with refractive index of 1.51 and density of 2.1 g/cm^3 was used as the lens liquid. As the surrounding liquid, a density-matched perfluorocarbon with refractive index of 1.293 was used.

The lateral dimensions of the prototype system are 8 mm × 8 mm, and the total thickness of the system is 1.525 mm. The lens aperture, which is equivalent to the size of the bottom of the V-groove, can be varied during lens production depending on the application.

The back focal length of such a lens with an aperture of 300 µm can be varied between 2.3 mm and infinity using voltages between 0 and 45 V.

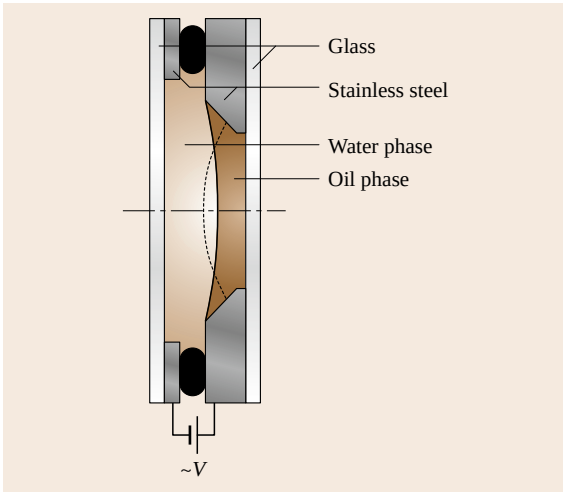

Fig. 8.69 Schematic representation of the liquid lens. Two immiscible liquids (conducting salty liquid and insulating oily liquid) are trapped between two glass windows. The liquid–liquid interface moves from continuous ($V = 0$) to the *dashed line* when voltage is applied. The optical axis is shown as a *short line* made up of *long dashes* (after [8.176])

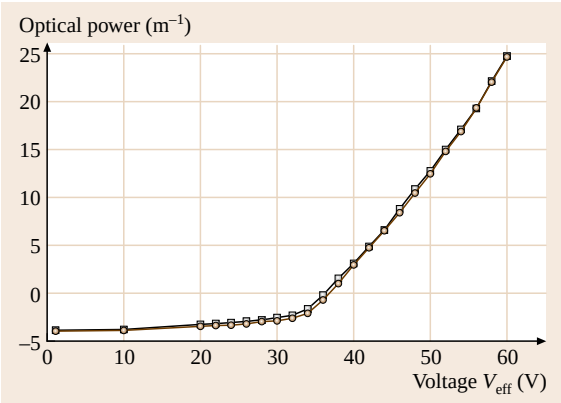

Fig. 8.70 Inverse focal length as a function of applied voltage for an electrowetting-based lens. *Two curves* which correspond to increasing (*circles*) and decreasing (*squares*) voltage are superimposed. The tiny hysteresis is most likely due to imperfect inner surfaces

Mechanical-Wetting Lenses

A type of lens called the mechanical-wetting lens has been proposed, combining the advantages of liquid lenses such as a smooth liquid–liquid optical interface and that overcome some of the real or perceived shortcomings of the electrically driven electrowetting lenses, such as electrolysis or Joule heating [8.179].

A cross-section of the central part of a mechanical-wetting lens can be seen in Fig. 8.71. A lens cell consisting of two subcells is filled with two immiscible liquids that form an interface at an aperture hole connecting both subcells. Both subcells have elastic membranes to apply outside pressure or give way of the pressure. By applying pressure to this membrane, the liquid inside one subcell becomes partially redistributed and therefore changes the shape of the internal optical interface. The membrane on the opposite subcell will bend outward to accommodate the volume change.

Membrane Lenses

Variable lenses based on membranes have been discussed since the beginning of the 19th century [8.180, 181]. More publications have been written and patents filed since then, but so far these devices have not made it to market, probably due to technical and material problems. They have mostly been discussed in the field of vision care in the form of spectacles with variable optical power.

Newer developments in the fields of materials science, micromechanical technology, and optics make the successful development and production of such devices seem promising. The interest of companies and agencies looking for components for lightweight optical zoom systems [8.182] used, for example, in unmanned aerial vehicles, handheld optical devices (camera phones), and surveillance cameras is helpful in this area.

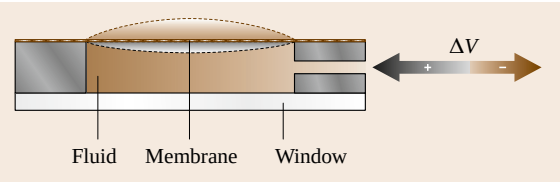

Fig. 8.72 Schematic cross-section of a membrane lens. The fluid is confined to the lens body between the glass window and the flexible membrane. The enclosed volume is changed by means of an external actuator. It is possible to obtain a converging lens (convex membrane) as well as a diverging lens (concave membrane)

The general setup of such a lens is shown in Fig. 8.72. A cavity enclosing a transparent optical liquid with refractive index n_l has at least one variable and flexible side-wall. For the optical liquids, water, salt solutions, or index-matching liquids are used. The volume of enclosed liquid is varied by means of actuators and kept constant for a certain optical power of the optical device. It is easily seen that such a device can be used as a variable plano-convex/concave lens.

Lens diameters are 0.5–20 mm [8.183–185]. Microlens arrays can also be fabricated [8.183].

Polydimethylsiloxane (PDMS) is usually used as the membrane material [8.183, 185], although other materials such as polyvinylidene chloride, polyethylene, and polyvinyl chloride have also been discussed [8.186]; the membranes are usually 10–100 μm thick.

Setups with two flexible membranes on opposite sides of the device are also discussed in literature [8.187, 188] as well as devices with two separate cavities [8.189]. Such devices enlarge the possible choices of membrane-based variable lenses from plano-concave/convex to biconcave/convex and convex–con-

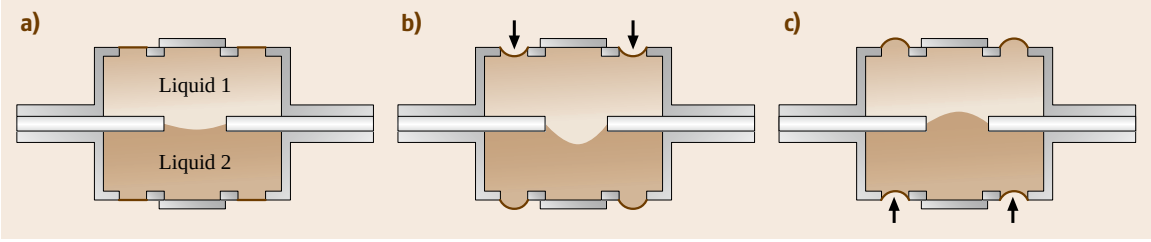

Fig. 8.71a–c Cross-section through a mechanical-wetting lens (after [8.179]). **(a)** Initial state, **(b)** further positive state, and **(c)** further negative state, assuming the refractive index of liquid 1 to be larger than the refractive index of liquid 2. Lens is actuated by deflecting a flexible membrane on the cell

cave and therefore increase the degrees of freedom in optical design setups.

Optical Performance of Membrane Lenses. The general optical performance of membrane lenses arises from the changes in the curvature of the membrane, starting from a curvature with infinite radius, where the lens acts as a parallel plate with no refractive power. With increasing pressure in the cavity, the liquid inside forms a convex lens, the lens radius decreases, and the refractive power becomes higher.

With decreasing cavity pressure, the membrane forms a concave shape, and the radius decreases and its diverging refractive power increases. Due to the more experimental character of these devices and the wide variety of different lens parameters, such as the aperture, membrane material, membrane thickness, and optical liquids used, it is impossible to present an exact characterization of the optical performance of such lenses.

In a more general approach an example of the optical performance of a membrane lens with two membranes taken from [8.182] is shown in Fig. 8.73.

The fluidic lens consists of a 4 mm-thick cylinder with diameter of 20 mm, covered with two 60 μm-thick PDMS membranes on both sides of the cylinder. As the optical liquid, a 63% sodium chromate solution with refractive index of $n_l = 1.5$ was used. The pressure inside the chamber was controlled by a battery-powered fluidic device consisting of a miniaturized pump, pressure sensor, valves, and an electronic control unit.

The transformation of the membrane shape from concave to convex is clearly seen, as well as the increase in optical power with decreasing radius of curvature of the membrane.

Aberrations in Membrane Lenses. The focal length of these variable membrane lenses is not the only interesting parameter. Other interesting parameters include the degree of sphericality and the apertures of the lenses that can actually be used optically.

The results of measurements of the curvature as a function of the applied pressure of a membrane lens with aperture of 200 μm and PDMS membrane thickness of 50 μm [8.183], taken by using a mechanical profiler, are given in Fig. 8.74.

It is obvious that the lens profiles found are not ideally spherical. The first reason is the nonlinear deflection of the PDMS membrane. The nonlinearity of the elastic PDMS membrane, however, is an intrinsic effect of the material and is not alterable. Other, more linear elastic materials have to be found. The other reason is the fixed edge of the membrane on a flat surface. This leads to an inflection line around the center of the lens at the lens edge. Outside this inflection line, the lens curvature of a generally convex lens is concave. So, the remaining convex usable aperture shrinks.

There are different ways to deal with these obstacles. The easiest is the development of such membrane lenses for a special optical design, which means that the necessary change in focal length can be minimized and the mechanical setup, such as the aperture size, mem-

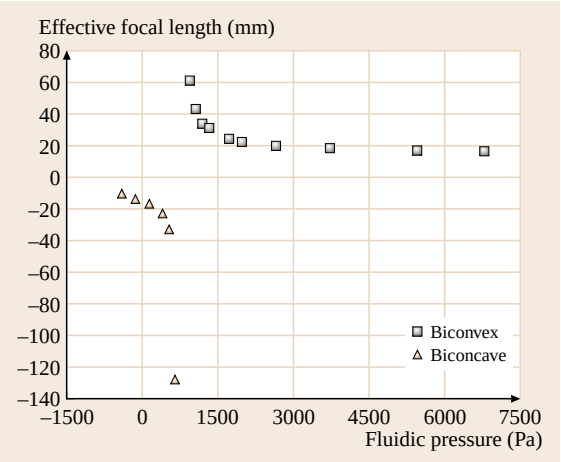

Fig. 8.73 Dependence of effective focal length on the fluidic pressure of the fluidic adaptive lens during lens-type transformation between biconvex and biconcave lens (after [8.182])

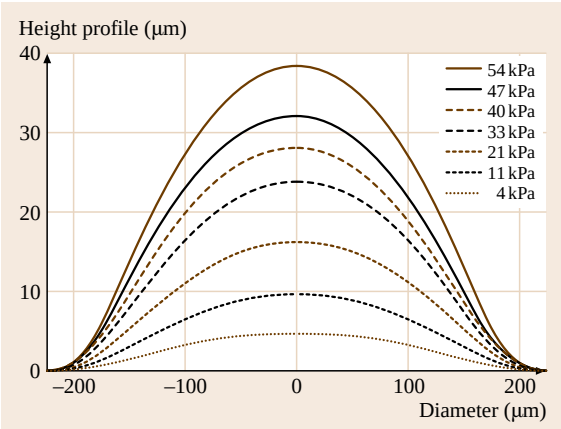

Fig. 8.74 Topography of a deflected membrane lens (aperture 400 μm) at different pressure values, measured with a surface profiler. The inflection points are seen at the ends of each graph (after [8.183])

brane thickness, and membrane fixtures of the lens, can also be optimized.

The following countermeasures can be used in the special-purpose lens mentioned above, as well as in multipurpose lenses. To counteract the nonlinearity of the PDMS membrane a variation of thickness with the radius can be considered. This would probably increase the complexity of the manufacturing process and therefore raise the manufacturing costs. To counteract the observable inflection point a different fixture for the membrane on the lens edge may be possible. The fixture has to be formed in such a way that the membrane runs asymptotically smoothly onto the surrounding lens body. This change from a mostly 2-D approach to a more three-dimensional (3-D) approach unfortunately also probably means a change from wafer-scale fabrication of multiple lens to a single-lens fabrication process. This leads to increased manufacturing costs for such devices.

A different approach of turning the shortcoming of such a single membrane into an advantage is the development of a double focal lens (Fig. 8.75) [8.190]. Here, a membrane with different thicknesses for the central and peripheral region is used. A pressure applied to the cell will result in different radii of curvature for the two regions, which will lead to a lens with two different focal lengths.

The permeability of the membrane to gases and liquids is another issue which has to be taken into account. A secondary experimental result observed while filling the lens mentioned in [8.183] is that any remaining bubbles quickly diffuse out of the system because the PDMS membrane is gas-permeable. On the other hand, this means that gas is also able to permeate into the lens in the case of concave lenses, which makes this lens type more likely to fail during its lifetime or makes the use of membrane lenses as concave lenses impossible.

For the thinnest membranes (thicknesses smaller than 10 μm) the membrane also becomes permeable to liquids. This leads to a loss of liquid over time and therefore to a slow change in the variable characteristic and a decay of the variable optical component in the long run.

More scientific research and development, i. e., development of new membrane materials, simulation of membranes in different fixtures, fabrication, optical, and environmental tests of membrane lenses, are necessary to approach a perfect variable lens.

Production of Membrane Lenses. There are various ways to produce membrane lenses. One method [8.185, 191] is it to produce the lens chamber and membrane separately using a soft lithography process. Afterwards the membrane and lens body are bonded together using an oxygen-plasma bonding technology. After the top of the lens has been formed, the bottom of the fluidic chamber is bonded to a thin glass slice for easy handling, again using an oxygen-plasma-activated bonding technique.

The detailed fabrication process of a membrane lens array is illustrated in Fig. 8.76. At first a ca. 10 μm-thick layer of photoresist is patterned onto a silicon wafer to form the mold for the microfluidic network. A second, ca. 100 μm-thick layer of photoresist is patterned on top of the first layer to create circular chambers for the lenses. The PDMS prepolymer mixture is spin-cast over the mold and subsequently cured at 150 °C. The total thickness of the PDMS layer is approximately

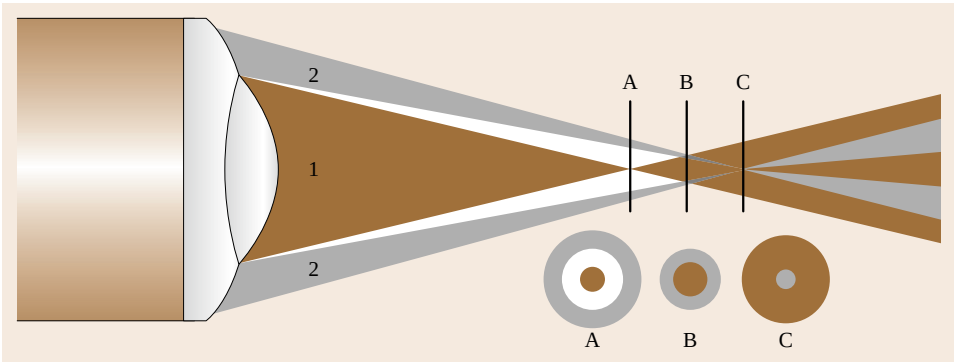

Fig. 8.75 Schematic of the beam transmission of a double-focus lens (after [8.190]). In plane A the beam passing through the central part of the lens (1) is in focus, while the beam passing through the peripheral part of the lens (2) is still converging. In plane B beam 1 is already diverging while 2 is still converging and in plane C 1 is converging while 2 is in focus

140 μm. The thickness of the PDMS membrane in the lens area is ca. 40 μm. The cured PDMS is peeled off from the mold, treated with oxygen plasma, and then irreversibly bonded to a glass substrate. Since the PDMS layer contains both the microfluidic network and the circular chambers, no alignment is required during the bonding process.

Another way of producing membrane lenses as well as membrane lens arrays is the use of standard microelectromechanical systems (MEMS) processing techniques [8.183]. This has the advantage that no transfer process is necessary and therefore all process steps can take place on the same mechanical basis, which ensures similar quality for all optical elements. Using cleanroom facilities ensures particle-free optical surfaces. Another advantage of using wafer-scale technology is that otherwise critical alignment steps during the assembly of various parts of the lens can be avoided. This technology seems to make the low-cost mass fabrication of such lenses possible.

A summary of the process is shown schematically in Fig. 8.77. Processing starts with photolithography on a silicon wafer polished on both sides in which the lens openings and the microfluidic channels are defined. A masking layer is deposited in wet oxidation and plasma-enhanced chemical-vapor deposition oxidation steps. The first oxide mask defines the contours of the circular lens openings with diameters of 300–600 μm, the fluidic channels, and the reservoir. This layer is structured by photolithography and subsequently opened by reactive-ion etching (RIE). In a second photolithography step, the photoresist layer is patterned. This second masking step defines the contours of the lens chambers and the reservoirs. These are then etched through half of the silicon wafer by an inductively coupled plasma (ICP) RIE process. The resist layer is removed afterwards. After coating the substrate with a primer to improve the adhesion of the PDMS to the silicon or silicon oxide, the PDMS film is spin-coated on top of the wafer. The PDMS film is cured and forms the pressure-actuated membrane, which encloses the working liquid and therefore defines the curvature of the lens.

In a second ICP RIE etch step the lens chambers, the reservoirs, and the fluidic channels are etched simultaneously, passivated by the structured SiO_2 layer. The etching stops abruptly when the SiO_2 layer at the front side is reached due to the etch selectivity of SiO_2. The remaining front-side SiO_2 layer is removed in a final RIE step. This means that the PDMS membrane is now stretched freely over the silicon lens chamber. To cap the fluidic channels and chambers, a thin Pyrex wafer is bonded to the back-side of the silicon substrate using a UV-curable optical adhesive. To minimize scattered light and cross-talk between the single lenses of an array, an aperture stop made of a 100 μm-thick structured chrome layer on the Pyrex wafer is required.

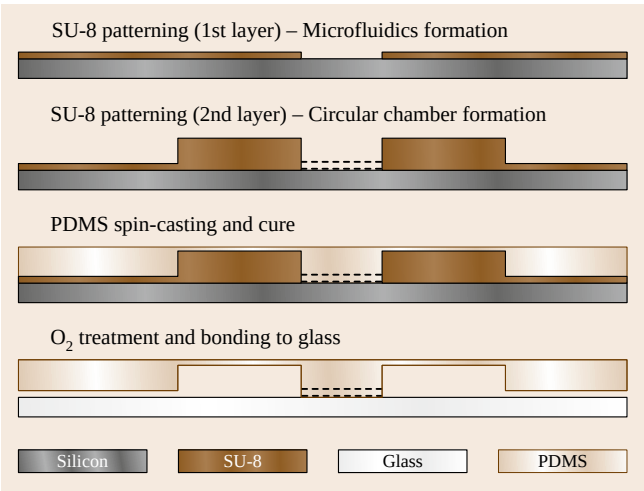

Fig. 8.76 For details see [8.191]

The wafer stack is then separated into individual chips by sawing. To prepare the fluidic lenses for operation, the cavity is filled with a liquid optical medium.

A similar process to fabricate membrane lenses with two flexible membrane sides is described in [8.188].

Actuation Mechanism. A rudimentary activation mechanism, mostly used in laboratory setups, is the use of a syringe pump to inject fluid into the lens chamber. Other actuation mechanisms also employ external pressure. To get a higher degree of control over the lens, the pressure is built up by, for example, piezoelectric elements, MEMS-based miniature pumps, or ferrofluids. For advanced variable optical lens systems it is necessary to employ automatic control including a pressure sensor to ensure uniformity of the optical power of the lens over a given amount of time. Highly integrated pressure sensors are made, for example, by MEMS technology [8.192]. Such controls are still in development and have to be integrated with the variable optical parts to give such new variable optical components a chance on the market.

External Pressure. Variable focusing in liquid-filled lenses has been demonstrated by deflecting the lens

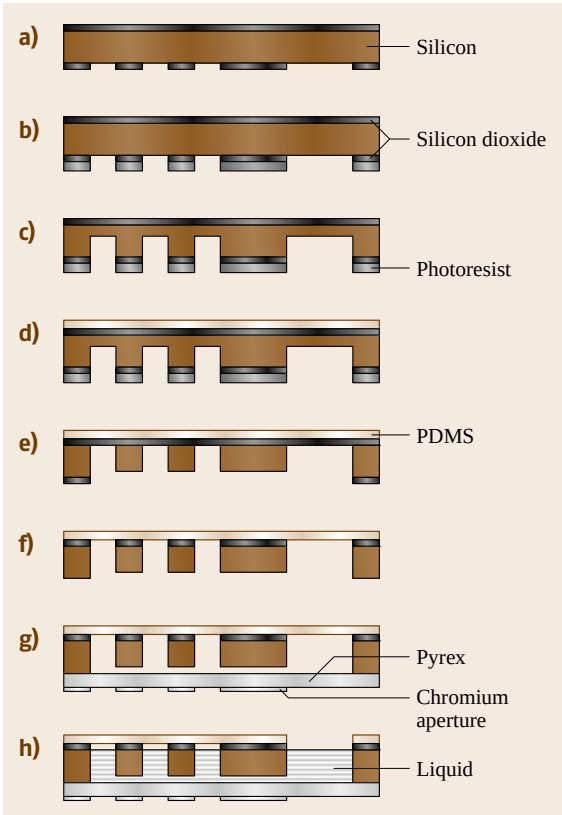

Fig. 8.77a–h Schematic process description. **(a)** Silicon wafer with both-side SiO_2 layer and with back-side opened by reactive-ion etching (RIE); **(b)** Photoresist, spin-coated, and structured; **(c)** First inductively coupled plasma RIE etching; **(d)** Spin-coating of primer and PDMS; **(e)** Second ICP RIE etching; **(f)** SiO_2 removal; **(g)** Bonding of the Pyrex wafer and patterning of the back-side chromium layer; **(h)** Sawing and filling of the devices (after [8.183])

membrane using pressure-driven mechanisms such as external pumps [8.184] or piezoelectric stack actuators [8.193].

Piezoelectric stack actuators are suitable actuators for driving variable optical lenses even though their working range is usually too short ($\approx 10\,\mu m$) to actuate the lens surface directly. There are two ways to solve this problem; both mechanically amplify the stroke of the piezoelectric actuator stack. The first is a mechanical lever that transforms the small stroke into a larger one, while the other way makes use of the incompressibility of the liquid. The cross-sectional area of the cylinder pressed by the piezoelectric actuator stack is several tens of times larger than that of the lens surface, and therefore the distortion of the lens surface is a couple of times that of the cylinder.

A special case of the external-pressure-based actuation method mentioned above, where acoustic pressure waves were used to change the shape of the air–water interface and therefore the optical properties of the lens, is described in [8.168].

A different approach is described by *Koyama* et al., where a standing wave in a closed aluminum cell filled with water and silicone oil forces changes to the profile of a curved interface between the two liquids [8.195]. The shape of the interface can be controlled by the driving force of the piezoelectric ultrasound transducers.

Magnetic Actuation. Ferrofluids provide another method to actuate a given variable membrane lens by magnetic forces. Ferrofluids are liquids with paramagnetic properties that combine rheological characteristics with strong force action. They consist of magnetite particles (Fe_3O_4) with diameter of 10 nm dispersed in a liquid [8.196, 197]. The possibility to fill any given or even changing geometry with ferrofluids and the easy integration into a system are the main advantages of this actuation method.

In Fig. 8.78 the actuator is shown as it generally functions [8.194]. A volume of ferrofluid is enclosed between two elastic membranes, which seal a chamber in a plastic housing. A magnetic field above the upper membrane attracts the ferrofluid and the upper membrane bulges upwards. The incompressible fluid causes

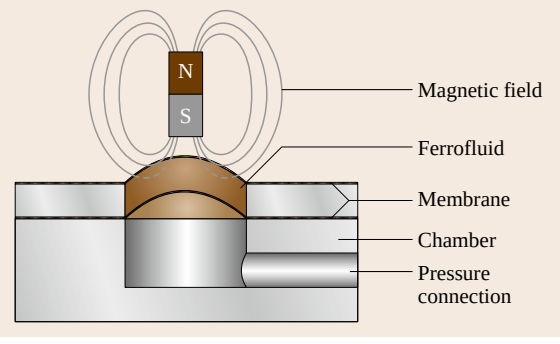

Fig. 8.78 Schematic view of a magnetic actuator. The ferrofluid is confined between two flexible membranes; the lower membrane separates the ferrofluid from the working fluid (pressure connection). The attractive force between the electromagnetic field and the ferrofluid leads to a decreasing pressure in the pressure connection and therefore a change in the optical active surface of the membrane lens connected to the actuator (after [8.194])

the lower membrane to follow accordingly. Thereby, a negative pressure can be generated below the second membrane. This negative pressure can be used to pump a secondary fluid that fills the chamber below the double membrane and features a pressure connection to a membrane lens. The magnetic field can be produced by means of an electromagnet and thereby control the shape of the membrane lens by an electric voltage.

Due to the effect that ferrofluids can only be attracted by magnetic fields, this actuator is only able to decrease the optical power of a given membrane lens.

Stimuli-Responsive Hydrogels. Another way to change the optical power of a lens is the incorporation of stimuli-responsive hydrogels, as described in [8.198]. The principal setup of such a lens system is shown in Fig. 8.57. There is a wide variety of hydrogels that react upon changing environmental conditions such as temperature or pH to incorporate or exclude water molecules in their structure, which results in a changing volume of the substances.

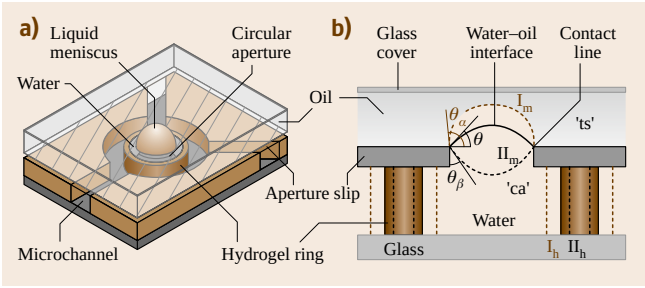

Fig. 8.79 Schematic view of a hydrogel lens setup. The interface between two immiscible optical liquids (water bottom, oil top) with different refractive indices forms an optical surface. The water–oil meniscus is pinned along the contact line 'ca–ts' between hydrophilic sidewall and bottom surface ('ca') and hydrophobic top surface ('ts') of the aperture. The water is confined between the glass substrates, oil, and hydrogel ring. The outside of the hydrogel ring is accessible to various other liquids to change the volume of the hydrogel ring. Changes in the volume of the hydrogel ring lead to changes in the confined volume and therefore in the shape of the water–oil interface (after [8.198])

8.8.2 New Variable Optical Components

Electrooptical Switches Based on Electrowetting

A concept for a 1 × 2 optical switch based on total reflection and electrowetting [8.173] is outlined in Fig. 8.80.

The proposed sandwich structure consists of a top and bottom glass substrate, each coated with an electrode structure and an insulating hydrophobic layer. One of the electrode structures is segmented, and it is possible to switch the different electrodes in a timely manner to move the droplet in between the sandwiched structure using electrowetting forces.

A 45° prism is attached to both glass substrates to avoid total reflection at the air–glass surface and allows light to be coupled into and out of the device. The collimated light is guided through the prism into the electrowetting device. Placing the liquid droplet in the optical path, the gap between the two glass substrates is index-matched and the light is transmitted through the sandwich configuration to output S2.

The liquid droplet can be driven out of the optical path by electrowetting forces due to the application of a voltage to the counterelectrodes in a timely manner. Now the gap between the top and bottom substrate is filled with air and not with index-matching liquids anymore. Total reflection of the light beam takes place at the interface between the glass and air. Therefore, the light will exit the device at the second output S1.

The concept has the potential to become highly integrated and applied in a matrix switch. In comparison with other concepts for optical switches it is important to note that this setup does not need precise movement and all optical parts that require precise alignment have fixed positions.

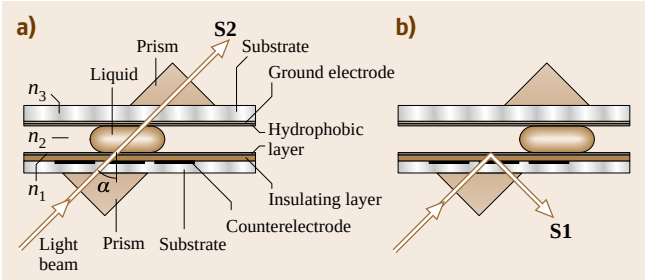

Fig. 8.80a,b Schematic drawing of the concept for an optical switch based on electrowetting. **(a)** The liquid droplet with refractive index close to the refractive index of the hydrophobic layers and glass is positioned in the beam path of the light by electrowetting. The light is transmitted nearly without any losses to S2. **(b)** The droplet is moved out of the beam direction. Total reflection occurs at the interface between the dielectric layer and air (after [8.173])

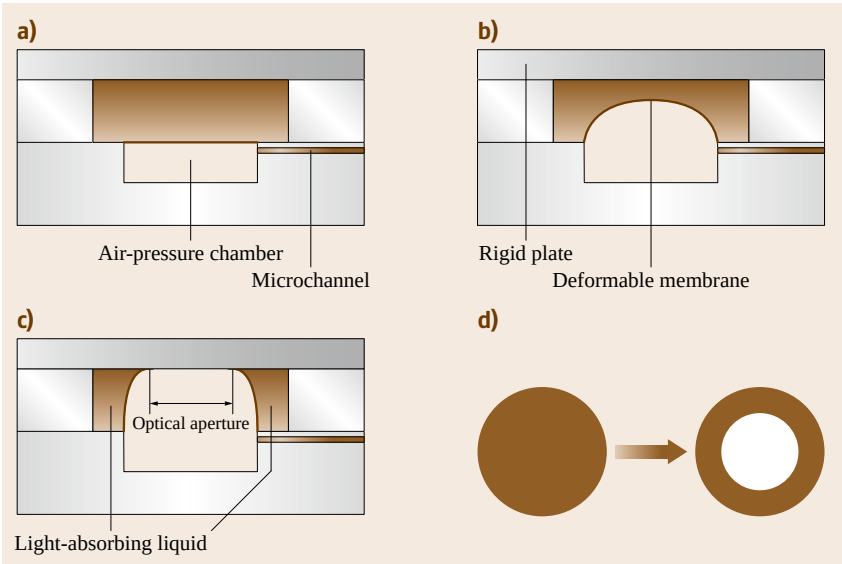

Fig. 8.81a–d Schematic drawing of the concept of a variable aperture based on optofluidic technology. A cell consisting of a rigid transparent plate and a transparent membrane on the opposite side is filled with a light-absorbing liquid **(a)**. Gas pressure can deflect the membrane **(b)** to the extent that the membrane is touching the rigid plate **(c)**, squeezing out the light-absorbing liquid and creating an optical transmission state. **(d)** Top views of the corresponding light field. *Left* is the light field of cases **(a)** and **(b)**, while *right* is that of case **(c)** (after [8.199])

Variable Apertures

A concept for a circular aperture with continuously adjustable diameter [8.199] is outlined in Fig. 8.81.

The proposed optofluidic device consists out of two subcells separated by a flexible PDMS membrane, sandwiched between two rigid, transparent plates. One of the subcells is filled with a light-absorbing liquid, while the other can be filled with various amounts of air by means of a mechanical air injection system.

As the air pressure increases, the membrane deflects upwards and squeezes out the light-absorbing liquids between the membrane and the upper rigid plate through capillary tubes connected to the upper subcell. When the membrane starts to touch the upper rigid transparent plate, an optical transmission state is created. Further increasing the pressure will increase the contact area of the membrane with the plate and therefore increase the diameter of the aperture.

The authors were able to create a device of size $15 \times 15 \times 2\,\mathrm{mm}^3$ that offered an aperture of variable diameter in the range of 0–6.3 mm.

It is also noteworthy that this concept allows for the easy creation of an array of simultaneous opening and shutting apertures with variable diameter.

8.8.3 Outlook on Variable Optical Components

Variable optical components have great potential to replace conventional optical systems in a wide variety of applications [8.188]. Applications in high-volume and low-cost markets, for example, cellphones and web cameras, are particularly appropriate for early use of components with intrinsic variable properties. The advantages of integrating these properties into the components will probably result in smaller form factors, more freedom in the design of such devices, easier and quicker assembly, and finally lower manufacturing costs and higher profit margins. The liquid lens from Varioptics (Lyon, France), which is based on electrowetting, is one of the components in larger-scale production already. Electronic controls are also available that can lead to the integration of such liquid lenses into barcode readers (Microscan, Renton, WA, USA) and other camera modules, enabling autofocus capabilities within a very small footprint. Other applications of such lenses for miniaturized still and video cameras will probably be seen in the coming months and years. Membrane lenses are not at this stage yet. More work has to be done to develop new membrane materials

and to integrate actuation and control into the variable component.

Other developments, such as variable filters or polarizers based on liquid crystals, will easily find special niche applications in which to succeed.

All technologies for variable optical components face strong competition from existing technologies. They have to find there way into optical designs and prove there advantages and abilities to potential users. Since existing technologies are already approved and in the market, there have to be clear advantages of using the new technologies. In the end, this will require lower manufacturing costs to replace existing operational solutions. The key to success will probably be an application that is made possible only through such a new technology.

The development of existing technologies is also progressing and continuing to give easier and cheaper solutions to the problems, and some technologies may become extinct due to changes in other areas.

8.9 Periodically Poled Nonlinear Optical Components

Obtaining quasi-phase matching (QPM) by periodically alternating the sign of the second-order nonlinear coefficient $\chi^{(2)}$ was first proposed in 1962 in a landmark paper by *Armstrong* et al. [8.200]. It took, however, nearly 30 years until efficient generation of frequency-doubled laser light with QPM in a periodically poled nonlinear material was realized [8.201–203]. The final breakthrough of QPM occurred with the first tunable laser source in the infrared wavelength regime using a bulk periodically poled lithium niobate crystal (PPLN) in an optical parametric oscillator (OPO) setup [8.204, 205].

This section will briefly review the physics of quasi-phase matching (Sect. 8.9.1). Because it continues to be a challenge, a detailed description of the actually techniques used to fabricate periodically poled crystals will be given (Sect. 8.9.2) followed by the standard techniques for the visualization of the obtained structures (Sect. 8.9.3). Finally, the currently most prominent applications for periodically poled crystals are described (Sect. 8.9.4).

8.9.1 Fundamentals

Second-Harmonic Generation (SHG)

In second-harmonic generation (SHG, also called *frequency doubling*) photons interacting with a nonlinear medium are effectively combined to form photons with twice the energy, and therefore twice the frequency of the initial photons (Chap. 3).

For efficient SGH three features must mainly be fulfilled:

1. The pump intensity I must be sufficiently high over a certain propagation length since, at least for small conversion efficiencies, the SHG generation is proportional to I^2
2. The nonlinear medium must have a high second-order nonlinear coefficient $\chi^{(2)}$
3. The light beams involved need to preserve their phase relationship over the propagation length.

Whereas (1) can be achieved by using high-power laser beams and for (2) a careful choice of the material is necessary, (3) requires additional measures since dispersion generally leads to a phase mismatch between the frequency of the pump laser beam (ω) and the frequency-doubled frequency (2ω).

This phase mismatch between ω and 2ω waves leads to destructive interference of the SHG light generated at the very beginning of the nonlinear crystal with that generated further inside the medium, thereby limiting the maximum output power (Fig. 8.82a). This problem can be overcome in birefringent crystals by choosing a particular orientation and keeping the crystal at a certain temperature such that both waves, ω and 2ω, propagate in the same direction and experience the same refractive index, so-called *noncritical phase matching* (NCPM). In general, these conditions are difficult to achieve, and because the value of $\chi^{(2)}$ also depends strongly on the orientation of the crystal, NCPM often results in an unsatisfying tradeoff.

There is, however, a very successful approach to preserving the phase relationship between ω and 2ω waves, so-called quasi-phase matching, which will be described in the following.

Quasi-Phase Matching (QPM)

For quasi-phase matching, the nonlinear susceptibility $\chi^{(2)}$ is modulated periodically to compensate for dispersion, i. e., in a nonlinear crystal, the orientation of the optical axis is periodically inverted. In ferroelectric materials this can be achieved by periodic inversion of the spontaneous polarization, i. e., of the

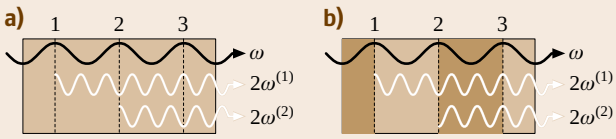

Fig. 8.82a,b Second-harmonic generation. **(a)** No phase matching: light generated at position 2 ($2\omega^{(2)}$) is out of phase with respect to the light generated at position 1 ($2\omega^{(1)}$). **(b)** Quasi-phase matching: by inversion of the sign of $\chi^{(2)}$, $2\omega^{(2)}$ is in phase with $2\omega^{(1)}$

ferroelectric domains (Fig. 8.82b). The period length Λ determines the wavelengths for which the specific nonlinear process is quasi-phase-matched. This Λ can be determined by an empirical relationship called the Sellmeier equation between the refractive indices n_i and wavelengths λ_i for a particular medium. Figure 8.83 schematically depicts the effect of QPM on the efficiency of second-harmonic generation in a nonlinear crystal.

The phase-matching condition for QPM and for the splitting of a pump wave into signal and idler waves is

$$\Delta k = k_\mathrm{p} - k_\mathrm{s} - k_\mathrm{i} = 2\pi/\Lambda \,, \qquad (8.108)$$

where k_p, k_s, and k_i are the wave vectors of the pump, signal, and idler waves, respectively, and Δk is the so-called phase mismatch, assuming that all wave vectors are collinear with the grating vector. Energy conservation requires $\omega_\mathrm{p} = \omega_\mathrm{s} + \omega_\mathrm{i}$.

Frequently Used Materials

For practical applications plenty of different properties of nonlinear crystals are of importance, first of all of course the magnitude of the nonlinear coefficient $\chi^{(2)}$, particularly if the available optical intensities are low. However, the optical transparency for all the involved wavelengths is also of major importance, as well as the optical damage threshold. The latter is a measure of the maximum optical intensity for a given wavelength and pulse duration supported by the crystal without being destroyed. Although there has been substantial improvement in the past years, the optical damage resistance of nonlinear optical crystals is still a challenging research area [8.206–208]. Properties such as the material's potential to be periodically poled, the availability of crystals with consistently good quality, large size and a reasonable price and finally chemical durability may also influence the choice for a specific material. Table 8.8 lists the main properties of some relevant nonlinear crystals. A more-detailed list can be found in [8.209].

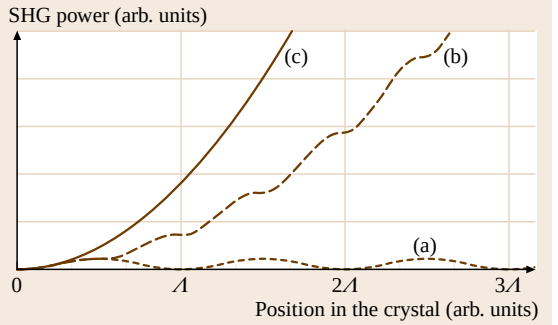

Fig. 8.83 Curve *a*: efficiency of second-harmonic generation in a nonlinear crystal without phase matching, with quasi-phase matching (curve *b*), and with perfect phase matching (curve *c*). There Λ denotes the period length of the periodically poled nonlinear crystal

Very recently, a new type of materials, so called oriented-patterned (OP) materials have been developed, with gallium arsenide (GaAs) being the most promising example [8.210]. This is mainly due to its large nonlinear susceptibility, broad transparency range, low optical absorption, high thermal conductivity, high laser-damage threshold, and last but not least well-developed material technology.

8.9.2 Fabrication of Periodically Poled Structures

Depending on the application, periodically poled structures with period lengths of a few to some tens of μm are required. The necessary interaction length, i. e., the size of the periodically poled structure should reach several mm, over a thickness of some hundreds of μm to obtain reasonable output power. The latter specification can be circumvented by using waveguide techniques, thereby achieving a much higher interaction length for the confined light. Although advantageous because the required material length is shorter, and also because the periodically poled structures are necessary only at the surface layer, the crucial drawback of this approach lies in the optical damage threshold of the material, which is why higher output powers are generally achieved in bulk periodically poled crystals.

Electric Field Poling

Poling of domain patterns is usually achieved via ferroelectric domain engineering: applying electric fields of appropriate polarity and field strengths above the so-called coercive field E_c to cause domain reversal.

Table 8.8 Selected properties of frequently used nonlinear crystal materials utilized in periodically poled devices [8.209, 211–213]. d_{im}: nonlinear optical coefficient; T: transparency range

Crystal	d_{im} (pm/V)	T (μm)	Optical damage (GW/cm^2)
Lithium niobate ($LiNbO_3$)	$d_{33} = -27$	0.36–5.8	0.5 (10 ns)
Lithium tantalate ($LiTaO_3$)	$d_{33} = -21$	0.32–5.5	
Potassium titanyl phosphate (KTP, $KTiOPO_4$)	$d_{33} = 8.3$	0.34–3.2	4.4 (1.3 ns)
Beta barium borate (BBO, β-BaB_2O_4)	$d_{22} = 2.3$	0.2–2.6	9.9 (1.3 ns)
Cadmium selenide (CdSe)	$d_{33} = 36$	0.75–25	0.06 (10 ns)
Gallium arsenide (GaAs)	$d_{14} = 94$	0.9–17	

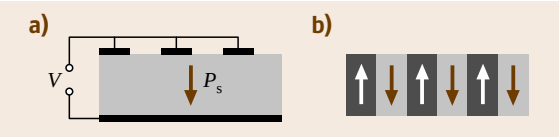

Fig. 8.84a,b Standard technique for the generation of periodically poled bulk nonlinear crystals. A single-domain crystal (spontaneous polarization P_s) is partially poled by applying a voltage through structured electrodes **(a)**. In **(b)** the resulting domain pattern is shown

The standard technique for the generation of periodic domain structures uses patterned electrodes generated using a photolithographic process (Fig. 8.84). This technique fails, however, for small poling periods ($\ll 5\,\mu m$) in thick crystals ($\geq 0.5\,mm$), because of an unavoidable spreading of the poled region with respect to the electrode size due amongst others to the enhanced electric fields at the electrode edges.

Corona Poling. To overcome these limitations, miniaturization of the electrodes is required. A possible solution relies on corona poling, thereby applying the required electric fields through an ultra-sharp tip (e.g., from a scanning force microscope) to the positions of the crystal to be poled [8.214]. A drawback of this technique is the sequential writing of domain patterns, which is therefore relatively slow. It is therefore preferred only for the generation of domain structures for storage applications [8.215].

E-Beam Poling. A similar technique uses the electron beam from an electron-beam lithography system to deposit electrons on top of the crystal, thereby generating the high electric fields required for poling. Gratings with periods as small as 1.6 μm across 500 μm-thick $LiNbO_3$ crystals have been obtained [8.216]. Even smaller structures of $< 200\,nm$ can be generated in thin ($< 10\,\mu m$) liquid-phase epitaxy (LPE) $LiNbO_3$ films [8.217]. As for corona poling, this technique is slow because it is sequential and lacks a precise long-range periodicity due to stepping misalignment.

Light-Assisted Poling

To overcome these limitations on the depth of domain growth, a very promising new technique has been developed: light-induced poling. Controlled domain reversal is obtained by applying a homogeneous electric field slightly smaller than E_c in addition to a modulated UV-light intensity pattern (ideally generated by two interfering laser beams) [8.218]. Because in certain crystals (namely Mg-doped $LiNbO_3$) UV light reduces the coercive field [8.219], the light pattern is transferred into a domain pattern. In recent experiments, all-optical switching of ferroelectric domains has also been achieved, thereby avoiding the application of any electric field to the crystal.

Poled Growth

In some materials, namely $LiNbO_3$, poling of domain patterns during crystal growth has been successfully demonstrated with period lengths smaller than 4 μm [8.220, 221]. Although quite promising, the quality, namely the long-range periodicity of those periodically poled crystals, is not yet satisfactory, therefore this technique still needs improvement for wider application.

For the generation of orientation-patterned GaAs, all-epitaxial growth has been utilized. This process is based on photolithography and molecular-beam epitaxy to grow a thin-film template with the desired periodic crystal inversions. In a further step, a thick film is grown on this sample by hydride vapor-phase epitaxy to fabricate bulk orientation-patterned crystals [8.212].

8.9.3 Visualization of Ferroelectric Domain Structures

For the improvement of the quality of domain patterns a reliable, easy-to-use visualization technique is

required. Freshly poled domain structures can be observed by means of optical microscopy due to stress-induced birefringence at the domain boundaries. The main drawbacks of this simple technique are its limited lateral resolution (a few μm) as well as the restriction to recently made domains. Among a multitude of visualization techniques [8.222], two standard methods are mostly applied, as discussed briefly below. Whereas the first is best suited for a large overview on the domain structures, the second enables an otherwise unreachable lateral resolution.

Domain-Selective Etching

This technique is based on the fact that the etch rate of a certain material depends on the orientation of the polar axis. As a consequence the domain configuration can be transferred into a topographical structure which can then be imaged by means of optical microscopy, or in the case of smaller domain patterns (< micron-sized) as a topographical image by scanning force microscopy. Although it is destructive, this technique is still that most often used, mainly because of its ease of use [8.223].

Piezoresponse Force Microscopy (PFM)

This technique takes advantage of the fact that all crystals exhibiting ferroelectric domains are also piezoelectric. Furthermore, inverting the orientation of the spontaneous polarization also inverts the piezoelectric tensor element. This is why applying an electric field to a crystal reveals the domain structure as a topographical structure via the converse piezoelectric effect. In PFM, a standard scanning force microscope is modified to allow application of voltages to the tip, thereby generating an electric field inside the crystal at the position of the tip while it scans across the surface. Depending on the orientation of the ferroelectric domain, the crystal expands or contracts underneath the tip, thus allowing one to map the domain configuration with a lateral resolution of some 10 nm. The thickness changes to be measured are on the order of only some 10 pm and hence a frequency-selective detection scheme is used, applying an alternating voltage to the tip with subsequent lock-in detection [8.224].

8.9.4 Applications

In general periodically poled nonlinear materials are used to obtain quasi-phase-matching conditions for frequency conversion and therefore a higher output light power at the desired wavelength. Frequency conversion in nonlinear optical materials can be classified as:

- Second-harmonic generation (SHG): $\omega + \omega \rightarrow 2\omega$
- Sum-frequency generation (SFG): $\omega_1 + \omega_2 \rightarrow \omega_3$
- Difference-frequency generation (DFG): $\omega_3 - \omega_2 \rightarrow \omega_1$
- Optical parametric generation (OPG): $\omega_3 \rightarrow \omega_1 + \omega_2$.

The current state of the art of the two main applications, frequency doubling via SHG and optical parametric generation as a source of infrared (IR), light will be presented in the following.

Second-Harmonic Generation (SHG)

Frequency doubling, thereby generating shorter wavelengths, is of special interest mainly because infrared light is relatively cheap, high-power IR laser diodes are available, howeven, laser light in the blue wavelength range is still difficult to obtain. For the experimental realization, there are several boundary conditions that need to be fulfilled. This is the reason why blue lasers based on frequency doubling in periodically poled nonlinear materials can only reach output powers of about 100 mW. Their main drawback currently lies in the optical damage threshold of the material. Note that the crystals need to have a high damage threshold for the pump as well as for the SHG light. Because the efficiency of SHG is proportional to I^2 of the IR pump light, a high power density inside the nonlinear medium is desired. From this point of view, waveguide techniques appear an ideal concept for efficient frequency doubling. However, optical damage of the crystals is still a crucial drawback. Currently, using MgO-doped periodically poled lithium niobate (PPLN), an output power of 25 mW (340 nm) out of 81 mW in the waveguide-based technique has been shown [8.225]. Typical values for an intracavity periodically poled potassium titanyl phosphate (PPKTP) frequency doubler, using a bulk crystal for frequency doubling, are 234 mW (461 nm) with 310 mW input power [8.226] or even 500 mW (473 nm) with 800 mW input power [8.227].

Optical Parametric Generation

Many applications require laser sources in the mid-infrared wavelength between 2 and 20 μm, mainly for spectroscopic measurements of organic and inorganic

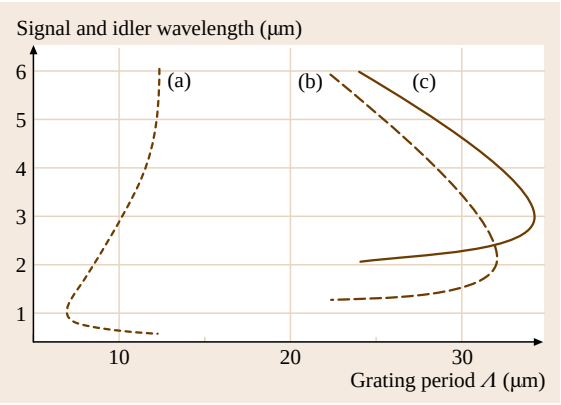

Fig. 8.85 Signal and idler output wavelengths of OPO operation for different grating periods Λ. The pump sources shown are *a*: Nd:YAG (2ω) laser – 532 nm; *b*: Nd:YAG laser – 1064 nm; *c*: Er-doped fiber laser – 1550 nm

molecules. A continuously tunable laser source with a narrow linewidth in this wavelength region is therefore highly desirable. A possible solution consists of using the OPG process, which allows the generation of the desired wavelength depending on the pump wavelength and the nonlinear material used. It can be tuned by choosing the phase-matching conditions, i. e., coarsely by the grating period Λ of the periodically poled nonlinear crystal and a fine adjustment by heating the crystal (Fig. 8.85). In order to make a powerful laser source, the nonlinear medium is brought into a cavity that is tuned on resonance for the nondesired wavelength. An overview of mid-IR frequency generation can be found in [8.209].

There are basically two different operation schemes for optical parametric oscillators (OPO). For continuous-wave operation a high pump-laser intensity is required to reach the threshold for frequency conversion. Another possibility consists of using an intracavity pumped setup, with the nonlinear medium placed inside the laser cavity.

Most OPOs, however, are pumped with nanosecond pulses from a Q-switched laser, thus easily reaching the required light intensities inside the nonlinear material. Typical emissions are nanosecond pulses in the near- or mid-infrared region with pulse energies up to a few millijoules.

8.10 Photonic Crystals

A photonic crystal (PC) is defined, in a narrow sense, as a crystal in which the dielectric constant ε varies periodically in specific spatial directions; for the reader's convenience we cite several textbooks and feature issues on PCs [8.228–235]. In order to control the light field, the lattice constant a should be comparable to the wavelength λ of the relevant light. In the case where the variation is along one direction, this is called a 1-D PC. Similarly, we define 2-D and 3-D PCs, corresponding to the respective cases where ε varies along two and three independent directions.

Figure 8.86 shows schematics of representative examples. For a 1-D PC, there is the well-known example of the periodic dielectric layered media; in this chapter, there is little mention of 1-D PCs, except for Sect. 8.10.4. In the case of 2-D PCs shown in Fig. 8.86b, interactions of air or dielectric axes in the plane perpendicular to the rod axis form a 2-D lattice; this plane is the 2-D PC plane. Let us consider the simple case of a 1-D PC. As is well known, states (or eigenmodes) of light in this PC with wavevector $\boldsymbol{k}$ parallel to this particular direction differ greatly from those in a uniform dielectric. Similarly, the respective eigenmodes of light with $\boldsymbol{k}$ in the 2-D plane for 2-D PC and with $\boldsymbol{k}$ in an arbi-

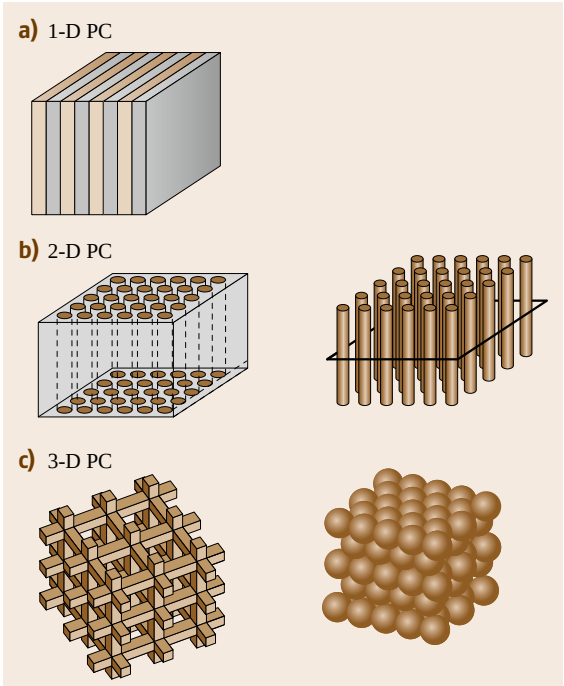

Fig. 8.86a–c Schematics of representative 1-D (**a**), 2-D (**b**), and 3-D (**c**) photonic crystals

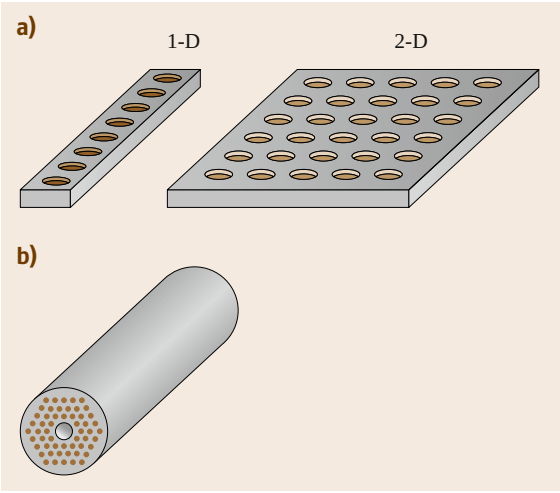

Fig. 8.87a,b Schematics of (**a**) photonic-crystal slabs and (**b**) photonic-crystal fiber

trary direction in the 3-D PC become unique compared with homogeneous 2-D and 3-D dielectrics. For 3-D PCs, there are a variety of examples other than the two shown in Fig. 8.86c. An array of polystyrene spheres suspended in water was the first 3-D PC sample, made as early as the 1960s, as shown in the example on the right-hand side of Fig. 8.86c. Currently, a similar sample called an artificial opal crystal made of SiO_2 is also being intensively studied, together with the so-called inverse opals.

The situation for the PC slabs shown in Fig. 8.87 also differs greatly from those for the corresponding 1-D and 2-D PCs. Namely, if the thickness of the slab is of the same order as or smaller than the relevant wavelength of light, the situation is completely different from 1-D (2-D) PCs, where the sample thickness is a priori assumed to be infinitely large. For the latter case, a plane wave propagating along one direction (1-D PC) or in the 2-D plane can be well defined, so that one needs to treat the problem three-dimensionally. Figure 8.87b shows a schematic of a PC fiber, another important example of PCs where the plane perpendicular to the fiber forms a 2-D PC lattice, except for the central portion along which light can propagate. There are two types of PC fibers, solid-core (holey index-guiding) fibers, in which the central potion is made of a dielectric, and hollow core (photonic band gap) fibers, in which it is filled with air.

Thus far we have classified dielectric-based PCs according to their dimensionality. However, there are other types of related systems which also show a photonic band gap (PBG). Those are metallo-dielectric or metallic PCs, quasicrystal PCs, 2-D random-media PCs, and nonlinear PCs, as described later. Concerning fabrication methods of the representative samples in the optical region see [8.230] and Sect. 8.10.5.

8.10.1 Photonic Band Structures

Light States in Photonic Crystals

In general, the eigenstates (modes) of light are specified by a set $(\boldsymbol{k}, \hbar\omega, \boldsymbol{e})$, where $\boldsymbol{e}$ is the unit vector denoting the polarization. The eigenstate in a PC where $\varepsilon(\boldsymbol{r})$ varies periodically with respect to $\boldsymbol{r}$ (position vector) differs greatly from that in a homogeneous medium. Suppose for simplicity that the dielectric (insulator) has the vacuum magnetic permeability μ_0. Assuming that the light is harmonic, i. e., $\boldsymbol{E}(\boldsymbol{r}, t) = \boldsymbol{E}(\boldsymbol{r})\exp(-\mathrm{i}\omega t)$ and $\boldsymbol{H}(\boldsymbol{r}, t) = \boldsymbol{H}(\boldsymbol{r})\exp(-\mathrm{i}\omega t)$, the equation, e.g., for $\boldsymbol{E}(\boldsymbol{r})$ can be derived from Maxwell's electromagnetic equations as

$$\mathrm{rot}\,\mathrm{rot}\,\boldsymbol{E}(\boldsymbol{r}) = [\omega^2\varepsilon(\boldsymbol{r})]\boldsymbol{E}(\boldsymbol{r})\,. \tag{8.109}$$

Namely, the problem is reduced to solving this equation, which was first done for a 3-D periodical array of dielectric spheres [8.236]. A similar equation can also be derived for $\boldsymbol{H}(\boldsymbol{r}, t)$, but with $\boldsymbol{H}(\boldsymbol{r})$ obtained from $\boldsymbol{E}(\boldsymbol{r})$ using the relation $\mathrm{rot}\,\boldsymbol{H}(\boldsymbol{r}) = -(\mathrm{i}\omega/c^2)\,\mu_0\varepsilon(\boldsymbol{r})\boldsymbol{E}(\boldsymbol{r})$.

The above equation can be solved by using, for example, the widely used plane-wave expansion method [8.229, 230]. Namely, the solution $\boldsymbol{E}_k(\boldsymbol{r})$ is expressed as a superposition of Bloch-type plane waves,

$$\boldsymbol{E}_k(\boldsymbol{r}) = \Sigma\boldsymbol{e}_k(\boldsymbol{G}_i)\exp[\mathrm{i}(\boldsymbol{k}+\boldsymbol{G}_i)\cdot\boldsymbol{r}]\,, \tag{8.110}$$

where $\boldsymbol{G}_i$ is the i-th reciprocal lattice vector, and the vector amplitude $\boldsymbol{e}_k(\boldsymbol{G}_i)$ is to be determined so as to satisfy (8.109). Substituting (8.110) and the Fourier expansion version of $\varepsilon(\boldsymbol{r}) = \Sigma\varepsilon(\boldsymbol{G}_i)\exp(i\boldsymbol{G}_i\cdot\boldsymbol{r})$ into (8.109) and setting the coefficients of each of the plane waves to zero, we get the eigenvalue equations for $\boldsymbol{e}_k(\boldsymbol{G}_i)$. From this equation, the secular equation for the eigenvalues ω^2 can be derived; needless to say, for each eigenstate, characteristic spatial patterns of electric $\boldsymbol{E}_k(\boldsymbol{r})$ and magnetic field $\boldsymbol{H}_k(\boldsymbol{r})$ are specified. We note that, in a 3-D PC with sufficiently large variation of ε, i. e., $\varepsilon = 10$ against 1 (air), we often need to include more than 1000 plane waves to obtain very accurate values of ω^2; this is because the coupling between light and matter is much stronger in the optical (visible) region than in the x-ray region, because of the much stronger Bragg diffraction.

We plot the eigenfrequency (eigenenergy) $\omega(\boldsymbol{k})$ thus obtained as a function of $\boldsymbol{k}$ in the reduced Brillouin zone (BZ), which is called the *photonic band* (PB); The PB is split into many bands, which are numbered by the band index n in order of inverse energy. The photonic band structure (PBS) shown by $\omega_n(\boldsymbol{k})$ is unique and quite different from that in homogeneous media in terms of the density of states (DOS) of light. A remarkable difference is that in a PBS there is often a particular energy region where no light states exist for any direction [8.237,238] or for a range of directions. We call the former a full (PBG) and the latter an incomplete photonic band gap (or stop band). Hereafter, we call them both simply PBGs when there is no need to emphasize the difference.

Here a question arises as to whether a PBS obtained for an infinitely large lattice makes sense in a realistic finite sample. This question is reasonable because true band states do not exist in the case of photons, in contrast to electrons which have definite bound states in the negative energy region. If escape from a finite PC to the exterior region is large, the PB picture valid for an infinite system would lose its practical meaning. A pioneering work examined this question as early as the 1980s [8.239], revealing that the PBS in the ideal case can be used for a finite structure if the (lossless) eigenstate is regarded as leaky. Several important examples of PBS are presented below.

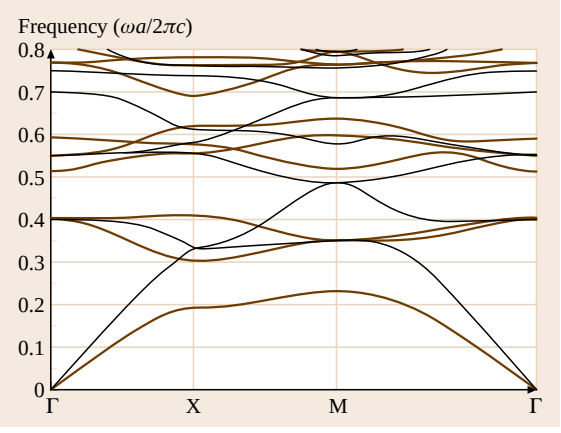

Fig. 8.88 Photonic band structure of a 2-D PC of cylinders arrayed in a square lattice: TM bands (*brown lines*) and TE bands (*black lines*). The cylinders of $\varepsilon = 12$ are arrayed in a lattice in air. The ratio of the radius r of the cylinders to a is 0.3. The frequency ω is shown in dimensionless units, i. e., normalized by $2\pi c/a$. Γ, X, and M denote high-symmetry points of the first Brillouin zone

2-D Band Structure

Figure 8.88 shows an example of a 2-D PBS for a 2-D PC of dielectric cylinders ($\varepsilon = 12$) arrayed in a square lattice in air. The eigenmodes can be specified by the polarization, and are classified as TM or TE modes for $\boldsymbol{E}$ or $\boldsymbol{H}$ parallel to the cylinders, respectively. It is important to note that, in this case, three 2-D PBGs are seen to open for TM modes; the existance of 2-D PBG was first evidenced experimentally in an optical (near-infrared) region for TM mode in a triangular lattice of air-rods [8.240]. Each band belongs to the specific irreducible representation of the relevant point group that depends not only on the polarization but also on the $\boldsymbol{k}$ direction. As a result, for example, if the space group of a wavevector $\boldsymbol{k}$ contains a mirror operation, then any state of that $\boldsymbol{k}$ is classified into even or odd symmetry according to whether $\boldsymbol{E}$ is symmetric or antisymmetric with respect to the mirror plane. This statement is important, for example, in coupling between external light and a PC state. Consider an external light beam incident at normal incidence on a flat surface of a PC sample. Then, if the group of the wavevector of the incident light $\boldsymbol{k}$ involves a mirror operation and the polarization is perpendicular to the mirror plane, the odd-parity (even-parity) modes cannot be coupled to even-parity (odd-parity) external light, and are called *uncoupled modes*. Finally, we note that the first and second bands are often called the dielectric and air band, respectively, since the electric field is localized to a considerable extent around the dielectric cylinders and the air background, respectively [8.228].

3-D Band Structure

Figure 8.89 shows an example of a PBS for an inverse diamond lattice structure, which is composed of tetrabonds consisting of air rods (diameter r) in a dielectric of $\varepsilon = 7$ with $r/a = 0.1$. The shape of the first BZ is the face-centered cubic (fcc) lattice. It is seen that a full PBG opens in all directions; the fact that a full PBG opens in this 3-D PC with diamond structure has been experimentally evidenced in the optical region [8.241]. This PBG corresponds to the well-known BG of electrons in a semiconductor such as GaAs, which also has the same BZ structure. The photonic and electronic structures resemble each other in many respects, which arises from the resemblance of the two different wave equations.

Band Structure of Slab-Type PCs

Air-hole semiconductor 2-D slab PCs [8.242] have been studied intensively. In particular, two kinds of slab PCs are the most important: the air-bridge type, in

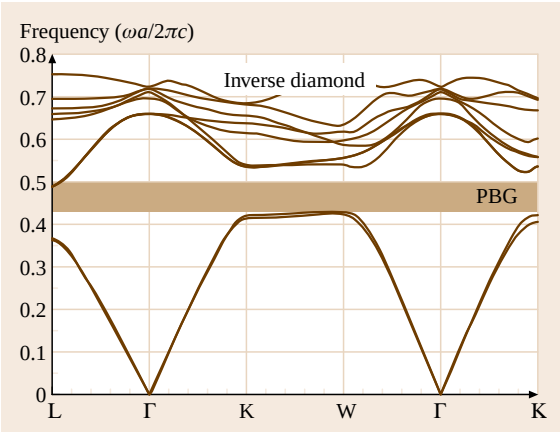

Fig. 8.89 3-D photonic band structure of the diamond lattice (a sample of inverse diamond structure; for details, see the text)

which the core is suspended in air, and the clad type. A slab PC with core made of AlGaAs or Si, and that of $SiO_2/Si/SiO_2$, are representative of the former and the latter, respectively. A typical PBS calculated for a triangular-lattice air-bridge PC is shown in Fig. 8.90.

The guided modes exist in the region below the so-called air light line, where light can be confined due to total internal reflection [8.243, 244]; light belonging to the modes inside the light cone are leaky; i. e., light escapes from the slab region, just like the case for conventional slab waveguides (WGs). It is seen that, for TE-like modes, there is an energy region where no guided modes exist. Usually, in the case of slab PCs the term PBG is used for this situation. It is important to note that, even in these 2-D PC slabs, strong 3-D confinement of light is realized with combined use of a 2-D PBG in the 2-D plane and total reflection in the direction perpendicular to the plane.

Band Structures of Other PCs

Metallic Photonic Crystal (MPC). In a MPC the plasmon modes of individual units can hop from one unit to another to form tight-binding plasmon bands. Due to the multipolar moments associated with the excited charge fluctuation, they can mix with light to become plasmon polariton bands, often called surface plasmon polariton (SPP) bands because of strong confinement on the metallic surface. Figure 8.91a,b shows a cross-sectional MPC structure including a hexagonal array of metallic dots on the metal/glass substrate and its SPP band diagram, respectively [8.245]. Here, P is the periodicity of the dot array. The SPP energy is strongly confined at the metal–air and/or metal–glass interface and decays exponentially far from the interface. The SPP band for the metal surface without any dot array is a single dispersive curve increasing monotonically towards ω_{sp} (the surface-plasmon angular frequency) below the light line, while the SPP band for a periodic surface structure like this case exhibits PC-like zone-folded bands, as shown in the figure. A large band gap, omnidirectional in favorable cases, originates from the large frequency difference between the different plasmon modes of individual units [8.246, 247]. Thus, MPCs have potential applications in waveguiding and signal processing using their wide band gaps. Furthermore, polariton bands in MPCs accompany a strong local field due to the charge fluctuation confined on the surfaces of arrayed units.

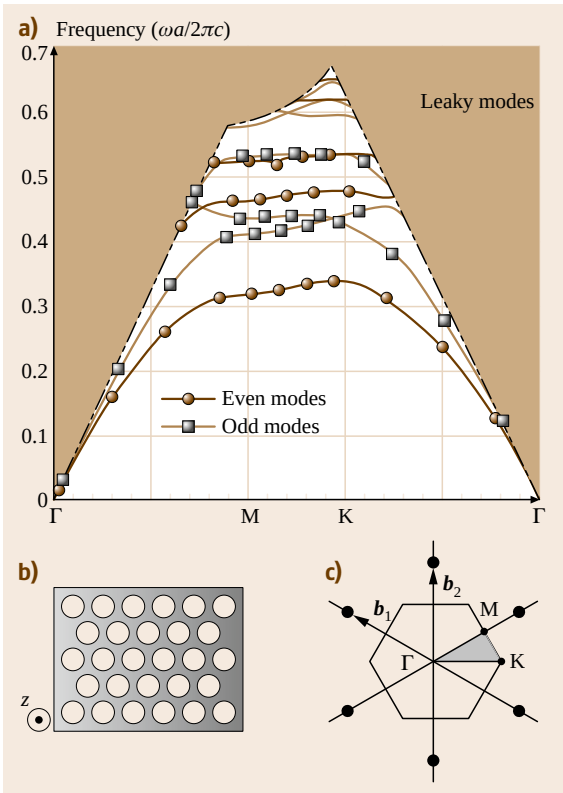

Fig. 8.90a–c Guided modes in a 2-D air-rod PC slab below the air light line. *Circles* and *squares* indicate even and odd modes, respectively. The parameters are such that $\varepsilon = 11.9$, $r = 0.44a$, and $d = 2a/3$, where r and d refer to the hole radius and the slab thickness, respectively [8.243] **(a)**. Triangular lattice in real space **(b)** and the corresponding Brillouin zone together with the reciprocal lattice point **(c)**

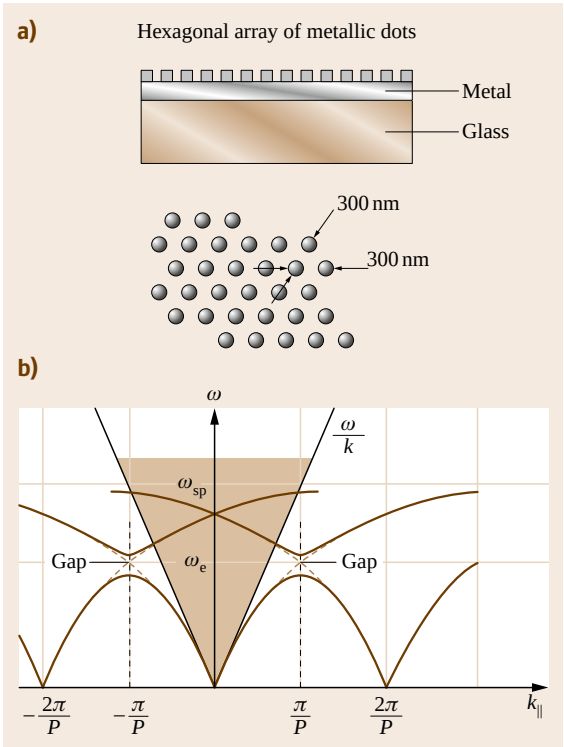

Fig. 8.91 **(a)** Cross-sectional MPC structure composed of a metallic dot array on a metal/glass substrate. **(b)** PC-like zone-folded bands for the SPP on the metallic-dot-array surface (courtesy of Prof. V. M. Shalaev, Purdue University)

One can then obtain a strongly enhanced optical signal when a weak optical signal somehow excites plasmon polariton bands. Efficient biosensors or biomedical sensors can therefore be designed using MPCs. Another motivation for MPC research is provided by the strong transmission of light in a MPC. This is enabled by perforating a thick metal slab periodically with holes of subwavelength dimensions [8.247]. The use of a slab MPC with an array of holes has attracted renewed interest for application of this extraordinary transmission for negative refraction and the superlensing effect in imaging [8.248, 249].

Quasi-PCs. Quasiperiodic systems, which are not translationally invariant in a strict sense but still have long-range order, can have a PBG [8.246]. Arrayed units stacked in a Fibonnaci sequence in 1-D or arranged by Penrose tilting in 2-D or 3-D space are examples of quasicrystals (QCs). In QCs, electrons or photons have a character intermediate between localization and delocalization. Therefore, by developing a well-controlled quasi-PC, on the one hand we can use well-localized states, which yields a very large quality factor when used, e.g., in lasing. At the same time, diffraction is observed by exciting a delocalized PB state, whose diffraction pattern is understood in terms of the reciprocal lattice of quasi-PCs. Using a delocalized state in lasing, the coexistence of the localization and delocalization characters has been demonstrated experimentally [8.250].

Random PCs. There are other related 2-D and 3-D systems. The former consists of parallel rods specified by well-controlled randomness of the rod sites, and the latter is a 3-D system with an amorphous diamond structure [8.251, 252].

Nonlinear $\chi^{(2)}$ PCs

A nonlinear photonic crystal (NPC) is defined as one in which there is a 2-D periodic spatial variation of the nonlinear second-order susceptibility $\chi^{(2)}$, while n is constant (not periodic) in the whole material [8.253]. This is a 2-D version of a periodically poled nonlinear grating (Sect. 8.9). Figure 8.91a shows schematically a cross-section of a typical example of a 2-D triangular $\chi^{(2)}$ structure, where the lattice is composed of cylinders with $-\chi^{(2)}$ in a medium with $+\chi^{(2)}$. Two-dimensional NPCs are attractive for achieving quasi-phase matching (QPM) two-dimensionally in nonlinear optical phenomena (NLOs), such as SHG. Namely, the phase mismatch $|\Delta \boldsymbol{k}^0| = |\boldsymbol{k}^{2\omega} - 2\boldsymbol{k}^{\omega}| \neq 0$, usually caused by the frequency dispersion of the refractive index, can be compensated with the help of the reciprocal lattice vector $\boldsymbol{G}_{n,m}$ (the order is given by $|n| + |m|$ with n, m being $\mathbb{Q}$ or integer) as follows,

$$\Delta \boldsymbol{k} = \boldsymbol{k}^{2\omega} - 2k^{\omega} \pm \boldsymbol{G}_{m,n} = 0\,, \tag{8.111}$$

where $\boldsymbol{k}^{2\omega}(\boldsymbol{k}^{\omega})$ is the wavevector of SH (fundamental) light; note that $|\boldsymbol{k}^{2\omega}| < 2|\boldsymbol{k}^{\omega}|$ in the normal dispersion region. The relation (8.111) is easily satisfied by making an appropriate angle between $\boldsymbol{k}^{\omega}$ and $\boldsymbol{k}^{2\omega}$ with the first-order $\boldsymbol{G}$ as shown in Fig. 8.91a. The efficiency of this process is proportional to the corresponding 2-D Fourier coefficient in the decomposition of $\chi^{(2)}(r)$. The fabrication method is similar to the 1-D case, usually by electrically poling a medium such as $LiNbO_3$ and $LiTaO_3$ crystal to alter the sign of $\chi^{(2)}$: domain regions are inverted [8.254, 255]. A typical period of NPC required for QPM is $\approx 10\,\mu m$ for SHG at $1.5\,\mu m$, which is much larger than the period in conventional PCs.

8.10.2 Unique Characteristics

We summarize the unique and outstanding features that 2-D and 3-D PCs generally exhibit. PCs are well suited for controlling light. This important potential arises primarily from their features.

Photonic Band Gap

As seen in Fig. 8.88 there are three PBGs for TM modes, although a full 2-D PBG common to both polarized modes does not open in this case. It is known that a 2-D PBG common to TE and TM modes exists for a triangular lattice of air cylinders only if the ε difference between the background material and the air (cylinders or holes) is large enough [8.230]. For a 3-D PBG, the diamond structure is recognized to be the best for opening a full PBG with a large gap width, as shown in Fig. 8.89; an inverse diamond structure also belongs to the diamond structure. For other structures, it is rather difficult to realize a full 3-D PBG with large width. However, it is generally recognized that a variety of unique devices can be developed with a PC without using a full 2-D or 3-D band gap, as will be shown below.

Defect Mode I. Classification

It is possible to introduce a defect or disorder into a particular lattice point or portion in an otherwise completely periodic PC lattice. Introducing this kind of defect creates a new eigenmode (eigenband) called a defect mode (defect band) in the PBG. An example of a zero-dimensional (0-D) or point defect in a 1-D or a 2-D PC of air cylinders or dielectric pillars is to change the size (diameter) of only the target cylinder/pillar compared with the host. One special case of this is to remove the cylinder or pillar completely. Another typical example of a 0-D defect in a 1-D PC is to alter the period at one lattice position, e.g., by changing the distance to the adjacent positions compared with the host. This kind of 0-D defect mode corresponds to an impurity state, analogous to a donor or acceptor state for electrons in a semiconductor; in the case of an air hole, increasing (decreasing) the hole size causes a decrease (increase) of the dielectric constant at that location, in good correspondence to the acceptor (donor) formation of electrons [8.228].

In addition to these 0-D defects, 1-D and 2-D types of defects, i. e., line and plane defects, can also be created and are important in controlling light. A 1-D defect in a 2-D PC of air cylinders or dielectric pillars can be created, for example, by leaving a single line of air cylinders imperforated, or removing a single line of pillars, i. e., introducing an empty (air) line, respectively. In a 3-D PC, e.g., made of air holes, a 1-D defect is such that a single line of holes are left unopened. A typical example of a 2-D defect is obtained, for example, by leaving one lattice plane structureless (homogeneous) in a 3-D PC.

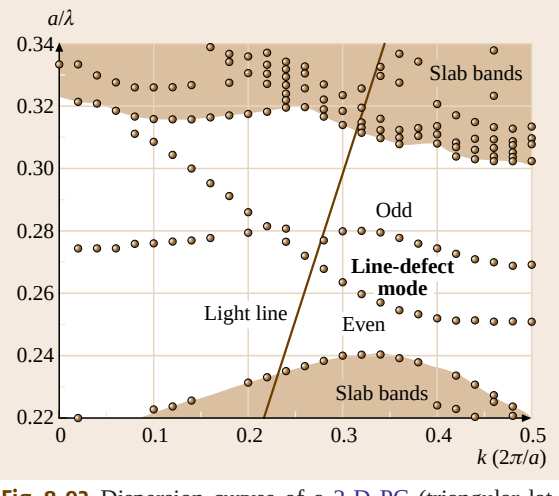

Fig. 8.92 Dispersion curves of a 2-D PC (triangular lattice) slab line-defect waveguide calculated by using the 3-D finite-difference time-domain (FDTD) method (see the text): both the frequency ω and wavevector $\boldsymbol{k}$ are shown in dimensionless units

Defect Mode II. Function

Let us discuss the physical properties of the defect modes. By exciting this mode, light can be localized around the defect, or the region with disorder.

Microcavity. As the 0-D defect mode is localized in a small spatial region, the mode does not have a definite wavevector $\boldsymbol{k}$. This feature is similar to that for impurity states of electrons in the band gap. This kind of defect serves as an optical microcavity, exhibiting outstanding characteristics. Recently, various kinds of microcavities have been intensively explored using a semiconductor-based slab PC. As a result, microcavities with Q-value as large as, say, $\approx 1 \times 10^6$ and with an extremely small volume on the order of $3 \times 10^{-14}\,\mathrm{cm}^3$ have even been developed [8.256]. Another type of superior microcavity or nanocavity has also been developed on the basis of the line-defect PC waveguide described below. Importantly, those extremely small microcavities provide efficient coupling between light and matter [8.235], so that they have the potential to be used in physics

and in applications, as described in Sects. 8.10.4 and 8.10.5.

PC Waveguide. Unlike the point-defect case, the line-defect mode shows a particular dispersion in a PBG [8.257]. A line defect in an air-bridge slab PC with air holes is introduced by filling a single line of air holes along the direction (adopted as the x-axis) in the triangular lattice; the z-axis is normal to the 2-D plane formed by the x- and y-axes. Figure 8.92 shows the dispersion curves of the TE-polarized line-defect modes, where the frequency is plotted as a function of k_x only in the relevant region including a large band gap (Fig. 8.90). The hatched areas, which are called the slab bands, are obtained by projecting all the band $\omega_n(k_x, k_y)$ in the first BZ onto the $\omega - k_x$ plane. One of the two modes is an *even mode*, characterized by its symmetric field profile with respect to the mirror plane (xz-plane), whereas the other mode having an antisymmetric profile is called an *odd mode*.

This line defect operates as a new type of waveguide (WG), known as a 2-D PC-slab line-defect WG. It is easy to fabricate a bend WG in a 2-D plane by combining two line defects in directions that differ by 60° among six equivalent Γ–K ones. Importantly, light belonging to the line-defect-guided modes propagates through a sharp corner without any loss [8.228, 230] (Fig. 8.93). Similarly, it is possible to design a stereoscopic PC WG using a combination of line defects with different directions in a 3-D PC. Based on the above WGs a new type of microcavity called the *double-heterostructured microcavity* can be designed. Photonic crystal fibers, which were pioneered by *Russell* et al. [8.234, 258], are also regarded as a kind of line defect introduced into the central portion in the 2-D PC.

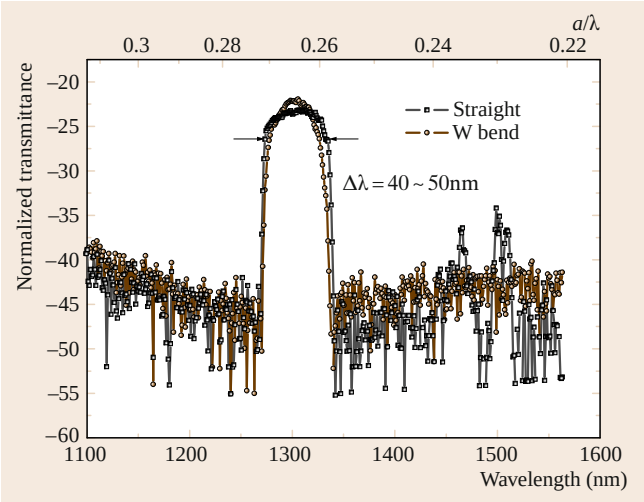

Fig. 8.93 Transmittance spectra for straight (*line with squares*) and double-60°-bend (*line with circles*) of 1 mm-long GaAs-based air-bridge 2-D PC line-defect WGs, measured using a halogen-lamp-based multichannel infrared detector spectroscopic system (see text). High-transmittance region in a PBG corresponds to the line-defect band of even modes below the air light line in Fig. 8.92

Small Group Velocity

Both the group velocity v_g and group-velocity dispersion (GVD) play an important role in the flow of light. Theoretically, v_g is given by the slope $\nabla_k \omega_n(\boldsymbol{k})$ of a band. Generally speaking, there are many portions or positions in a PC where the band slope is flat, which makes v_g anomalous. At the band edge, v_g should always become extremely small. A position with such a flat energy dispersion is also encountered at anticrossed (upper and lower) bands; a photon at such points is sometimes called slow light [8.259] or a heavy photon, in analogy with the heavy electron [8.260]. A relatively flat band with a small v_g is also frequently encountered in 2-D and 3-D PCs. Moreover, there are many bands where v_g becomes negative. A small v_g indicates that the electric field strength becomes very large, or equivalently that the DOS is very large. This fact is very important, since the effective interaction length between light and matter becomes longer due to the smallness of v_g. More specifically, the enhanced light–matter interaction caused by the small v_g greatly intensifies, e.g., the radiation field involved in many physical processes in PCs (Sects. 8.10.4 and 8.10.5).

Polarization Dependence

In the case of 2-D PCs, and 2-D and 1-D PC slabs, the PBS is highly polarization dependent (Figs. 8.88 and 8.90). Therefore, the propagation characteristics of light incident from outside differ remarkably for such a PC sample; in contrast, the polarization dependence is less remarkable for 3-D PCs, in particular, with the diamond lattice. As a consequence, a unique polarizer can be developed (Sect. 8.10.5).

Peculiar Band I. Anomalous Refraction

There are a variety of peculiar PBs or band points where anomalous features manifest themselves from the viewpoint of crystal optics. Theoretically, the property of light in a PC as well as a homogeneous system is determined by the space group of $\boldsymbol{k}$, i. e., the group

of symmetric operations that leave the vector $\boldsymbol{k}$ in question at rest. The irreducible representation of the group $\boldsymbol{k}$ thus entirely determines the anisotropic properties. From this group-theoretical analogy, PCs naturally embody all the optical properties exploited in crystal optics to date, often on a much larger scale. Furthermore, the band folding effect operates in PCs in that the magnitude $|\boldsymbol{k}|$ also introduces remarkable optical diversity [8.260, 261].

To understand the propagation characteristics of light, we need to examine the equifrequency (energy) surface (EFS) of frequency ω obtained by sweeping $\boldsymbol{k}$ over the entire BZ. The propagation characteristics of light at such a peculiar point are very complicated. The directions and magnitudes of the phase and group velocities are generally different from each other [8.261]. First of all, Snell's law of refraction does not hold in general in PCs. We list several other anomalies here:

1. Multirefraction phenomena. This is because there exist several EFSs for a given ω in k space. As a result, if all of these are excited simultaneously by incident light of ω, refraction will be double, triple, quadruple, etc., according to the number of excited bands.
2. Conical refraction. There happens to be a singular point in $\boldsymbol{k}$ space where the group velocity, i. e., the vector normal to the EFS of the band, is not uniquely determined, e.g., at the intersections between two EFSs and at the point where an EFS shrinks to a point. In this phenomenon a light beam with that $\boldsymbol{k}$ propagates in the PC along the surface of a certain cone.
3. Superprism effects. Generally speaking, several bands participate simultaneously in constructing an EFS; there, the direction of v_g, which is normal to the EFS, does not coincides with that of $\boldsymbol{k}$. A special case occurs such that the direction of v_g changes drastically when the direction of $\boldsymbol{k}$ is varied slightly. This is called the superprism effect [8.262, 263].

Peculiar Band II. Negative Refractive Index and Left-Handed Properties

Left-handed (LH) material is usually defined to be one having permeability μ and ε that are both negative [8.233, 249]. When a LH system is homogeneous, propagating plane-wave light with wavevector $\boldsymbol{k}$ has the LH property in the sense that the direction of the Poynting vector is reverse to that of $\boldsymbol{k}$, and, as a result, three vectors, i. e., the electric field, magnetic field, and $\boldsymbol{k}$, compose in this order a left-handed system. The LH system is well defined in this way, when only a single $\boldsymbol{k}$ is involved. In a homogeneous LH system, negative refraction takes place by necessity, in which an incident light beam is refracted at the entrance surface in the wrong way. In the case of PCs, any PB state is composed of many plane waves whose wavevectors are mutually different. Therefore, both concepts of negative refraction and LH property have to be referred to as the average of these plane waves. In this context we should note that the group velocity of the $(n, \boldsymbol{k})$ state, defined to be $\nabla_k \omega_n(\boldsymbol{k})$, is just a quantity referring to this average.

The direction of the group velocity is often quite different from that of $\boldsymbol{k}$ due to the superprism effect mentioned above, and the case $\nabla_k \omega_n(\boldsymbol{k}) \mid \cdot \mid \boldsymbol{k} \mid < \mid 0$ is very frequently encountered. Therefore, the phenomenon of negative refraction indeed occurs very often in PCs, in which the beam direction of incident plane-wave light bends at the PC surface in the wrong way, the direction of the inside beam being an average of many plane waves composing an excited PB state. It is important to note that the negative refraction in PCs takes place in ordinary PCs, which have μ and ε both positive, and has been demonstrated by examining the inside beam direction using numerical simulation and experiment [8.264, 265]. Negative refraction is important in achieving superlensing effects in PCs [8.248]. The precise LH nature in PCs, on the other hand, is hard to define, because the direction of the inside beam is an average of many Poynting vectors. Some of them may compose a LH system with the wavevector $\boldsymbol{k}$, defined within the first Brillouin zone. However, as for the actual wavevector, taking an umklapp shift by a reciprocal lattice vector into account, that Poynting vector will certainly make up a normal right-handed system. In spite of this ambiguity, however, negative refraction using PCs opens a way to pursue negative refraction and LH propagation in the optical region.

8.10.3 Characterization Technology

We describe how to examine the characteristics of a fabricated sample. One can examine the appearance and surface of a sample by using optical microscope, scanning electron micrography (SEM) and atomic force micrograph (AFM). Here we survey the optical characterization method.

General Method

A commonly used, simple method to experimentally investigate a PBS sample is to observe either the transmittance (T) or reflectance (R_e) spectrum, or both.

For the leaky PBS or PC modes, angle-resolved T [8.247, 266] or R [8.245, 267] measurement is a powerful method for a sample with a 1-D or 2-D periodic plane under the concept analogous to the well-known 1-D grating case. Specifically, in reflection spectroscopy we impinge light on the top surface of a sample and observe reflected light with θ (incident angle) and φ (azimuth angle) fixed [8.268]. When incident photon energy $\hbar\omega$ coincides with the guided-mode energy, anomaly (dip) appears, being superimposed on the ordinary reflection spectrum, at such a particular angle as satisfying the grating diffraction law, $\boldsymbol{k}_{\parallel}^{r} = \boldsymbol{k}_{\parallel}^{\text{in}} + \boldsymbol{G}$ where $\boldsymbol{k}_{\parallel}^{r}(\boldsymbol{k}_{\parallel}^{\text{in}})$ denotes the in-plane wave vector of reflected (incident) light. The $\omega - \boldsymbol{k}$ dispersion curves of PBs in the 2-D plane can be obtained from a set of such spectra observed varying θ and ϕ as parameters; the dip (ω) position moves as θ is varied for a fixed φ. Although being very useful, this method is restricted to obtaining information of leaky modes or the dispersion inside the air light-cone. Moreover, if the incident plane is chosen as being a mirror plane in parallel to the high-symmetry direction, incoming light can not couple to the so-called uncoupled PC modes.

The above restriction, however, can be removed by placing a semisphere prism coupler made of material such as ZnSe or Si possessing large n-value close on the top surface. Note that use of such a prism enables an evanescent coupling between in-pane PC mode and propagating field in the semisphere [8.269]. In this way true guided modes outside the air-light cone can be observed and their $\omega - \boldsymbol{k}$ dispersions can be thereby obtained. Up to now, such angle-resolved attenuated total reflection (ATR) measurements have been made also for a semiconductor-based 2-D slab line-defect WG of triangular lattice of air-rods, where two-kinds of line-defect TE-guided modes, even-mode and odd-(uncoupled) mode defined in relation to the above mirror plane (Sect. 8.7.2) exist in the 2-D slab PBG. Note that not only even modes but also odd modes can be observed with use of $\varphi \neq 0$, since the plane is no longer a mirror plane [8.270].

End Fire Method for 2-D PC Slab WG

In the case of 2-D PC slab WGs generally we need to directly couple external light to guided modes through an extremely small facet of WG (end fire coupling). Use of a conventional spectrometer is not necessarily suited for this purpose, particularly in the optical communication wavelength range of 1.10–1.60 μm. One typical way of specifying a band range of guided modes is to couple light from a set of wavelength-tunable diode lasers to a sample at an entrance facet, and to detect transmitted light at an exit facet; thereby we obtain the T spectrum, from which the propagation loss is also extracted. To do so, a lensed single-mode optical fiber [8.271], or a very small lens with a large F number, is usually employed for efficient coupling at both facets. For leaky modes, by detecting light scattered vertically or observing the far-field pattern, one can map the dispersion of the leaky modes as described above [8.272]. The above wavelength scanning method with use of coherent light is not necessarily adequate because of stability and unwanted stray light (noise) arising from interference caused by imperfections of a sample.

Here we describe another useful spectroscopic system (homemade), which is composed of a small white lamp (halogen lamp; incoherent source), a monochromator, and a cooled 1-D multichannel infrared detector (InGaAs), together with a pair of lensed fibers and other optical components [8.271]. This system covers a broad wavelength range from 850–1600 nm, and it typically takes only ≈ 10 min to obtain a T spectrum reflecting the line-defect guided modes in a 2-D PC slab WG and PBG. Figure 8.93 shows an example T spectrum observed using this system; note that agreement between straight- and bend-WGs results is very good [8.273].

Scanning Near-Field Optical Microscope (SNOM)

Scanning near-field optical microscope (SNOM) is the only method for directly investigating detailed nature of guided modes of a 2-D PC slab line-defect WG, in contrast to the indirect ones described thus far. As already described, the guided mode does not couple to an external light with vertical $\boldsymbol{k}_z$ components, but accompanies evanescent light on the top surface. Therefore, the distribution of guided modes and their Bloch harmonics, and the PBS can be obtained with use of a SNOM; by picking up the evanescent light using an optical-fiber tip of a SNOM, one can image the propagation of light along the WG. Using the fast Fourier transform of a spatial modulation pattern, one can obtain information on the propagation constant $|\boldsymbol{k}|$. Two systems are used. One is such that it enables detection of the local light intensity distribution [8.272, 274], and the other, the local field amplitude and phase [8.275, 276]. For the latter (heterodyne) method, the interference signal between the collected light and a frequency-shifted reference beam from the same laser used for exciting the WG modes is detected and analyzed using a lock-in amplifier; note that by using short laser pulses one can suppress, through the time-of-flight technique, the background arising from Fabry–Pérot reflections and

scattering out of the structure, and one can also obtain information for v_g, GVD, and the decay constant of the mode under study.

Simulation Methods

In all cases above, we need to compare experimental data with theoretical simulation and the corresponding PBS. For this purpose, 3-D finite-difference time-domain (FDTD) simulation plays an important role and is therefore widely used; e.g., for SNOM it is used to describe the electric field propagation pattern. For this case we solve the Maxwell wave equation in the time domain to obtain the variation of the field amplitude emitted from an electric dipole placed in front of an input facet of WG; we can also simulate a T spectrum in this way. Note that the 3-D FDTD method is also useful for obtaining a PBS.

8.10.4 Enhancement and Suppression of Light–Matter Interactions

One can alter drastically the strength of light–matter interaction in a PC making use of one of the following characteristics, i. e., (1) slow light and (2) microcavity, both giving rise to strong light confinement, and (3) PBG. For example, one can enhance or suppress radiation due to Purcell effects [8.277].

Spontaneous Emission

Let us first consider spontaneous emission (SE), being a typical example of radiation, in 2-D and 3-D PCs. We focus on SE arising from emitters such as quantum wells (QWs), quantum dots (QDs) and rare-earth ions embedded in a PC, or from the constituent material of a PC itself; emitters are excited optically or electrically. Enhancement or suppression of SE with wavelength λ_{SE} is observed corresponding to whether λ_{SE} coincides with λ_{SL} (slow-light wavelength) or λ_C (resonant wavelength of microcavity), or is within a band-gap range.

Slow-Light Case. An experiment is mainly performed for 2-D PC slabs and those line-defect WGs in such a way that radiation due to guided modes is observed. The result depends highly on the orientation of the electric dipoles, i. e., whether it is parallel or perpendicular to the slab plane. It is found that the intensity of SE light with a small v_g coming out from an exit facet is stronger compared with that with a normal v_g; radiation does not come out if λ_{SE} lies within the gap range. This is because the SE intensity under study reflects the relevant DOS or DOM (density of light modes) (Purcell effect).

Microcavity Case. Physics is classified into (a) weak and (b) strong coupling regimes.

(a) Weak Coupling. In 3-D PCs, radiation from emitters of nanometer size embedded in a sample does not occur if λ_{SE} is within a 3-D PBG range [8.278]. In contrast, if λ_{SE} is outside the range, radiation can be observed similarly to the homogeneous medium case. As a result, the SE spectra observed by varying the observation direction are similar to one another, and are such that the intensity for a range of the PBG is suppressed. On the other hand, for the case that a point defect (microcavity) is introduced into a light-emitting layer in a 3-D PC, strong emission from the cavity is observed when λ_{SE} with a broad spectral with a broad spectral width covers a gap range [8.237]. In contrast, for λ_{SE} lying outside the gap range, rather homogeneous emission from the entire region is observed. It is also found that the estimated Q-value is almost independent of defect size, in contrast to the 2-D case below.

Similar experiments have been carried out in a point-defect cavity in a 2-D PC slab [8.279–281]. As there are two WG modes, true guided (lossless) and leaky modes, we need to take into account radiation escaping through the top surface of the slab; in this sense, the 2-D PC slab WG is intrinsically a 3-D system. Regarding the emission observed vertically (emission passing through the top surface), which arises from QDs in a microcavity, the result strongly depends on whether λ_{SE} coincides with λ_C or not. As a result, the emission intensity is found to be much stronger in the former than in the latter. Moreover, it is also found that the temporal decay constant of the intensity is much shorter (lifetime is longer) in the former than in the latter. These facts can be well explained by considering the existence of two kinds of above-mentioned modes. In other words, these facts reflect redistribution of DOS; note that the DOS in the vertical direction remains almost constant with and without the cavity.

(b) Strong Coupling. For a high-Q cavity with a small modal volume V, the quantity Q/V becomes huge, indicating that $|\boldsymbol{E}|$ inside the cavity becomes very large. In this case, the system is categorized as being in the *strong coupling* regime if the Rabi frequency $(\boldsymbol{\mu}\cdot\boldsymbol{E})/\hbar$ exceeds, aside from a numerical factor, the mean of the decay rates of the cavity and the dot emission, where $\boldsymbol{\mu}$ is the electric dipole moment. In fact, Rabi split-

ting of $\approx 170\,\mu$eV was observed recently. It is found that anticrossing phenomenon between λ_{SE} of radiation from a single QD in a cavity and λ_C is observed on varying the former as a function of temperature at low temperatures [8.282]. This finding opens the door to the study of cavity quantum electrodynamics (QED) in a solid-state QD, and also for observing single-photon emission; note that cavity QED has been studied thus far only in a gaseous atom system.

Extraction Efficiency of Light

The external extraction efficiency η of light is closely related to the SE characteristics of 2-D PC slab described above. It is expected that 2-D PC slab will be used to improve η of light-emitting diodes (LEDs) embedded in other materials [8.283]; η of light emitted to free space is usually poor (less than 10%), being restricted by internal total reflection. Specifically, when a planar LED is placed in parallel to a 2-D PC slab plane, η should be much improved owing to *leaky modes* of the PC as well as redistribution of radiation. In view of the practical importance, III–V semiconductor LEDs, in particular, GaN (blue and violet regions)-based LEDs have been intensively studied [8.284–286]. Unlike the early-stage case of InGaAsP-based LED [8.287], nowadays the current-injected LED region is separated from a PC region (triangular lattice of air-rods), e.g., the PC layer is formed all around or just on the LED. Up to now, many elaborate researches on a desirable property of PC concerning the parameters and type for attaining high η have been made. For example, it is found that some quasicrystal 2-D PCs are more efficient in extracting light than the regular 2-D PC [8.287–289]. Though thereby η is currently being improved considerably, yet it does not reach a theoretical value. Similar works are also done in an organic LED [8.290] and other emitters [8.291, 292].

Raman Scattering

We consider nonparametric Raman scattering (RS) from optical phonon of the constituent medium of PC in semiconductor-based PC-slab line-defect WG; in this case PM is not required. This type of RS is closely related to stimulated Raman scattering (SRS, third-order NLO), which is expected to provide a useful amplifier in future ultrafast, all-optical integrated circuits. Utilizing slow-light guided modes for both pump (ω_p) and signal (ω_s), the signal intensity should grow in proportion to $(v_g^{\omega_p} \cdot v_g^{\omega_s})^{-2}$. A few experiments were performed in such a way that variation of the signal intensity was observed as a function of ω_s near a band gap. A strong signal enhancement due to slow light is obtained in an AlGaAs-based WG and a Si-on-insulator (SOI)-based WG [8.291–295]. Considering strong light confinement in the WG too, the above observation implies that SRS should occur in an only-1-mm-long sample with an input pulse with an energy of ≈ 1 pJ and 3 ps in duration under an appropriate condition [8.296]. A similar signal enhancement is also observed using a microcavity in 2-D PC slab [8.297]. Recently, SRS under continuous excitation has been observed using double microcavities formed in Si-based PC slab WG [8.298]. Four-wave mixing phenomenon closely related to SRS is also reported [8.299].

Nonlinear Optical Phenomena (NOP)

The induced nonlinear electric polarization P^{NL} is proportional to E^2, E^3, ..., so that the signal (radiation) intensity in the optical parametric process (OPP) is proportional to I^2, I^3, ... (I; intensity); use of short light pulse with large peak power and small energy is advantageous in NLOs. Therefore signal enhancement effect due to increase of $|E|$ in NLOs benefited by slow light or resonant light in microcavity is expected to be by far larger compared to the linear case [8.300, 301]. In OPPs, use of PM is also crucially important for efficient signal generation. We describe the OPP case in the first part and the non-OPP case in the latter.

We start with 1-D finite periodic multilayer stacks [8.302]. There are many experimental and theoretical works on signal enhancement using a microcavity, a defect layer sandwiched in two Bragg reflectors ([8.301] and references therein). Here we describe an important example of a special stack called mixed half-quarter wave stack, which is capable of achieving simultaneously strong field enhancement for both the fundamental (ω)- and harmonic (2ω)-light, and PM, making thereby this very attractive for high-efficiency SHG. This system consists of alternating layers of two different materials possessing nonzero $\chi^{(2)}_{ijk}$, which are stacked such that $k_{1z}a = \pi$ and $k_{2z}b = \pi/2$ with k_{iz} ($i = 1, 2$) wave-vector component normal to the layers [8.303]; we name the two unit layers 1 and 2 with the respective thickness a and b, and take $z(x)$ axis parallel (perpendicular) to the stack. For the normal incidence this stratified structure provides stop bands (SBs) in the transmission spectrum around central wavelengths $\lambda^{(1)}_{gap} \cong 0.66 \times \lambda_0$ and $\lambda^{(2)}_{gap} \cong 1.22 \times \lambda_0$ where λ_0 is a central Bragg wavelength for the conventional quarter-wave stack. In any case, the SB with high reflectivity is surrounded by a series of narrow resonances, or oscillatory structures of transmission in

which transmittance is maximal and reflectivity drops considerably. Note that the above cancellation of reflectivity corresponds to a total phase-shift of an integral value of π accumulated as light propagates through the medium. The effective n-value introduced on the basis of the above fact [8.304], or structural dispersion is capable of not only achieving PM between ω- and 2ω-light, but also compensating the intrinsic color dispersion of media under appropriate conditions, if $\Delta n = | n_1 - n_2 |$ with n is large enough.

Importantly also, the mode DOSs (proportional to v_g) and spectral widths of those resonances become larger and narrower, respectively, as N (unit-cell number) increases; the sample length $L = N\Lambda$ with $\Lambda = a + b$ a period [8.306]. Since both ω and 2ω can be tuned to those resonances, the PM-SHG intensity should grow as L^6. Experimentally, $N^{5.3}$ dependence is actually achieved for an AlGaAs-AlO_2 (amorphous) stack [8.307]. A similar work on GaN-based stack is also reported [8.308]. For other related works, see [8.309–311].

We turn to 2-D and 3-D PCs. A few slow-light and/or PM enhancement experiments on third-harmonic generation (THG) have been performed in 3-D PCs [8.312]. Enhancement of SHG is also observed in a 3-D PC in the reflection (diffraction) configuration [8.313]. Those enhancements occur at the band-gap edges with the help of achievement of PM like the above mentioned 1-D PC. New unique methods for achieving PM in 2-D and 3-D PCs are also theoretically proposed [8.314, 315].

Now we describe the non-OPPs, particularly optical Kerr (OK) effects (third-order nonlinearity) including their related phenomena such as gap-soliton, bistability [8.301] and self-phase modulation (SPM). A number of experimental and theoretical researches have been performed on signal enhancement due to a microcavity, both the point-defect type in 2-D slab and 1-D type of defect-stack sandwiched by two Bragg reflectors ([8.301] and references therein).

In most cases such enhancement originates from photogenerated free-carriers; later we show many examples in Sect. 8.10.5. OK nonlinearity in semiconductors is induced either by real (one- or two photon) excitation of free carriers [8.235, 316] or virtual optical excitation [8.317]. The latter examples are observed recently in two-photon transparent region [8.318, 319]. Note that the magnitude of nonlinearity is much larger in the former than in the latter, but the response (recovery) time of the former is by far slower compared to the latter. This fact is important in developing PC-based devices: this is particularly true for those used for high-repetitive pulses. As for important NLOs in the PC fibers, see other sections regarding optical fibers in this book.

8.10.5 Device Applications

The band diagram of a PC, as mentioned above, has the following features: (i) the appearance of the PBG, (ii) dispersion in the vicinity of the PBG, and (iii) strong polarization dependence. Based on these unique fea-

network systems; some of them are commercially available. Figure 8.94 shows proposed typical PC devices categorized into the following (i) to (iii) [8.305]. Optical resonators and microlasers are included in category (i) *optical confinement in the PBG*, while dispersion compensators and polarization discriminators are included in categories (ii) *dispersion* and (iii) *polarization*, respectively. Couplers and optical switches are includede in these categories. Typical examples for each category are introduced in this section.

Optical Waveguide and Fabrication Technology

PBG properties are predominantly determined by the refractive index (n_{ref}) contrast in the PC. A variety of 1-D to 3-D PC structures with different n_{ref} contrasts have

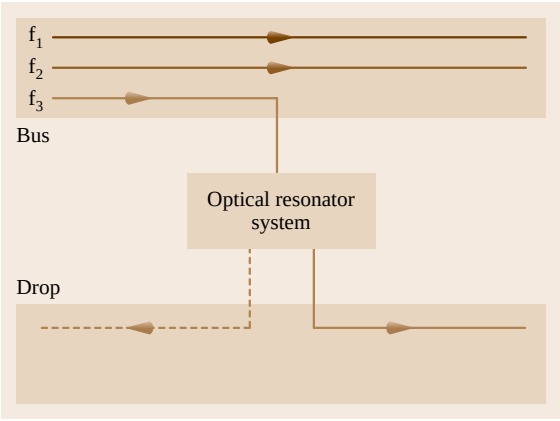

Fig. 8.98 Concept of a channel drop filter with optical resonator coupled to parallel straight waveguides

been reported so far [8.242, 320, 321]. Among them, a 3-D autocloned structure with an intermediate n_{ref}

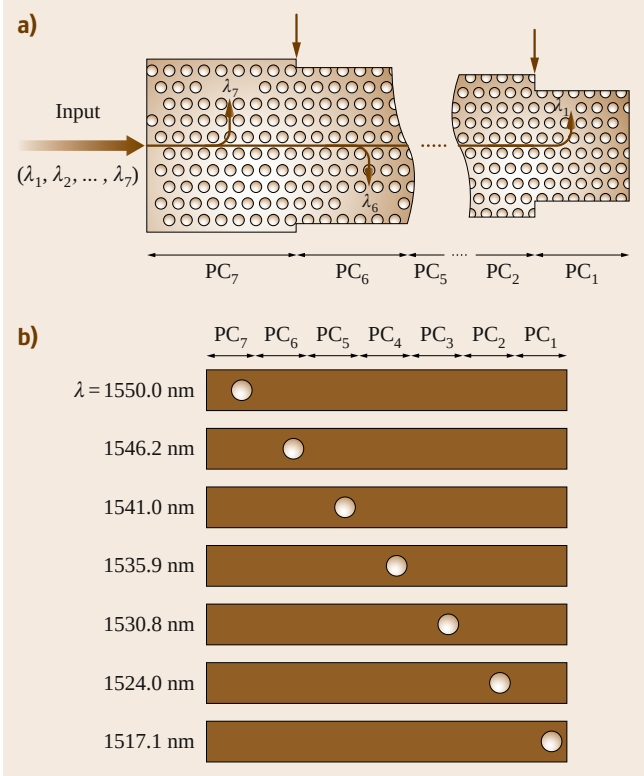

Fig. 8.99a,b 2-D PC add–drop filter with coupled straight waveguides and point-defect microcavities **(a)** and observed near-field patterns of the output beams **(b)**

contrast has attracted much attention for wide practical applicability [8.320, 322], while a 2-D air-hole array structure has great potential for practical applications because a wide range of semiconductor planar processing technologies is available [8.242].

The autocloned 3-D PC waveguide can be fabricated by a combined sputtering deposition and sputter etching process on a patterned substrate [8.320, 322]. A unique feature of this 3-D waveguide is its ability to retain the same 3-D periodic structure throughout the multilayer deposition up to several tens of layers. The periodicity in the vertical direction is controlled by the alternating deposition of different thin films, while that in the horizontal plane is controlled by the initial pattern on the substrate. So far, this approach has already been applied to several kinds of silicon-oxide-based optical components such as a polarization discriminator [8.323, 324].

The 2-D PC air-bridge-type slab waveguide, on the other hand, exhibits strong optical confinement in the vertical direction with excellent transmittance characteristics [8.257, 325–327]. A typical fabrication process using a heteroepitaxial thin-film substrate includes electron-beam lithography for patterning the 2-D PC, dry etching for forming an air-hole array, and selective wet etching for eliminating the sacrificial underlayer. Figure 8.95 shows a scanning electron beam micrography (SEM) image of this kind of waveguide on a silicon-on-insulator (SOI) substrate [8.326]. The waveguide exhibits low-loss single-mode propagation for wavelengths ranging from 1520 nm to 1620 nm with propagation losses as small as 8 ± 2 dB/cm [8.326]. Many groups have already demonstrated applications of this type of waveguide to channel filters, slow-wave devices, and all-optical switches, as shown later.

Advanced PC Waveguide Design

A conventional PC waveguide design method is the finite-different time-domain (FDTD) method [8.328], while a recently developed topology optimization (TO) method is a 2-D finite-element frequency-domain-based tool for solving a reverse problem [8.329]. The TO method is capable of drastic improvement of bandwidth and transmittance in the PC waveguide. The TO procedure is performed to maximize the transmittance of the output port by modifying the refractive index distribution in the design domain. An example of a TO-designed waveguide intersection is shown in Fig. 8.96, with a TO-designed intersection pattern (Fig. 8.96a) and experimental results (Fig. 8.96b) [8.330]. In the measured transmission spectra, "ad" means transmittance

between ports a and d, while "ac" means undesirable crosstalk between ports a and c. It is worth noticing that the crosstalk (ac), which is comparable to ad for the standard design, is suppressed by −15 dB for the TO design, and furthermore, the transmission spectra (ad) is very similar to that for the straight waveguide over the whole wavelength range. The results clearly show that the TO method is quite desirable for designing non-straight 2-D PC waveguides.

Optical Delay Line and Dispersion Compensator

Due to the low group velocity in the PC waveguide, some unique applications can be considered [8.331, 332]. One is the application of the low group velocity to a miniaturized optical delay line in ultrafast optical communication systems. An impurity band-based coupled cavity waveguide (CCW) using coupling of localized defect modes is available for this purpose [8.333]. A problem of the CCW with a finite number of defects is the undesirable appearance of some resonant peaks in the transmission and group delay spectra. These peaks seriously degrade the transmission properties. In particular, an optical ultrashort pulse in the delay line accompanies serious distortion of short pulses. This problem can be improved by the introduction of additional defects in the CCW or modification of the periodicity at the edge of the CCW [8.334]. In fact, optimized design of 1-D and 2-D CCWs has achieved quasiflat impurity bands suitable for transmission of ultrashort pulses and made them quite attractive for constructing short-distance delay lines, and other nonlinear devices for ultrashort optical pulses.

Another unique application using the strong dispersion in the PC is a dispersion compensator in the 1-D CCW [8.335, 336]. Before the new design, a series of resonant peaks, remaining because of the finite number of defects in the transmittance and the group-delay spectra, impeded the desirable operation of the dispersion compensator. A light pulse propagating along the CCW spreads the pulse width, thus suffering from serious propagation loss due to the resonant peak. Moreover, the resonant peak in the group-delay spectrum causes the dispersion compensator to be uncontrollable. The schematic structure of the new CCW is shown in Fig. 8.97a [8.336]. Each layered structure in the defect layer, distributed Bragg reflector (DBR) layer, and edge DBR layer was optimized in thickness, as shown in the picture. The result shows smooth wavelength dependence of the group delay spectrum without resonance peaks, as shown in Figure 8.97b. The smooth decay or increase in the group delay spectrum is used for the dispersion compensator.

Optical Channel Drop Filter

A channel dropping filter (CDF), which manipulates one channel of a wavelength-division multiplexed (WDM) signal while leaving other channels undisturbed, is an essential component of an optical communication system. A resonant-cavity CDF is an attractive candidate for the CDF because of the potential capability to select a single channel with a very narrow line width, as shown by the schematic picture in Fig. 8.98 [8.337]. The two waveguides, bus and drop, are coupled through an optical resonator system, leading a single frequency channel to be transferred out of the bus and into the drop in either the forward or backward direction, while prohibiting cross-talk between the bus and the drop for all other frequencies. A ring cavity is a candidate for the resonant system in the CDF. However, it has some drawbacks such as radiation losses and multiple resonances leading to degraded transfer efficiency. Alternatively, a PC microcavity of wavelength size has been proposed to address the drawbacks of the ring cavity. For this case, a cavity mode specific to this kind of resonator can no longer be characterized as propagating states. Instead, mul-

tiple cavity modes considering the symmetry of the channel drop system have been found to play an important role for achieving 100% transfer efficiency in this system.

As advanced CDFs, several multiple-wavelength add/drop filters have been reported [8.338, 339]. Figure 8.99 shows such an add/drop filter using coupling of a straight waveguide and neighboring PC nanocavities as output ports composed of three missing point defects with wavelength-dependent sizes [8.340]. Figure 8.99a shows a schematic plan view of the 2-D PC array, single line-defect straight waveguide, and point-defect output ports. Multiple wavelengths in the input light are separated at wavelength-dependent output ports. Experimentally demonstrated results are shown by the near-field patterns of the output beams with different wavelengths observed from different output ports in Fig. 8.99. It is shown that seven wavelengths are clearly separated by this device.

High-performance CDFs have also been demonstrated by using more sophisticated couplers with straight waveguides and separate microcavities [8.341] and directional couplers with two parallel waveguides [8.342], though detailed characteristics are not presented here.

High-Q Cavity

A variety of optical resonators, as shown in Fig. 8.94, with ultrahigh-Q PC PBG microcavities have been reported by using point-defect engineering of specific air-hole arrays [8.343–346]. Figure 8.100 shows a proposed 2-D PC double-heterostructure microcavity and its schematic frequency ranges corresponding to the transmission and mode-gap regions [8.256, 347]. The double-heterostructure microcavity consists of a triangular-lattice structure with lattice constant of a_1 and a deformed triangular-lattice structure with a face-centered rectangular lattice constant of a_2 ($> a_1$) in the waveguide direction. The light wave of a specific energy can be localized in the latter region and results in the desirable Gaussian field distribution. Thus, experimental results have exhibited a Q-factor as high as 600 000. This kind of microcavity could be applied in high-sensitivity optical sensors, as part of an optical memory, etc. [8.348].

Slow-Light Device

Slow light with a remarkably low group velocity in the PC has attracted much attention in recent years for a variety of advanced photonic applications: Micro/nanoscale localization of optical energy thanks to slow light enhances optical nonlinear effects as the timescale for light–matter interaction is greatly increased. On the other hand, development of sophisticated all-optical information processing that can slow, store, switch, and delay optical data bits using PC-based slow light will provide all-optical routers and all-optical buffer memories that serve to provide dynamic control over the flow of data around next-generation telecommunication networks, without the need to convert optical data into the electronic domain [8.235, 263, 349, 350].

Slow light occurs near (or at) a cutoff point called the band edge in the band diagram [8.259]. Figure 8.101a shows the schematic operation, band diagram, and group-index spectra for a dispersion-compensator application with a chirped struc-

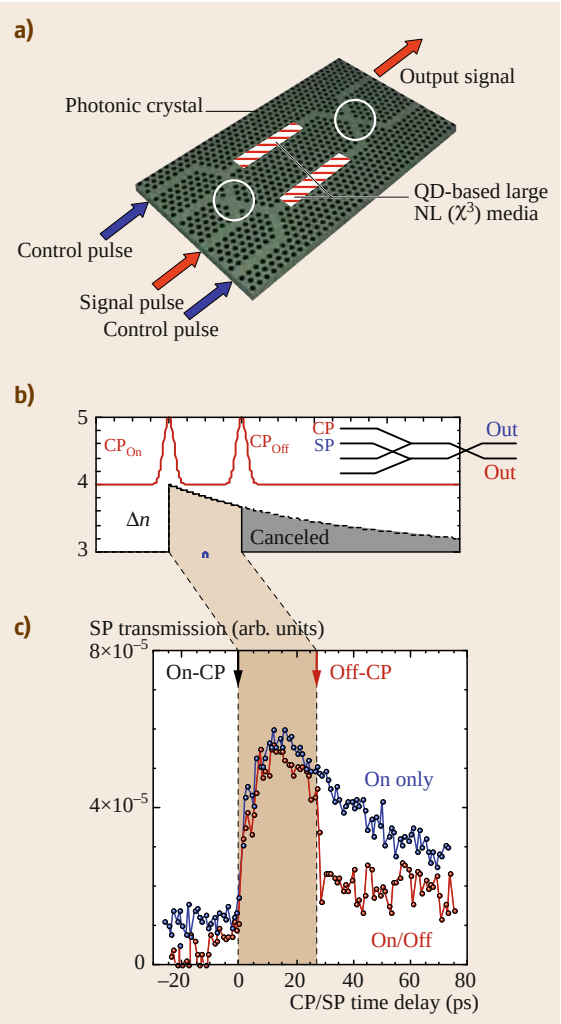

Fig. 8.102a,b Schematic of a 2-D PC-based symmetrical Mach–Zehnder (SMZ)-type GaAs all-optical switch **(a)** and its output switch responses **(c)** operated under time-differential phase modulation **(b)**

ture [8.351], while Fig. 8.101b shows the same for a pulse compressor as a zero-dispersion slow-light device application. The ability to control the velocity of a light pulse in this way opens the door to a host of new and exciting opportunities, as mentioned above.

All-Optical Switch

An optical spatial/time-domain switch is inevitable in a photonic network system. In particular, a PC-based ultrafast all-optical switch operating with optical control and signal pulses is attracting much attention for an ultrafast and ultralow-power switch capable of operating at speeds much higher than the limit of electronic switches [8.352–355].

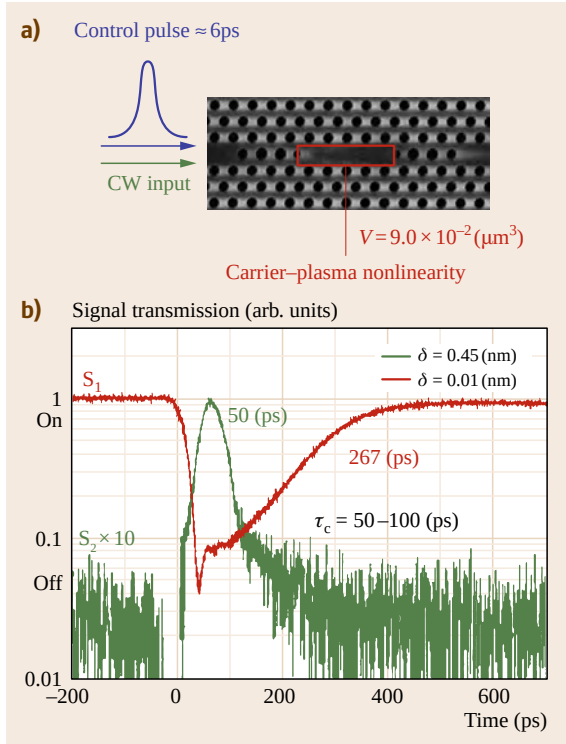

Fig. 8.103a,b Schematic of a 2-D PC-based all-optical switch with silicon microcavity **(a)** and its output switch response operated under carrier-induced optical nonlinearity **(b)**

Figure 8.102a shows a symmetrical Mach–Zehnder (SMZ)-type all-optical switch using GaAs 2-D PC air-bridge-type slab waveguides and optical nonlinear quantum dots (QDs) embedded in the waveguide [8.353]. The PC platform involves several directional couplers as well as bends and Y branches, while the QD exhibits absorption saturation as third-order optical nonlinearity. The principle of the ultrafast switching is time-differential phase modulation with on- and off-control pulses, as in Fig. 8.102b, where a slow carrier-relaxation component in QDs is canceled as a result of the phase shift difference between the two parallel QD arms. As a result, an output response with 2 ps rise/fall times and window width of 20–30 ps has been achieved, as shown in Fig. 8.102c [8.356]. The result shown here corresponds to switching with a single

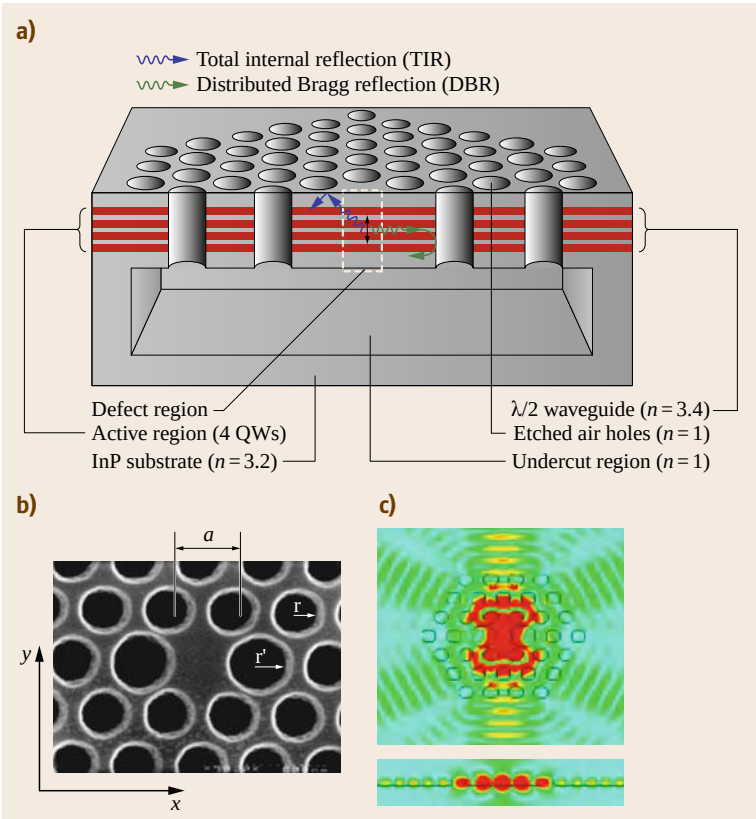

Fig. 8.104a–c Schematic of an InP-based 2-D PC laser with point-defect microcavity. **(a)** Cross-sectional view of the air-bridge structure. **(b)** Modified air-hole array near the point-defect microcavity and **(c)** calculated electromagnetic wave distributions

short input pulse. However, switching with 20–40 GHz repetitive short pulses has also been achieved experimentally [8.357]. The principle of switching with the MZ-type interference configuration has also been verified theoretically by other groups [8.358].

On the other hands, many groups have reported 2-D PC switches by using a bistable effect in silicon [8.359, 360], and a microcavity or directional coupler in both silicon and III–V materials [8.361–364]. Figure 8.103 shows an all-optical switching in a silicon PC microcavity [8.361]. The carrier-induced optical nonlinearity based on a two-photon process and carrier-plasma dispersion in the microcavity generates a large index shift, much larger than the thermooptic nonlinear index shift per unit input energy, thus resulting in ultrafast optical switching with low switching energy. The device is based on a four-lattice-point end-hole-shifted (L4) cavity coupled inline to input/output waveguides with high Q (11 500–23 000), as shown in Fig. 8.103a. As shown in Fig. 8.103b, the switching time was approximately 50–300 ps, much faster than the carrier recombination in bulk silicon ($\approx \mu$s). This fast carrier relaxation may be attributed to the short diffusion time for generated carriers in the microcavity [8.361].

PC Lasers

To date, a variety of PC lasers have been developed with different lasing mechanisms and PC structures [8.263]. Most of them are based on PC slabs because they are relatively easy to fabricate. These may be categorized into (1) point-defect lasers and (2) band-edge lasers. The concept of the lasers in category 1 was first put forward by *Yablonovitch* [8.237]. By using an ultrasmall point-defect optical cavity in a PBG, which enables ideal control over spontaneous emission, an ultralow-threshold or thresholdless laser should be possible in principle. A typical example of this kind of laser is shown in Fig. 8.104a, where an InP-based 2-D PC microcavity with four layers of quantum well is formed to be an air-bridge structure to confine light in the vertical direction [8.365]. In the lateral direction, a triangle-lattice air-hole array with a single point defect at the center is perforated to form the microcavity, as shown by the SEM image at the left-hand side of Fig. 8.104b.

In the figure, the radii of two particular inner air holes are increased, while an optically pumped cavity emits light from the point defect region, as predicted by the calculated electromagnetic wave distributions shown in Fig. 8.104c. Optically pumped lasing operation has been verified. This is the first report of PC-based microcavity laser application.

The band-edge laser in category 2 makes use of the low group velocity and feedback mechanism arising from the Bragg diffractions contributing to the band edge. The feedback is 2-D, and therefore this type of PC laser may be regarded as a 2-D laser in contrast with the 1-D laser based on distributed feedback (DFB). In this case, there is no need for the PC to have a PBG; in other words, even a weakly modulated PC suffices for this purpose. However, a category 2 laser utilizing a PBG-related band edge with strong feedback has also been studied [8.366, 367]. A unique feature of this type PC laser is that coherent operation is possible over a wide 2-D area. In the case of what is called *Γ-point* lasers using higher bands, for example, at the cross point on the vertical axis in Fig. 8.91a, the laser emits in the vertical direction as a result of diffraction. This novel type of vertically emitting laser emits within a narrow solid angle and has the advantage that single-frequency operation is realized at high powers [8.367]. Figure 8.105 shows this kind of 2-D PC laser formed by integrating the PC with a gain media using a wafer fusion technique. The 2-D PC structure formed on an *n*-InP substrate (wafer B) and the gain media formed by sandwiching an InGaAsP/InP multiple-quantum-well active layer (wafer A) were stacked and heated in a hydrogen atmosphere at 620 °C and were bonded firmly. A 300 μm-diameter gold electrode was evaporated on the surface of the bonded wafer, allowing the surface-emitted light to be observed from the surrounding area. Lasing was successfully achieved at room temperature. Category 2 lasers were also developed, based on line-defect PC waveguides [8.368].

Regarding the laser material, quantum wells (QWs, typically GaInAsP/InP), quantum dots (QDs, GaAs/InAs), and organic materials are employed, being embedded in a 2-D PC slab. In most cases, optical pumping is adopted, but in some cases, electrical pumping is also employed.

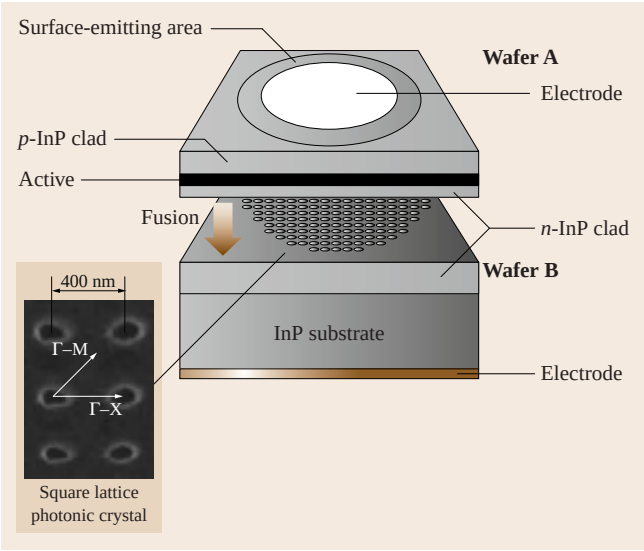

Fig. 8.105 Schematic of an InGaAsP/InP-based 2-D PC laser

Tunable Coherent Light Sources Based on the Smith–Purcell Effect

Electrons traveling along a straight trajectory are accompanied by a photon cloud, which decays exponentially away from the trajectory. The associated light can thus be observed only in the immediate neighborhood of the trajectory. If light scatterers are arranged periodically within the decay range, the radiated photons suffer from umklapp scattering and become visible in the far field. The acquired momentum change shifts the phase-space point of the radiated photon from the outside to the inside of the light cone. This is called Smith–Purcell (SP) radiation. Usually, SP radiation is observed using a metal grating. If a PC is used in place of the grating, the movement of the phase-space point is influenced by the presence of the band structure. In fact, the SP spectrum, characterized by a series of sharp radiation signals, can be observed by placing a PC near a high-energy electron beam [8.369], in satisfactory agreement with theoretical calculations [8.370]. Note that much stronger radiation is available compared with conventional gratings. SP radiation is an interesting example of the use of PCs for electron–photon interactions.

9. Optical Detectors

Optical detectors are applied in all fields of human activities from basic research to commercial applications in communication, automotive, medical imaging, homeland security, and other fields. The processes of light interaction with matter described in other chapters of this handbook form the basis for understanding the optical detectors physics and device properties.

This chapter starts with a brief historical sketch of first experiments facilitating development of optical detectors. The overview of photo detector types is followed by the description of the most important properties and different detection regimes.

A detailed description of different types of optical detectors is presented in the following sections. The device structure and physics as well as important materials for fabrication, figures of merit, and brief application notes are given for photoconductors, photodiodes, quantum well photodetectors, semiconductor detectors with intrinsic amplification, charge transfer detectors, photoemissive detectors, and thermal photodetectors. The chapter includes also a brief overview of imaging systems, principles of black and white and color photography, and recent developments in polymer-, hybrid-, and nanotechnology-based optical detectors.

All photodetectors make use of the effects of light interaction with matter. In fact, this interaction occurs through the photoelectric effect, which in major cases is the primary step in the photon detection process.

Among the predictions of Maxwell's theory of electromagnetism, published in 1865, was the existence of electromagnetic waves moving at the speed of light, and the conclusion that light itself was just such a wave. This challenged physicists to experimentally generate and detect electromagnetic radiation. The first successful attempt in generating light was made by Hertz in 1886, who used a high voltage induction coil to cause a spark discharge between two pieces of brass. Hertz also succeeded in building the receiver capable of detecting the light generated by his emitter.

There were many attempts to explain the effects observed by Hertz, all of which remained unsuccessful until 1899, when Thomson established that ultraviolet light caused electrons to be emitted from a metal surface. In 1902, Lenard studied how the energies of the emitted photoelectrons varied with the light intensity. He discovered that there was a well-defined minimum voltage that stopped any electrons emitted from the illuminated cathode against reaching the collector electrode. He also found that this voltage did not depend at all on the intensity of light. However, Lenard found that the maximum energy of the ejected electrons did depend on the illumination wavelength – the shorter wavelength, the higher the energy of the ejected electrons.

In 1905 Einstein gave a very simple interpretation of Lenard's results. He just assumed that the incoming radiation should be thought of as quanta of energy $h\nu$, with ν the frequency and h the Planck constant. When these photons hit the metal, they could give up some or all of their energy to an electron. An energy that is equal to the product of the metal work function φ_m and elementary charge q would be required to release the electrons from their bonds to the metal. The remaining energy would appear as kinetic energy of the released electron. Thus, the maximum kinetic energy E_k, the emitted electrons could have is

$$E_k = h\nu - q\varphi_m \,. \tag{9.1}$$

Thus Einstein's theory makes a very definite quantitative prediction: there is a minimum light frequency for a given material that emits electrons, for which the quantum of energy is equal to the work function. Light below that frequency will not cause photoemission independently on the light intensity. The effect of the photoelectron emission from solids upon illumination is now called photoelectric effect.

The photoelectric effect can be thought of as either an external or intrinsic effect. In the external effect, the electron is ejected completely from the material, while for the case of an intrinsic photoelectric effect, the motion of electron remains confined within the material. The above experiments on the photoelectron release from the metal are typical examples of the external photoelectric effect. The intrinsic photoelectric effect can be exemplified by the processes of photon absorption in semiconductor crystals, chromophores, macromolecular aggregates, etc. In those cases, the work function of (9.1) should be substituted with the activation energy, for example the band gap E_g for semiconductors. The emitted photoelectron participates in the creation of a qualitatively new state that can be characterized by the electronic circuitry.

9.1 Photodetector Types, Detection Regimes, and General Figures of Merit

9.1.1 Types of Photodetectors

Photodetectors can be divided by the methods used to detect photons and record information: photovoltaic detectors, photoconductors, photoemissive detectors, thermal detectors, charge transfer devices, photographic detectors, etc.

Photovoltaic Detectors

The photovoltaic effect is the generation of a potential across an active region of the detector. For the photovoltaic effect to occur, the barrier has to exist to separate photogenerated carriers. These detectors employ an intrinsic photoelectric effect. For example, when the photon flux irradiates the p-n junction of a semiconductor detector, non-equilibrium electron–hole (e–h) pairs are formed if the photon energy exceeds the forbidden gap energy E_g (Fig. 9.1). Due to the electric field existing across the junction (built-in electric field), electrons are swept from the p region to the n region, and holes from the n region to the p region. This process results in a positively charged p region and negatively charged n region of the semiconductor, creating a potential difference on the contacts.

Photoconductive Detectors

Photoconductive detectors also employ an intrinsic photoelectric effect. In photoconductive detectors, the conductivity σ changes upon illumination if the photon energy is larger than the detector band gap E_g (Fig. 9.2). The conductivity change depends on the particular detector and its properties, and in the simplest case of either p-type or n-type semiconductor can be described as

$$\Delta\sigma = \Delta n q \mu \,, \tag{9.2}$$

in which q is the elementary charge, Δn is the number of non-equilibrium carriers photoexcited over the band gap, and μ is the carrier mobility.

Photoemissive Detectors

Photoemissive detectors employ the external photoelectric effect. For example, if a photocathode and an anode are placed in a vacuum chamber, and an external voltage is applied, then the photocurrent is proportional to the number of incident photons if their energy $h\nu$ is higher than the electron affinity ψ of the photocathode (Fig. 9.3). Another example of a photoemissive detector – the photomultiplier tube (PMT) will be discussed later in this chapter.

Thermal Detectors

Unlike most other detectors, thermal detectors do not produce non-equilibrium carriers per se, but they use the energy of the absorbed light to heat the substrate. During the secondary steps, the dissipated energy

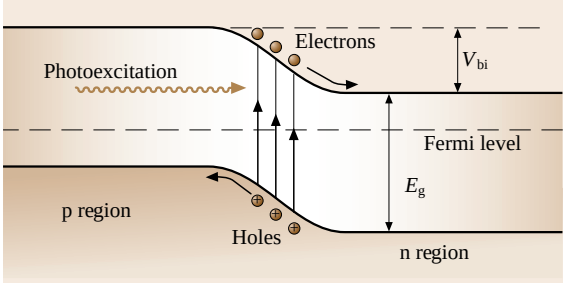

Fig. 9.1 Photovoltaic effect. The contact of p-type and n-type semiconductors creates the barrier with the built-in potential V_{bi}, which facilitates separation of photogenerated carriers

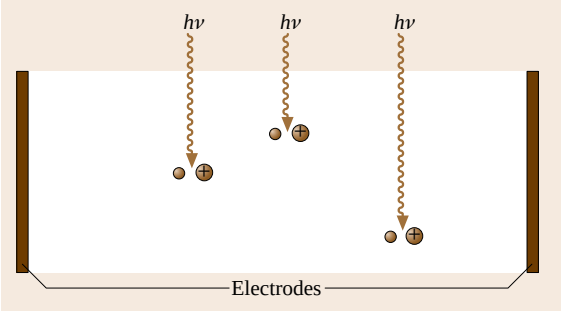

Fig. 9.2 Photoconductive detector. Upon illumination, non-equilibrium carriers are created increasing the conductivity of the detector

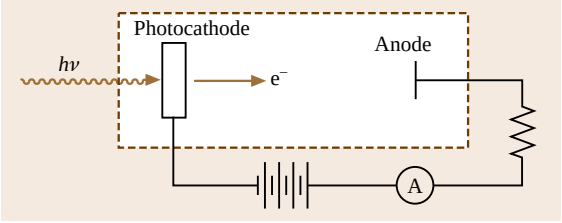

Fig. 9.3 A schematic of a simplest photoemissive detector

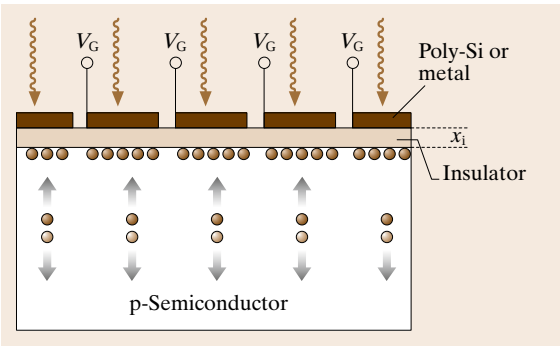

Fig. 9.4 An example of the charge transfer sensor. Each active pixel of the sensor is created by the capacitor that consists of the top electrode (poly-Si or semitransparent metal film), insulator layer of a thickness x_i, and underlying semiconductor. Light penetrates the semiconductor bulk through the semitransparent electrode and generates non-equilibrium carriers in the semiconductor bulk. Applying the gate voltage V_g, the non-equilibrium carriers are separated and stored in the potential well underneath each electrode separately

causes some other physical parameter to change, thus completing the light receiving function. Examples of thermal detectors include semiconductor bolometers, superconductive bolometers, pyroelectric detectors, and thermistors.

Charge Transfer Devices

Charge transfer devices normally operate by storing the non-equilibrium charges created by light in the potential well of the metal–insulator–semiconductor (MIS) capacitor (Fig. 9.4) and further transferring the stored charges across the semiconductor substrate towards the readout electronics.

Photography

Photography is a process based on chemical changes initiated by a photon absorbed by a silver halide micro crystal or a dye molecule attached to that micro crystal and incorporated in the photographic emulsion. These changes accumulate and amplify during exposure of photographic film to light, forming a latent image. After further chemical processing the image becomes visible.

9.1.2 Noise Sources

Among all characteristics of a photodetector, noise performance is especially important, since it determines the detector sensitivity. The noise associated with a detector can be divided into two major groups:

1. Photon noise:
   - Noise due to an optical signal
   - Noise due to background radiation.
2. Detector-generated noise:
   - Johnson noise
   - Shot noise
   - Generation–recombination noise
   - $1/f$ noise
   - Temperature fluctuations
   - Microphotonics.

Photon Noise

Assuming the Poisson statistics of the photon flux, the noise σ_N in an incident optical photon flux Φ containing $\bar{N}$ photons in a given period of time Δt can be expressed in units of number of photons per second by

$$\sigma_N = \sqrt{\bar{N}} = \sqrt{\Phi \Delta t}\,. \tag{9.3}$$

As will be shown below, the relative strength of the photon noise originating from different sources determines different regimes of the detector operation.

Johnson Noise

Johnson or Nyquist noise is caused by the thermal motion of charge carriers in a resistive element. This is a white source noise. In general, the Johnson noise power transfer through the circuit with an effective frequency bandwidth Δf is described as [9.1]

$$P_J = kT\Delta f\,, \tag{9.4}$$

where k is the Boltzmann constant and T is the absolute temperature.

The Johnson noise voltage V_J (or current i_J) can be determined as the voltage (current) that causes the noise power given by (9.4) to be transferred between two equal values noise producing resistors R. Alternatively, the Johnson noise voltage (current) can be calculated from statistical mechanics using the expression for the noise power spectrum for a classic system at equilibrium [9.2]

$$V_J = \sqrt{4kTR\Delta f} \quad \text{and} \quad i_J = \sqrt{\frac{4kT\Delta f}{R}}\,. \tag{9.5}$$

Shot Noise

The shot noise generated in a detector is due to the discrete (stochastic) nature of photoelectron generation.

The variance of the shot noise current is

$$i_{\mathrm{sh}}^2 = \frac{q^2}{\Delta t^2}\overline{(n-\bar{n})^2} = \frac{q^2\bar{n}}{\Delta t^2} = 2qI\Delta f\,, \tag{9.6}$$

in which q is the elementary charge, n and $\bar{n}$ are the immediate and average numbers of photoexcited carriers produced in a time period Δt, the photon statistics is assumed to be Poisson (meaning that $\overline{(n-\bar{n})^2} = \bar{n}$), and the mean photocurrent is $I = \bar{n}q/\Delta t = 2\bar{n}q\Delta f$. Finally, the shot noise for the detector is

$$i_{\mathrm{sh}} = \sqrt{2qI\Delta f}\,. \tag{9.7}$$

Shot noise is a white source noise and the expression (9.7) can be integrated over the whole bandwidth of interest Δf to get the total shot noise of a detector. Equation (9.7) for the shot noise is usually applied only to photon detectors that contain a potential barrier such as photovoltaic detectors.

Generation–Recombination Noise

The generation–recombination noise is an analog of the shot noise applicable for the photoconductor. This type of noise is caused by the fluctuations in current carriers generation (due to photons, thermal generation, etc.) and recombination and is expressed by [9.2]

$$i_{\mathrm{G\text{–}R}} = 2I\left(\frac{\tau\Delta f}{n\left[1+(2\pi f\tau)^2\right]}\right)^{1/2}, \tag{9.8}$$

where the mean current I is due to all sources of current carriers, τ is the carrier lifetime, n is the total number of free carriers, and f is the frequency at which the noise is measured. This type of noise is not a white noise source since there is a clear frequency dependence. It can be shown that the total generation–recombination shot noise contribution for the photoconductor depends on the photoconductive gain G (which is the number of electrons generated per initial photogenerated electron) and can be approximated by

$$i_{\mathrm{G\text{–}R}} = 2\sqrt{qIG\Delta f} \tag{9.9}$$

for the white-noise limit case $(2\pi f\tau)^2 \ll 1$. In the opposite case $\Delta f\tau \to \infty$, the generation–recombination shot noise contribution approaches the limit

$$i_{\mathrm{G\text{–}R}} = \frac{qIG}{\tau}\,. \tag{9.10}$$

1/*f* Noise

This noise is also known as flicker noise. The power spectrum of this noise falls rapidly with the frequency $(1/f)$. The origin of this noise is not well understood, but is often attributed to the imperfect ohmic contact or to the surface-state traps and dislocations [9.1]. The $1/f$ noise component does not present a fundamental limit to sensitivity. With current improvements in the device technology, the $1/f$ noise can be reduced to negligible levels.

Temperature Fluctuations

In thermal detectors, any fluctuations in the temperature of the detector element that are not due to a change in the signal will produce additional noise in the output signal. The temperature fluctuations can be expressed using the analogy with the shot generation–recombination current (9.8), in which the carrier lifetime is substituted with the heat relaxation time constant $\tau_{\mathrm{H}} = \Theta/K$, where K stands for the thermal conductance and Θ is the heat capacity

$$T_{\mathrm{rms}} = 2\left(\frac{KkT^2\Delta f}{K^2+(2\pi f\Theta)^2}\right)^{1/2}. \tag{9.11}$$

In (9.11) we used the notation $\bar{T}$ for the average temperature of the detector.

Microphonic Noise

The microphonic noise is caused by the mechanical displacement of wiring and other components of the detector. The mechanical vibrations of the detector may cause the capacitance change of the detector elements, which is the prime reason for the microphonic noise.

9.1.3 Detection Regimes

A common problem of any type of optical detector is terminating the photodetector with a suitable load resistor and the trade-off between the bandwidth and signal-to-noise ratio.

If we consider the equivalent circuit of a photodetector terminated with a load resistor R_{L}, then the output voltage $V = IR_{\mathrm{L}}$ has a bandwidth (3 dB high-frequency cutoff) given by

$$\Delta f = \frac{1}{2\pi R_{\mathrm{L}}C}\,, \tag{9.12}$$

where C is a stray capacitance across the photodetector.

Two main noise contributions are added to the signal. One is the Johnson noise (9.5) of the load resistance $R = R_{\mathrm{L}}$, the other is the shot noise (9.7) in the case of the photovoltaic detector or (9.8) in the case of the photoconductor. To calculate the shot noise

(generation–recombination) current, one should take into account the total photocurrent under illumination, which is the sum of the signal current I_p and the dark current I_D

$$I_{light} = I_p + I_D \,. \tag{9.13}$$

Since the Johnson noise and shot noise are statistically independent, the resulting noise current quadratic mean value for the most general case of a photodetector with the intrinsic gain G is

$$i_n^2 = 2q(I_p + I_D)\Delta f G^2 F + \frac{4kT\Delta f}{R_L} \,. \tag{9.14}$$

For detectors with no intrinsic amplification the gain $G = 1$ and the excess noise factor $F = 1$. In general, the excess noise factor F depends on the gain and originates due to the statistical nature (Markov process) of current amplification (Sect. 9.7.2).

From (9.12) and (9.14) it can be seen that bandwidth and noise optimization impose opposite requirements on the value of R_L. To minimize the noise current the largest possible R_L is required; on the other hand, to maximize Δf the smallest possible R_L has to be used.

It is generally accepted that the best possible sensitivity performance is achieved when the shot noise is dominant compared to the Johnson noise, i. e.

$$2q\left(I_p + I_D\right)\Delta f G^2 F \geq \frac{4kT\Delta f}{R_L} \,, \tag{9.15}$$

which implies a certain limiting condition on the minimum value of the load resistor. Using (9.14), the signal-to-noise ratio of the detector is calculated as the ratio of the average signal photocurrent $I = I_p G$ to the total noise current i_n

$$\frac{S}{N} = \frac{I}{i_n} = \frac{I_p G}{\left[2q(I_p + I_D)\Delta f G^2 F + 4kT\Delta f / R_L\right]^{1/2}} \,. \tag{9.16}$$

Analyzing (9.16), two detection regimes can be defined, according to whether the signal I_p is larger or smaller than the value

$$I_0 = I_D + \frac{2kT}{qR_L FG^2} \,. \tag{9.17}$$

Assuming $I_p \gg I_0$ and $F = 1$, obtain

$$\frac{S}{N} = \left(\frac{I_p}{2q\Delta f}\right)^{1/2} \,. \tag{9.18}$$

This S/N value is called the *quantum noise limit* of detection. This limitation cannot be overcome by any detection system. In fact, (9.18) is a direct consequence of the quantum nature of light and the Poisson photon statistics.

In the small signal regime, $I_p \ll I_0$, the signal-to-noise ratio is

$$\frac{S}{N} = \frac{I_p}{(2qI_0\Delta f)^{1/2}} \,, \tag{9.19}$$

which is the *thermal noise limit* of detection.

9.1.4 Figures of Merit

To compare the measured performance of different detectors of the same type, certain figures of merit are used. One such figure – the signal-to-noise ratio – was introduced in the previous section. Here we will consider the other most important figures of merit that are generally applicable to almost all photodetectors.

Responsivity

Responsivity $\Re$ is the ratio of the detector output (in amperes or volts) to the intensity of input optical flux Φ_p (in W). For example, the spectral photocurrent responsivity $\Re_I(\lambda, f)$ of the detector at a given wavelength is

$$\Re_I(\lambda, f) = \frac{I_p}{\Phi_p(\lambda)} \,, \tag{9.20}$$

where I_p is the measured photocurrent. The black body responsivity $\Re(T, f)$ is the detector output divided by the incident radiant power from a black body source of temperature T modulated at a frequency f that produces the observed output [9.3]

$$\begin{aligned}\Re_I(T, f) &= \frac{I_p}{\int_0^\alpha \int_\lambda \Phi_p(\lambda)\,\mathrm{d}\lambda} \\ &= \frac{I_p}{A_{source}\sigma_{SB}T^4 A_{det}/\pi L^2} \,,\end{aligned} \tag{9.21}$$

in which α is a solid angle at which the detector is seen from the source site, A_{source} and A_{det} are the source and detector area, respectively, L is the distance between the source and detector, and $\sigma_{SB} = 5.67032 \times 10^{-12}\,(\mathrm{W/cm^2\,K^4})$ is the Stefan–Boltzmann constant. Note that the black body responsivity is a measure of the detector response to the incident radiation integrated over all wavelengths.

Quantum Efficiency

Quantum efficiency η is the probability that photoelectron is produced when the photon is incident on the detector. For the incident optical power Φ_p that

produces the photocurrent $I_p = \Re_I \Phi_p$, the quantum efficiency is calculated as

$$\eta = \frac{\left(\frac{I_p}{q}\right)}{\left(\frac{\Phi_p}{h\nu}\right)} = \frac{h\nu}{q}\Re_I \,, \tag{9.22}$$

where q is the elementary charge, h is the Planck constant, and ν is the photon frequency.

Noise Equivalent Power

The noise equivalent power (NEP) of the detector is the incident on the detector optical power Φ_p required to produce an output signal equal to the noise output. Sometimes NEP is specified for a 1 Hz bandwidth. It can also be defined as the value of the optical input power necessary to produce a signal-to-noise ratio (S/N) of 1. Since the current signal output is $I_p = \Re_I \Phi_p$, the signal-to-noise ratio is

$$\mathrm{S/N} = \frac{\Re_I \Phi_p}{i_n} \,, \tag{9.23}$$

where the rms noise output current i_n is given by (9.14). Putting the left-hand side of (9.23) to unity, we obtain

$$\mathrm{NEP} = \frac{i_n}{\Re_I} \,. \tag{9.24}$$

For the case when the thermal noise dominates all other noise sources, the system signal-to-noise ratio is described by (9.19). The noise equivalent power in this case defines the value S_0 known as the device sensitivity

$$S_0 = \mathrm{NEP} = \frac{2}{\Re_I}\sqrt{\frac{kT\Delta f}{R_L}} = \frac{2h\nu}{\eta q}\sqrt{\frac{kT\Delta f}{R_L}} \,. \tag{9.25}$$

This expression is valid for a photovoltaic device or for a photoconductor with no intrinsic gain ($G = 1$ and $F = 1$).

For the specific case that describes the photon-limited performance, the system signal-to-noise ratio is described by (9.18). This operation mode is typical for the photomultiplier tubes, microchannels, and some detectors with the intrinsic multiplication in the visible and near infrared spectral range. In the infrared spectral range, photon-limited performance is typical also for photovoltaic, photoconductive, and some thermal detectors. As mentioned above, the ultimate performance of detectors is reached when the detector and amplifier noise are low compared to the photon noise. The photon noise is fundamental, in the sense that it does not arise from any imperfection in the detector or its associated electronics, but rather from the detection process itself, as a result of the discrete nature of the electromagnetic field. The radiation falling on the detector is a combination of optical fluxes from the target (signal) Φ^S (in number of incident photons per second) and from the background Φ^B (also in number of incident photons per second). An infrared photon detector that achieves background-limited performance is called *background-limited infrared photodetector* (BLIP). The noise equivalent power for the BLIP case is then obtained from (9.24) and (9.18), using (9.22) for the quantum efficiency η, and taking into account that the radiant flux $\Phi_p^{B,S} = \Phi^{B,S} h\nu$,

$$\mathrm{NEP_{BLIP}} = h\nu\sqrt{\frac{2\Phi^B \Delta f}{\eta}} = \sqrt{\frac{2h\nu\Phi_p^B \Delta f}{\eta}} \,. \tag{9.26}$$

Detectivity

The detectivity D of a detector is the reciprocal of the noise equivalent power

$$D = \frac{1}{\mathrm{NEP}} \,. \tag{9.27}$$

A more useful figure of merit is the specific detectivity D^*, which does not depend on the detector area A_{det} and bandwidth Δf,

$$D^* = D\sqrt{A_{det}\Delta f} = \frac{\sqrt{A_{det}\Delta f}}{\mathrm{NEP}} \,. \tag{9.28}$$

D^* may be used to directly compare detectors of different size whose performance was measured within different bandwidths. The relationship between spectral $D^*(\lambda, f)$ and black body $D^*(T, f)$ is [9.2]

$$D^*(T, f) = \frac{\int_0^\infty D^*(\lambda, f)\Phi(T, \lambda)\mathrm{d}\lambda}{\int_0^\infty \Phi(T, \lambda)\mathrm{d}\lambda} \,. \tag{9.29}$$

For the case of BLIP limit, any shot noise-limited detector will have $D^*(\lambda, f)$ given by

$$D^*_{\mathrm{BLIP}}(\lambda, f) = \frac{\sqrt{A_{det}\Delta f}}{\mathrm{NEP_{BLIP}}(\lambda, f)} = \frac{1}{h\nu}\sqrt{\frac{\eta A_{det}}{2\Phi^B}} \,. \tag{9.30}$$

9.2 Semiconductor Photoconductors

A photoconductor is a light sensitive resistor that in the simplest case may be built of a slab of semiconductor with ohmic contacts on opposite sides (Fig. 9.2). The intrinsic photoelectric effect is the dominant mechanism that creates non-equilibrium carriers in the conduction band of an intrinsic photoconductor. In an extrinsic photoconductor, the excitation of the shallow impurity levels is involved. The long-wavelength cutoff for such a simple case is given by

$$\lambda_c = \frac{hc}{E_g} , \tag{9.31}$$

where E_g is the semiconductor band gap and c is the speed of light. The conductivity of a non-illuminated intrinsic semiconductor device is

$$\sigma_0 = n_0 \mu_n q + p_0 \mu_p q , \tag{9.32}$$

where n_0, p_0, μ_n, and μ_p are the equilibrium concentrations of free electrons and holes and their mobilities, respectively, and q is the elementary charge. The reciprocal value is called resistivity and is defined as

$$\rho_0 = \left(n_0 \mu_n q + p_0 \mu_p q\right)^{-1} . \tag{9.33}$$

Under illumination, the non-equilibrium carriers are created in concentration

$$\Delta n = \Delta p = \frac{\eta_{ex} \Phi \tau}{A_{det} W} , \tag{9.34}$$

where η_{ex} is the external quantum efficiency, defined above as a probability that photoelectron is produced when the photon is incident on the detector; Φ is the photon flux in photons per unit time, τ is the carrier lifetime, A_{det} and W are the detector active area and thickness. From (9.32) and (9.34) one can obtain the relative change in conductivity of the illuminated photoconductor

$$\frac{d\sigma}{\sigma} = \frac{q\left(\mu_n + \mu_p\right)\eta_{ex}\Phi\tau}{\sigma A_{det} W} . \tag{9.35}$$

The light-driven photoconductor resistance R_{det} change is described by

$$dR_{det} = -R_{det}\frac{q\left(\mu_n + \mu_p\right)\eta_{ex}\Phi\tau}{\sigma A_{det} W} . \tag{9.36}$$

For the extrinsic semiconductor, the sum $\left(\mu_n + \mu_p\right)$ should be replaced with the mobility of the available carrier.

9.2.1 Photoconductors – Figures of Merit

Responsivity

If the load resistor R_L is connected in series with the photoconductor and the two resistors are biased with a DC voltage V_0, then the light-induced voltage drop across a uniformly illuminated photoconductor will be expressed as

$$dV = \frac{V_0 R_L R_{det}}{\left(R_L + R_{det}\right)^2}\frac{q\lambda\eta_{ex}\tau\left(\mu_n + \mu_p\right)}{\sigma hc A_{det} W}\Phi_p , \tag{9.37}$$

where Φ_p is an input radiant flux (in W), λ is a wavelength, h is the Planck's constant, and c is the speed of light. The voltage and current spectral responsivities are obtained from (9.37)

$$\Re_V = \frac{dV}{\Phi_p} = \frac{Iq\lambda\eta_{ex}\tau\left(\mu_n + \mu_p\right)}{\sigma hc A_{det} W}\frac{R_L R_{det}}{R_L + R_{det}} \quad [\mathrm{V/W}] , \tag{9.38}$$

$$\Re_I = \frac{Iq\lambda\eta_{ex}\tau\left(\mu_n + \mu_p\right)}{\sigma hc A_{det} W} \quad [\mathrm{A/W}] , \tag{9.39}$$

where $I = V_0/(R_L + R_{det})$ is a total DC current through the detector.

Photoconductive Gain

Photoconductive gain expresses the number of electrical carriers circulated in the circuit per absorbed photon. The physical parameters that affect the gain in a photoconductor are the minority carrier lifetime and the majority carrier transit time. Analyzing (9.39) for the photocurrent responsivity, the photoconductive gain of the intrinsic detector can be defined as

$$G = \frac{I\tau\left(\mu_n + \mu_p\right)}{\sigma A_{det} W} . \tag{9.40}$$

A similar expression for the extrinsic photoconductor with the carrier having the mobility value μ is

$$G = \frac{\tau\mu E}{d} = \frac{\tau}{t} , \tag{9.41}$$

where $E = I/\sigma A_{det} W$ is the electric field across the detector, d is the spacing between the electrodes, and $t = d/\mu E$ is the total carrier transit time between the two electrodes assuming that the electric field is far from saturation.

Noise

1. 1/f Noise. The $1/f$ dependence holds for the noise power. The noise current/voltage varies as $1/\sqrt{f}$. This noise is always present in the photoconductors since they operate at bias current. The empirical expression obtained for the mean square noise current is [9.3]

$$\overline{i_{1/f}^2} = \frac{\text{const} \cdot I^2 \Delta f}{f^\beta} , \tag{9.42}$$

where const is the proportionality constant, Δf and f are the bandwidth and frequency, and β is the constant close to 1.

2. Johnson Noise. For the semiconductor with the internal resistance R_{det}, the Johnson noise mean square current is expressed with by the right-hand side of (9.5).

3. Generation–Recombination Noise. The mean square generation–recombination noise current due to the photon and thermal excitation of the semiconductor is given by [9.4]

$$\overline{i_{\text{G–R}}^2} = 4q \left(q\eta_{\text{ex}} \Phi A_{\text{det}} G^2 + q G_{\text{th}} G^2 \right) , \tag{9.43}$$

where Φ is an incident photon flux, G is the gain, and G_{th} is the thermal generation rate.

Noise Equivalent Power (NEP)

The signal-to-noise ratio for the conductor may be obtained using (9.5) and (9.43) as

$$\text{S/N} = \frac{\Re_{\text{I}} \Phi_{\text{p}}}{i_{\text{n}}} = \frac{\Re_{\text{I}} h\nu \Phi}{\sqrt{\overline{i_{\text{J}}^2} + \overline{i_{\text{G–R}}^2}}} , \tag{9.44}$$

where $\Re_{\text{I}}$ is the current responsivity given by (9.39) and $\Phi_{\text{p}} = h\nu\Phi$ is the incident radiant power. The related figure of merit – NEP – can be obtained from (9.44) by setting $\text{S/N} = 1$.

For the case of the photon-limited conductor, the noise equivalent power is determined by the generation–recombination noise current and can be expressed using (9.26)

$$\text{NEP} = \frac{\sqrt{\overline{i_{\text{G–R}}^2}}}{\Re_{\text{I}}} = h\nu \sqrt{\frac{2\Phi^{\text{S,B}} \Delta f}{\eta_{\text{ex}}}} , \tag{9.45}$$

where $\Phi^{\text{S,B}}$ is the input signal/background photon flux per unit time on the detector. For the case when Johnson noise is dominant,

$$\text{NEP} = \frac{\sqrt{\overline{i_{\text{J}}^2}}}{\Re_{\text{I}}} = \frac{h\nu}{q\eta_{\text{ex}} G} \sqrt{2kT \Delta f \left(\frac{1}{R_{\text{det}}} + \frac{1}{R_{\text{L}}} \right)} . \tag{9.46}$$

Detectivity

The specific detectivity for the photon-limited conductor is determined by

$$D^*(\lambda, f) = \frac{1}{h\nu} \sqrt{\frac{\eta_{\text{ex}} A_{\text{det}}}{2\Phi^{\text{S,B}}}} . \tag{9.47}$$

For the Johnson noise-limited conductor the corresponding specific detectivity is

$$D^*(\lambda, f) = \frac{q\eta_{\text{ex}} G}{h\nu} \sqrt{\frac{A_{\text{det}}}{2kT} \left(\frac{R_{\text{L}} R_{\text{det}}}{R_{\text{L}} + R_{\text{det}}} \right)} . \tag{9.48}$$

9.2.2 Photoconductors: Materials and Examples

Lead–Salt–Based Compound Photoconductors

PbS, PbSe, and PbTe cells are the most common known examples of semiconductor-based photoconductors. They are sensitive to radiation in infrared spectral range, have high quantum efficiency, fast time response, and can operate at room temperature. Cooled lead-salt photoconductors have detectivity close to the background limit.

Lead-salt-based photodetectors are manufactured by either chemical deposition or evaporation of thin ($\approx 1\,\mu\text{m}$) polycrystalline layers of lead salts. The layers are usually sensitized by the controlled introduction of oxygen. It was found that the conductivity of the film changes from n-type to p-type with increasing exposure to oxygen at 300 K.

By controlling parameters such as dopants, deposition temperature, passivation coating, and film thickness the performance characteristics such as resistance, responsivity, time response, spectral response range, noise, and signal-to-noise ratio can be tailored over a wide range. The wavelength of peak response for different lead-salt photodetectors can be tuned widely within the range from $\approx 2.4\,\mu\text{m}$ to $> 5\,\mu\text{m}$. The spectral response can be extended in infrared by cooling detectors as a consequence of the positive temperature coefficient of the energy gaps [9.5].

Mercury Cadmium Telluride (MCT) Photoconductors

MCT photoconductor ($Hg_{1-x}Cd_xTe$) can be made to operate over different spectral regions simply by tuning the Cd/Hg ratio. The photoconductive $Hg_{1-x}Cd_xTe$ detector is a good intrinsic detector and can achieve background-limited sensitivities at operating temperatures substantially higher than the extrinsic detectors.

$Hg_{1-x}Cd_xTe$ photoconductors are typically fabricated from n-type material with an excess concentration of ionized donors of about $10^{14}\,cm^{-3}$ [9.1]. This large intrinsic carrier concentration is the result of excess mercury atoms that exceed the stoichiometry and reside interstitially in the lattice. For a typical $Hg_{1-x}Cd_xTe$ detector with a square optically active area and 10 μm thickness, the resistance is rather small (≈ 200 Ω). The disadvantage of such a low-resistance detector is that high currents can flow with relatively low voltage, which produces high dissipation power and limits the detector application to the low voltage range.

Selenium Photoconductors

Amorphous selenium (α-Se) is widely used to build the photoconductor arrays in the direct conversion systems for γ-radiation detection.

9.3 Semiconductor Photodiodes

Semiconductor photodiodes are the most popular photodetectors capable of operating in both photovoltaic and photoconductive modes.

9.3.1 Function of the Semiconductor Photodiode

p–n Diode in Thermal Equilibrium

The semiconductor photodiode can be considered as a variation of a regular p-n junction diode. The p-n junction is obtained by joining together semiconductors of opposite doping. Once in contact, the thermodynamic equilibrium is attained by lining up the Fermi levels across the whole structure. Electrons from n-type semiconductor diffuse into the p region and holes from p-type semiconductor into n region and a surplus is created of negative electric charge in the p region and of positive charge in the n region. This creates an electric field that sweeps mobile charges out of junction region creating the so-called space-charge region depleted of mobile carriers (Fig. 9.5).

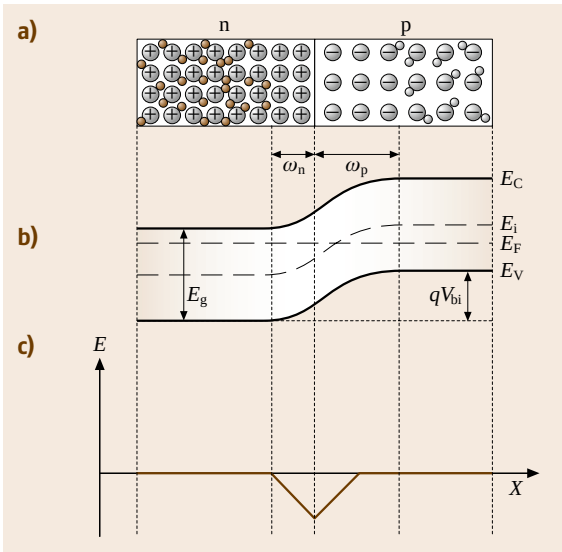

Fig. 9.5a–c Abrupt p-n junction in thermal equilibrium. **(a)** Space-charge distribution: *small circles* show mobile electrons and holes, *large circles* indicate ionized donors and acceptors; **(b)** energy-band diagram; **(c)** electric field distribution

Using the band model, the requirement of lining up the Fermi levels of n-type and p-type semiconductor species results in the built-in potential V_{bi}, which for the thermal equilibrium case is given by [9.6]

$$V_{bi} = \frac{1}{q}\left(E_i^p - E_i^n\right) = \frac{kT}{q}\ln\frac{N_A N_D}{n_i^2}\,, \tag{9.49}$$

where E_i^p and E_i^n are the intrinsic levels in the neutral p and n regions, N_A and N_D are the acceptor and donor doping concentrations, and n_i is the intrinsic carrier density that is obtained using the values for the energy band gap E_g and the effective densities of states N_V and N_c in the valance band and conduction bands, respectively

$$n_i = \sqrt{N_V N_c}\exp\left(-\frac{E_g}{2kT}\right)\,, \tag{9.50}$$

$$N_V = 2\left(\frac{2\pi m_p kT}{h^2}\right)^{3/2} \text{ and}$$

$$N_c = 2\delta\left(\frac{2\pi m_n kT}{h^2}\right)^{3/2}\,. \tag{9.51}$$

The effective masses of electrons m_n and holes m_p as well as the conduction band degeneracy factor δ (a number of equivalent minima in the conduction band) are specific for each semiconductor.

The space-charge region (depletion region) extends from the junction into the n and p regions. For the sim-

plest case of the two-sided abrupt junction, the width $w = w_n + w_p$ (Fig. 9.5) of the depletion region is found from the requirement that the electric field at the boundaries of the space-charge region is zero and that the potential difference equals the built-in voltage

$$w = w_n + w_p = \sqrt{\frac{2\varepsilon\varepsilon_0 (N_A + N_D)}{qN_A N_D} V_{bi}} , \qquad (9.52)$$

where ε_0 is a vacuum permittivity, ε is the semiconductor dielectric constant, and w_n and w_p are the space-charge region widths of the n-type and p-type regions of the semiconductor, separated by the junction.

p–n Diode with External Bias

For a forward bias V, the voltage across the junction will decrease from the equilibrium value V_{bi} to $(V_{bi} - V)$ and the width of the space-charge region will shrink correspondingly. For the reverse bias condition, the voltage across the junction will increase to the value $(V_{bi} + V)$ causing the expansion of the space-charge region. The width of the space-charge region (depletion region) with the external bias V is given by

$$w = \sqrt{\frac{2\varepsilon\varepsilon_0 (N_A + N_D)}{qN_A N_D} (V_{bi} \mp V)} , \qquad (9.53)$$

in which the $\mp$ signs are for the forward- and reverse-bias conditions, respectively.

The total current density J for the ideal photodiode is expressed by the Shockley equation (curve 1 in Fig. 9.6) [9.6]

$$J = J_s \left[\exp\left(\frac{qV}{kT}\right) - 1\right] \equiv q\left(\frac{n_{p0} D_n}{L_n} + \frac{p_{n0} D_p}{L_p}\right)\left[\exp\left(\frac{qV}{kT}\right) - 1\right] , \qquad (9.54)$$

where J_s is the so-called saturation current density, n_{p0} and p_{n0} are the minority carrier concentrations at the equilibrium in the p and n regions, respectively, and the carrier diffusion constants D_n and D_p are given by the Einstein relationship

$$D_n = \frac{kT}{q}\mu_n \quad \text{and} \quad D_p = \frac{kT}{q}\mu_p , \qquad (9.55)$$

in which μ_n and μ_p are the carrier mobilities. The carrier diffusion lengths L_n and L_p are

$$L_n = \sqrt{D_n \tau_n} \quad \text{and} \quad L_p = \sqrt{D_p \tau_p} , \qquad (9.56)$$

with τ_n and τ_p describing electron and hole lifetimes. The equilibrium concentration of minority carriers is determined from $p_{n0} = n_i^2/n_{n0} \approx n_i^2/N_D$ for the n-type semiconductor and $n_{p0} = n_i^2/p_{p0} \approx n_i^2/N_A$ for the p-type semiconductor.

Equation (9.54) was obtained for the ideal photodiode with the abrupt junction, using the Boltzmann approximation for the carrier concentrations throughout the space-charge layer, assuming that the minority carrier densities are small comparatively to those of the majority carrier (a low injection assumption), and assuming no generation–recombination current in the space-charge area that imposes a related requirement of the constant electron and hole currents through the depletion layer.

Using (9.53), one can obtain an expression for the depletion layer capacitance per unit area, which is one of the main figures that determine the time response of the semiconductor photodiode. For the two-side abrupt junction

$$C_j = \frac{\varepsilon\varepsilon_0}{w} = \sqrt{\frac{\varepsilon\varepsilon_0 q N_A N_D}{2(N_A + N_D)(V_{bi} \mp V)}} . \qquad (9.57)$$

p–n Diode Under Illumination

To derive the total photocurrent generated in the bulk of the p-n semiconductor diode, assuming a very shallow p-layer on top of the n-type substrate and neglecting the thermally generated current, one has to consider separately the photocurrent generated in the charge-space region of the width w and the photocurrent from the neutral region of the semiconductor bulk.

Case 1 – Front Illuminated Photodiode. Consider first the situation when light penetrates the photodiode bulk from the p side and the surface p^+ layer is much thinner than the light absorption length $1/\alpha$ ($\delta \ll 1/\alpha$, α is the absorption coefficient) (Fig. 9.7a). This case is typical for the so-called front-illuminated photodiodes. Assume

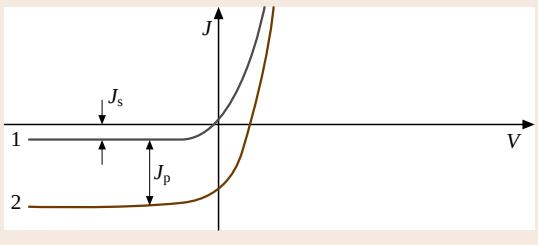

Fig. 9.6 *I–V* characteristics of the ideal photodiode in the dark (1) and under illumination (2)

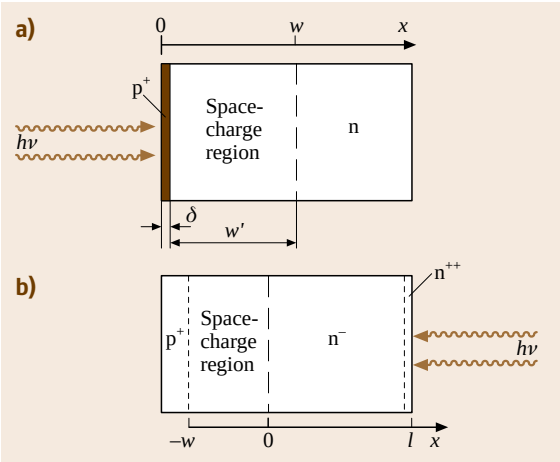

Fig. 9.7 (**a**) Operation of the front-illuminated p/n junction photodiode. The junction depth δ is very small so that $w \approx w'$. The drift photocurrent originates in the space-charge region and the diffusion current comes from the non-depleted n region. (**b**) Back-illuminated photodiode operation. The carriers' injection occurs from the diode back surface assuming that the photocurrent contains the diffusion component only

further that the crystal thickness is much larger than the light penetration depth, meaning that all light quanta are absorbed during a single passage inside the crystal. We will also neglect the effects of surface recombination of carriers to simplify consideration.

The e–h pairs generated in the space-charge region of a p-n junction by light absorption are separated by the electric field, giving rise to a drift photocurrent J_{dr}. Those carriers that are generated in the neutral, not depleted part of the semiconductor bulk ($x > w$) may also reach the space-charge region via the diffusion mechanism if the diffusion distance is shorter than the carrier diffusion depth L_{n} and L_{p}. This current is treated as the diffusion current J_{diff}.

The electron–hole photo-generation rate $G(x)$ in the semiconductor bulk at the distance x from the surface is determined from

$$G(x) = \frac{\partial \Phi(x)}{\partial x}\,\mathrm{d}x = \Phi_0 \alpha \exp(-\alpha x)\,, \tag{9.58}$$

in which Φ_0 is the incident optical photon flux per unit area, α is the absorption coefficient, and $\Phi(x) = \Phi_0 \exp(-\alpha x)$ in accord with the Beer–Lambert law is the photon flux inside the semiconductor bulk at the distance x from the photodiode surface. The drift current is then

$$J_{\mathrm{dr}} = -q \int_0^w G(x)\,\mathrm{d}x = q\Phi_0 \left[1 - \exp\left(-\alpha w\right)\right]\,. \tag{9.59}$$

For $x > w$, the minority carrier density p_{n} in the semiconductor bulk is determined by the one-dimensional diffusion equation

$$D_{\mathrm{p}} \frac{\partial^2 p_{\mathrm{n}}}{\partial x^2} - \frac{p_{\mathrm{n}} - p_{\mathrm{n0}}}{\tau_{\mathrm{p}}} + G(x) = 0\,. \tag{9.60}$$

Since the sample thickness was assumed to be much thicker than $1/\alpha$, the boundary condition at $x = \infty$ is $p_{\mathrm{n}} = p_{\mathrm{n0}}$. The boundary condition at $x = w$ is also $p_{\mathrm{n}} = p_{\mathrm{n0}}$ because the electric field in the depletion region sweeps away non-equilibrium carriers effectively. Hence, the solution of (9.60) for $x > w$ is given by

$$p_{\mathrm{n}} = p_{\mathrm{n0}} - A \exp(-\alpha w) \exp\left(\frac{(w-x)}{L_{\mathrm{p}}}\right) + A \exp(-\alpha x)\,, \tag{9.61}$$

$$A = \frac{\Phi_0}{D_{\mathrm{p}}} \frac{\alpha L_{\mathrm{p}}^2}{\left(1 - \alpha^2 L_{\mathrm{p}}^2\right)}\,. \tag{9.62}$$

The diffusion current density is then

$$J_{\mathrm{diff}} = -qD_{\mathrm{p}} \left(\frac{\partial p_{\mathrm{n}}}{\partial x}\right)_{x=w} = q\Phi_0 \frac{\alpha L_{\mathrm{p}}}{1 + \alpha L_{\mathrm{p}}} \exp(-\alpha w)\,. \tag{9.63}$$

Combining (9.59) and (9.63) we obtain the total photocurrent density

$$J_{\mathrm{p}} = J_{\mathrm{dr}} + J_{\mathrm{diff}} = q\Phi_0 \left(1 - \frac{\exp(-\alpha w)}{1 + \alpha L_{\mathrm{p}}}\right)\,, \tag{9.64}$$

which shows that the photocurrent J_{p} is proportional to the incident photon flux Φ_0.

If the thermally generated current (9.64) is not negligible, then the total photodiode current is

$$J_{\mathrm{total}} = q \left(\frac{n_{\mathrm{p0}} D_{\mathrm{n}}}{L_{\mathrm{n}}} + \frac{p_{\mathrm{n0}} D_{\mathrm{p}}}{L_{\mathrm{p}}}\right) \times \left[\exp\left(\frac{qV}{kT}\right) - 1\right] + J_{\mathrm{p}}\,, \tag{9.65}$$

and the corresponding typical current–voltage (I–V) characteristic of the photodiode under illumination is shown in Fig. 9.6 (curve 2).

If the external leads of the photodetector are shorted, the voltage across the junction is kept constant at the built-in potential level and the photocurrent will flow. This current is called the *short circuit current* (J_{sc}) and can be approximated from (9.65) by putting $V = 0$

$$J_{sc} \cong J_p \,. \tag{9.66}$$

If alternatively the leads are open, the voltage across the junction will drop to such a value that the flow of photo-generated carriers is compensated for by an increase of the diffusion current given by (9.54). This voltage change appears as an output voltage on the device leads and is called the *open circuit voltage* (V_{oc}), which, ignoring the change of the depletion width under illumination, can be calculated from (9.65) by putting $J_{total} = 0$ is

$$V_{oc} = \frac{kT}{q} \ln\left(\frac{\Phi_0 \left[\frac{\exp(-\alpha w)}{1+\alpha L_p} - 1 \right]}{n_{p0} D_n / L_n + p_{n0} D_p / L_p} \right) . \tag{9.67}$$

Case 2 – Back-Illuminated Photodiode. In this case the junction is created on one side of the semiconductor crystal and light penetrates from the other side of the structure. It is interesting to consider the situation when light is absorbed mostly in the neutral region of the semiconductor. To further simplify the description, assume that absorption occurs within a very thin surface layer of the photodiode's backside (absorption coefficient $\alpha \to \infty$). This means that the carrier surface photo generation rate is described with the δ function

$$G(x) = \Phi_0 \alpha \exp\left[-\alpha\,(l-x)\right] \delta(x-l) \,, \tag{9.68}$$

where l is the distance between the depletion region edge and light penetrating surface (Fig. 9.7b). We also will *not* neglect the surface recombination events, which may be important for the back-illuminated diode with an extended diffusion region.

Since the excess carriers are extracted at the edge of the depletion region, the boundary condition at $x = 0$ is $p_n = p_{n0}$. The other boundary condition is obtained from the diffusion current at the surface

$$J_{diff}|_{x=l} \equiv q D_p \left(\frac{\partial p_n}{\partial x} \right)_{x=l} = q\Phi_0 - q S_r \left[p_n(l) - p_{n0} \right] \,, \tag{9.69}$$

where S_r is the surface recombination rate in cm/s and $p_n(l)$ is the minority carrier concentration at the surface.

For the chosen boundary conditions, the solution of the diffusion equation is

$$p_n = p_{n0} + \frac{\Phi_0 \left[1 - \left(\frac{S_r}{D_p} \right) \alpha\delta(x-l) L_p^2 \right] \sinh\left(x/L_p\right)}{\left(D_p/L_p\right) \cosh\left(\frac{l}{L_p}\right) + S_r \sinh\left(l/L_p\right)} + \frac{\Phi_0 \alpha \delta(x-l) L_p^2}{D_p} \,. \tag{9.70}$$

The photocurrent in this case contains the diffusion component only and is calculated as

$$J_p = J_{diff}|_{x=0} = q D_p \left(\frac{\partial p_n}{\partial x} \right)_{x=0} = \frac{q\Phi_0}{\cosh\left(l/L_p\right) + \left(S_r L_p / D_p\right) \sinh\left(l/L_p\right)} \,. \tag{9.71}$$

p-i-n Photodiode

The efficiency of non-equilibrium carriers' collection into the external circuit is much higher in the charge-space region than in the neutral region of the semiconductor. The width w of the space-charge region increases as $\left(\sqrt{N_{A,D}}\right)^{-1}$ with decrease in the donor/acceptor concentrations $N_{A,D}$ (9.53). The space-charge layer width will be maximized if the intrinsic layer is inserted between the p-type and n-type layers, resulting in the p-i-n structure as shown in Fig. 9.8. In practice, the intrinsic layer is often substituted with the low-implant concentration layer. The behavior of such p-i-n photodiodes is described by the same equations as presented above; however, those equations can be

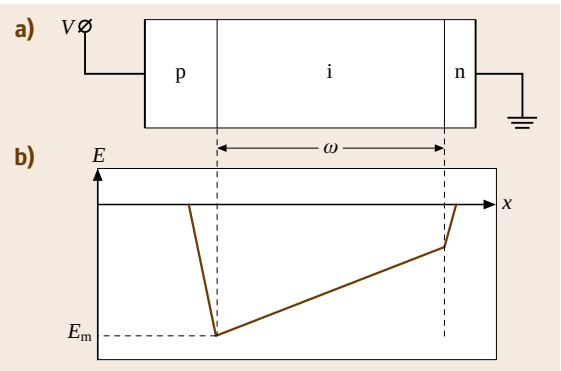

Fig. 9.8 **(a)** Biased p-i-n photodiode and **(b)** electric field distribution at reverse bias conditions. The depletion width w and maximum field strength E_m depend on the magnitude of the applied reverse bias. The slope of the electric field distribution in each region depends on the donor/acceptor concentration

simplified in some cases because the dopant concentrations on different sides of the junction are significantly different.

9.3.2 Photodiodes – Figures of Merit

Quantum Efficiency and Responsivity

The external quantum efficiency of the photodiode is defined as the ratio of the number of carriers producing photocurrent to the number of incident photons Φ_0. Using this definition and (9.64), for the front-illuminated photodiode we obtain

$$\eta_{ex} = \frac{J_p/q}{\Phi_0} = 1 - \frac{\exp(-\alpha w)}{1+\alpha L_p} \,. \tag{9.72}$$

Note that the right-hand side of (9.72) is valid for a relatively large value of αw, when light is completely absorbed during the first passage through the semiconductor bulk and nothing is reflected from the backside of the die.

For the case of a back-illuminated photodiode described above, the external quantum efficiency is obtained from (9.71)

$$\eta_{ex} = \frac{J_p/q}{\Phi_0} = \left[\cosh\left(\frac{l}{L_p}\right) + \frac{S_r L_p}{D_p}\sinh\left(\frac{l}{L_p}\right)\right]^{-1} . \tag{9.73}$$

The internal quantum efficiency is defined as the ratio of the number of electron–hole pairs generated by light to the number of photons absorbed in the semiconductor bulk

$$\eta_{in} = \frac{\eta_{ex}}{(1-R_F)} = \frac{J_p/q}{\Phi_0(1-R_F)} \,, \tag{9.74}$$

in which R_F is the reflection coefficient of the light incident surface.

The photodiode current responsivity is the ratio of total output photocurrent I_p (in A) to the incident optical power Φ_p (in W)

$$\Re_I = \frac{I_p}{\Phi_p} = \frac{\eta_{ex} q}{h\nu} = \frac{\eta_{ex} q \lambda}{hc} \approx \frac{\eta_{ex}\lambda[\mu m]}{1.24} \quad [A/W] \,, \tag{9.75}$$

where ν is the photon frequency, c is the speed of light in a vacuum, and λ [μm] is a wavelength in micrometers.

Carrier Collection Efficiency Function

The internal quantum efficiency $\eta_{in}(\lambda)$ of an ideal photodiode for the case $\alpha w \gg 1$, when all penetrating quanta of light are absorbed by the crystal of the thickness h and non-equilibrium carriers all participate in the photocurrent can be calculated using a simple expression

$$\eta_{in}(\lambda) = 1 - \exp[-\alpha(\lambda)h] \equiv \int_0^h \mathrm{d}x\alpha(\lambda)\exp[-\alpha(\lambda)x] \,, \tag{9.76}$$

in which x is the photodiode penetration depth starting from the surface. In a real, non-ideal, structure not all of the photo-generated, non-equilibrium carriers are collected by the external circuit and participate in the current. This effect is accounted for by the carrier collection efficiency function $P(x)$ [9.7]

$$\eta_{in}(\lambda) = \int_0^h \mathrm{d}x P(x)\alpha(\lambda)\exp[-\alpha(\lambda)x] \,. \tag{9.77}$$

When $\alpha w \ll 1$, more than one passage of light inside the photodiode crystal occurs and the expression for the quantum efficiency should be modified. For the case of two passages, we obtain [9.8]

$$\eta_{in}(\lambda) = \int_0^h \mathrm{d}x P(x)\alpha(\lambda)\exp[-\alpha(\lambda)x] + R_B\exp[-\alpha(\lambda)h] \times \int_0^h \mathrm{d}x P(h-x)\alpha(\lambda)\exp[-\alpha(\lambda)x] \,, \tag{9.78}$$

in which the first term in the right-hand side describes the number of carriers collected into the external circuit due to the first passage of radiation inside the crystal and the second term describes the corresponding number for the radiation reflected back into the crystal from the rear surface of the die (R_B is the die backside reflection coefficient). The backside reflection is considered as a specular reflection here. Assuming that the quantum efficiency $\eta_{in}(\lambda)$ is known from the experiment, the carrier collection efficiency function can be retrieved from (9.78) [9.9]. Note that usually $P(x) = 1$ inside the depletion region except for the thin surface layer of the photodiode. The expression (9.78) can be easily expanded to the case of multiple passages of light inside the semiconductor photodiode bulk.

Shunt Resistance, Series Resistance, and Forward Characteristics

The photodiode equivalent circuit can be represented as a source of current with a source (or shunt) resistance R_{sh}, connected in parallel to it, and a series (or

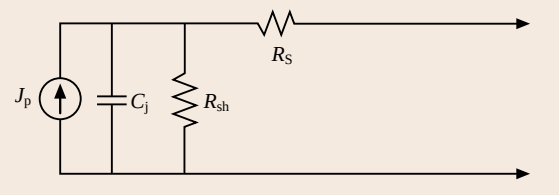

Fig. 9.9 Simplified equivalent circuit of the photodiode. J_p is a photocurrent, C_j a junction capacitance, R_{sh} a shunt resistance, and R_s a series resistance

forward) resistance R_s in series (Fig. 9.9). For the ideal photodiode, $R_{sh} = \infty$ and $R_s = 0$. The photodiode shunt resistance is defined as a dynamic resistance at the origin and can be calculated from (9.54)

$$R_{sh} = \left.\frac{\partial V}{\partial I}\right|_{V=0} = \frac{kT}{qJ_sA_j} , \tag{9.79}$$

with A_j standing for the junction area and J_s for the saturation current density. Shunt resistance is an important characteristic of any photodiode since it defines the thermal noise current.

Series resistance R_s of a photodiode is defined as the sum of a total resistance R_{cont} of the ohmic contacts and resistance of the undepleted semiconductor bulk. In the most general case, the series resistance can be expressed as

$$R_s = \frac{1}{A_j}\int_{x_1}^{x_2} \rho(x)\,dx + R_{cont} , \tag{9.80}$$

where $\rho(x)$ is the semiconductor bulk resistivity, x_1 is the depletion layer edge, and x_2 is the semiconductor bulk boundary. For the planar structure with a shallow abrupt junction as shown in Fig. 9.5, the series resistance can be calculated as

$$R_s \approx \frac{d-w}{A_j}\rho + R_{cont} , \tag{9.81}$$

where d is the substrate thickness, w is the charge-space region width given by (9.53), and ρ is the substrate resistivity, which is $\rho_n = (n\mu_n q)^{-1}$ for the n-type substrate and $\rho_p = \left(p\mu_p q\right)^{-1}$ for the p-type substrate.

As is evident from the Shockley equation (9.54), the junction resistance for the ideal semiconductor diode $R_j = \partial V/\partial I$ approaches zero with the forward voltage increase. However, (9.54) does not account for the generation and recombination of carriers in the depletion region, the high-injection conditions, and not perfect ohmic contacts. These three factors can alter significantly the forward current even at a relatively small forward bias.

The major recombination-generation process in the depletion region is the capture of the injected carriers, which adds the recombination current J_{rec} to the Shockley equation. It can be shown that this current is proportional to the intrinsic carrier density n_i, the trap density N_T, the carrier capture cross section σ_{capt}, and the carrier thermal velocity $v_{th} = \sqrt{3kT/m^*}$ (with m^* standing for the carrier effective mass) [9.6]

$$J_{rec} \approx \frac{qw}{2}\sigma_{capt}v_{th}N_Tn_i \exp\left(\frac{qV}{2kT}\right) . \tag{9.82}$$

Combining (9.82) and (9.54), the forward current J_f for the p-n structure can be approximated for $p_{n_0} \gg n_{p_0}$ and $V_f > kT/q$ by

$$J_f \approx q\sqrt{\frac{D_p}{\tau_p}}\frac{n_i^2}{N_D}\exp\left(\frac{qV_f}{kT}\right) + \frac{qw}{2}\sigma_{capt}v_{th}N_Tn_i\exp\left(\frac{qV_f}{2kT}\right) . \tag{9.83}$$

In general, the experimental forward current can be fitted with the dependence

$$J_f \propto \exp\left(\frac{qV_f}{\gamma kT}\right) , \tag{9.84}$$

where γ is an ideality factor that equals 2 when the recombination current dominates and is closer to 1 when the diffusion current becomes dominant. Equation (9.84), which relates the forward current and voltage, is used to estimate how close the photodiode properties are to those of an ideal photodiode.

Breakdown Voltage

As it follows from the Shockley equation, the reverse-bias current saturates at high voltages if the minority carrier diffusion into the space-charge region is the only mechanism to build up the reverse dark current. An additional increase in the reverse dark current value occurs due to the generation of carriers in the space-charge region, which may result from the thermal generation of carrier either in the semiconductor substrate itself or within various defects in the semiconductor volume. The latter effect depends on the defects/impurity concentration, while the former effect can be expressed with the thermal generation rate G_{th} as

$$G_{th} = \beta n_0 p_0 = \beta n_i^2 = \frac{n_i}{\tau_g} , \tag{9.85}$$

in which $\beta = \left(n_i\tau_g\right)^{-1}$ is the proportionality constant, τ_g is the carrier generation lifetime, and $n_i^2 = n_0 p_0$ is

the thermal equilibrium intrinsic carrier concentration with n_0 and p_0 describing the equilibrium concentration of electrons and holes. The generation current density within the space-charge region of width w is

$$J_g = qwG_{th} \,. \tag{9.86}$$

A further increase of the photodiode reverse bias beyond the value, at which w extends through the whole semiconductor bulk (a reach-through regime), results in such a high electric field that an electrical breakdown occurs and the reverse-bias current increases dramatically. The two mechanisms that are generally considered to be involved are the Zener breakdown and the avalanche breakdown.

Zener Breakdown

This mechanism involves interaction of the electric field with the covalently bound electrons. At a large reverse bias, the conduction band of the n-type region occurs to be shifted well below the top of the valence band of the p-type region of the semiconductor diode. The occupied energy levels in the valence band of the p-type semiconductor line up with the unoccupied energy levels in the conduction band at the n-side and a strong electric field facilitates tunneling of the valence electrons through the potential barrier from the p-side towards the n-side of the semiconductor. The barrier height is equal to the semiconductor band gap E_g and the tunneling probability ϑ can be found from the expression for tunneling through a triangular-shaped barrier [9.10]

$$\vartheta \approx \exp\left(-\frac{8\pi\sqrt{2m_e}E_g^{3/2}}{3qhE}\right) , \tag{9.87}$$

where m_e is the electron mass, h is the Planck's constant, and E is the electric field. The tunneling current density can be estimated as

$$J_{tunn} = qn_Z v_d \vartheta \,, \tag{9.88}$$

in which n_Z and v_d are the density and drift velocity of the valence electrons arriving at the Zener barrier, respectively.

Avalanche Breakdown

Avalanche breakdown occurs when the electric field is high enough to trigger the multiplication processes during collisions of accelerated in the field carriers with atoms of the substrate. The probability of the multiplication process depends not only on the electric field value, but also on carrier ionization rates and the extent of the avalanche region. The avalanche process can be characterized with the multiplication factor M, which in the case of one type of carrier (either $\alpha_n \gg \alpha_p$ or $\alpha_p \gg \alpha_n$) can be written as [9.11]

$$M_{n,p} = \exp\left(\int_0^L \alpha_{n,p}(x)\,dx\right) , \tag{9.89}$$

where L is the width of the multiplication region and $\alpha_{n,p}(x)$ are the electron/hole ionization rate, which depends on the coordinate x inside the multiplication region. For the case $\alpha_n = \alpha_p$, the condition for avalanche breakdown can be deduced as $M \to \infty$

$$\int_0^L \alpha_{n,p}(x)\,dx = 1 \,. \tag{9.90}$$

Since the ionization rate is a function of the electric field, which varies inside the space-charge region, the breakdown voltage V_B is not easy to calculate precisely. However, the following empirical formula was shown to be valid for different semiconductors [9.12]

$$V_B \approx 60\left(\frac{E_g(\text{in eV})}{1.1}\right)^{3/2}\left(\frac{N_B(\text{in cm}^{-3})}{10^{16}}\right)^{-3/4} , \tag{9.91}$$

where N_B is the background dopant concentration in the light doped side.

More details on avalanche breakdown will be presented below in the section on avalanche photodiodes.

Noise Current

1/f Noise. The noise current/voltage for this type of noise varies as $1/\sqrt{f}$. The experimentally measured relationship for the mean square noise current is [9.4]

$$\overline{i_{1/f}^2} = \frac{\text{const}\cdot I_{DC}^2 \Delta f}{f^\beta} , \tag{9.92}$$

where *const* is the proportionality constant, Δf and f is the bandwidth and frequency, and β is the constant close to 1. Note that this noise is a function only of the direct-current component of the semiconductor photodiode I_{DC}. In modern designs, this noise is negligibly small.

Johnson Noise. For the semiconductor photodiode, the Johnson noise mean square current is expressed by

$$\overline{i_J^2} = \frac{4kT\Delta f}{R_{eq}} , \tag{9.93}$$

in which the equivalent resistor is determined as $1/R_{eq} = 1/R_{sh} + 1/R_s$ with R_{sh} and R_s defining the shunt and series resistors of the photodiode, respectively. The series resistance is usually much smaller than the shunt resistor and can be neglected.

Shot Noise. The mean square shot noise current of the photodiode consists of the two main components: the photon-generated component and the dark current component of the semiconductor diode shot noise current

$$\overline{i_{sh}^2} = \sqrt{2q\left(I_p + I_D\right)\Delta f}\,, \tag{9.94}$$

with $I_p = I_s + I_B$ describing the photocurrent produced by the signal and background radiation (I_s and I_B are the signal and background current, respectively) and I_D accounting for the contribution of all sources of the dark current.

Signal-to-Noise Ratio and Noise Equivalent Power (NEP)

The signal-to-noise ratio of the semiconductor photodiode can be found using (9.93) and (9.94)

$$\begin{aligned} \mathrm{S/N} &= \frac{\Re_I \Phi_p}{i_n} = \frac{\Re_I h\nu\Phi}{\sqrt{\overline{i_J^2} + \overline{i_{sh}^2}}} \\ &\approx \frac{I_p}{\sqrt{2q(I_p + I_D)\Delta f + 4kT\Delta f/R_{sh}}}\,, \end{aligned} \tag{9.95}$$

where $\Re_I$ is the current responsivity given by (9.75), $\Phi_p = h\nu\Phi$ is the incident radiant power, and the approximate equality sign is due to the substitution $R_{eq} \approx R_{sh}$. By putting the signal-to-noise value to 1, one may calculate the photodiode NEP as $\mathrm{NEP} = \Phi_p\big|_{S/N=1} = i_n/\Re_I$. In the case of a photon-limited performance the optical signal is rather strong in comparison with all sources of noise currents and $(I_D + 2kT/qR_{sh})/q\Delta f \ll 1$. For that case, the photodiode NEP is determined by the quantum noise associated with the signal photon flux Φ^S (or the background photon flux Φ^B) itself

$$\mathrm{NEP} = h\nu\sqrt{\frac{2\Phi^{S,B}\Delta f}{\eta_{ex}}}\,. \tag{9.96}$$

In the case of a very low optical photon flux, when $I_p \ll (I_D + 2kT/qR_{sh})$, the thermal noise of the shunt resistance and/or the photodiode leakage current noise becomes dominant and the corresponding value of NEP is given by

$$\mathrm{NEP} = \frac{h\nu}{\eta_{ex}}\sqrt{\frac{2\Delta f}{q}\left(I_D + \frac{2kT}{R_{sh}q}\right)}\,. \tag{9.97}$$

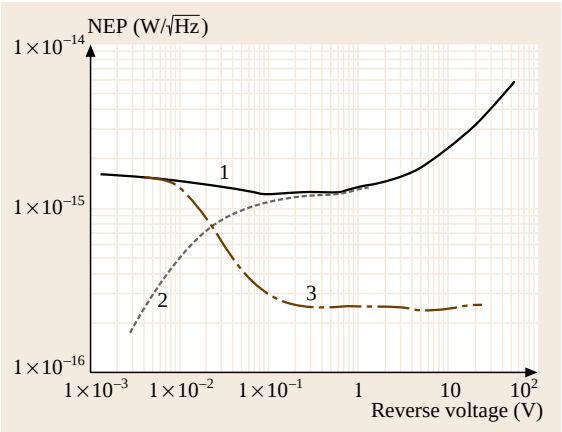

Fig. 9.10 A typical NEP dependence on the reverse bias for a 1 mm^2 Si photodiode at room temperature (*curve 1*). The Johnson noise component is shown with the *curve 3* and shot noise – with the *curve 2*

A typical NEP plot versus reverse bias is shown in Fig. 9.10 for a 1 mm diameter silicon photodiode. At low bias values, the Johnson noise component is usually dominant over the other noise sources, whereas the shot noise component becomes increasingly large at large reverse bias values, when the dark leakage current increases.

Detectivity

The photodiode detectivity is derived using a general expression for detectivity $D = 1/\mathrm{NEP}$. The specific detectivity for the photon-limited photodiode is determined by the expression

$$D^*(\lambda, f) = D\sqrt{A_{det}\Delta f} = \frac{1}{h\nu}\sqrt{\frac{\eta_{ex}A_{det}}{2\Phi^{S,B}}}\,, \tag{9.98}$$

in which A_{det} is the photodiode active area and superscripts (S,B) correspond to either signal or background photon flux, whichever is greater. For the Johnson noise limited photodiode with the load resistor R_L the specific detectivity is

$$D^*(\lambda, f) = \frac{q\eta_{ex}}{h\nu}\sqrt{\frac{A_{det}}{2kT}\left(\frac{R_L R_{sh}}{R_L + R_{sh}}\right)}\,. \tag{9.99}$$

Time Response and Frequency Bandwidth

In the process of light quanta detection by photodiodes, the final step is usually the non-equilibrium carrier collection into the external circuitry, which occurs either through the drift or diffusion mechanism with the time

constants τ_{drift} and τ_{diff}, respectively. Since the diffusion and drift processes are independent of each other, the resulting response time is calculated as

$$\tau_r = \sqrt{\tau_{drift}^2 + \tau_{diff}^2 + \tau_{RC}^2} \,, \tag{9.100}$$

in which τ_{RC} is the time constant determined by the terminal capacitance C and load resistor R_L. The cut-off frequency f_c of the photodetector also defines the 3 dB break point and is given by

$$f_c = \frac{1}{2\pi\tau_r} \,. \tag{9.101}$$

The upper limit for the carrier diffusion time can be estimated from the following straightforward considerations. The carriers' diffusion length is related to the diffusion time and diffusion constants $D_{n,p}$ for electron and holes as

$$L_{n,p} = \sqrt{D_{n,p}\tau_{diff}^{n,p}} \,. \tag{9.102}$$

Assuming the carrier lifetime is long enough to allow the non-equilibrium carriers to move without recombination along the carrier concentration gradient, $\tau_{diff}^{n,p}$ for electrons and holes is calculated from (9.102) as the time necessary to diffuse through the undepleted region of the semiconductor bulk

$$\tau_{diff}^{n,p} = \frac{L_{n,p}^2}{D_{n,p}} \equiv \frac{(d-w)^2}{D_{n,p}} \,, \tag{9.103}$$

where d and w are the semiconductor substrate thickness and depletion region width, respectively. The diffusion constants can be calculated from the known Einstein relation

$$D_{n,p} = \frac{kT\mu_{n,p}}{q} \,, \tag{9.104}$$

where $\mu_{n,p}$ are the carrier mobilities, specific for each semiconductor.

The upper limit for the carrier drift time τ_{drift} across the space-charge region can be estimated as

$$\tau_{drift}^{n,p} = \frac{w}{v_{drift}^{n,p}} = \frac{w}{\mu_{n,p}E} \,, \tag{9.105}$$

where in the right-hand side we used the known phenomenological relationship that defines the carrier mobility as the ratio of the average drift velocity to the applied electric filed E

$$v_{drift}^{n,p} = \mu_{n,p}E \,. \tag{9.106}$$

This expression is valid for the relatively low electric field strength, when effects like electron-phonon scattering can be neglected. At high values of E, the carrier drift velocity saturates and becomes independent of E [9.13].

Ways to reduce the photodiode time response and to make the cutoff frequency larger will be discussed below.

9.3.3 Semiconductor Photodiodes – Materials

The choice of semiconductor photodiode material depends primarily on the spectral range of interest. Figure 9.11 shows absorption coefficients versus wavelength for the most common semiconductors. For the spectral range below ≈ 1100 nm, Si is usually used. However, since both Si and the other popular semiconductor material – Ge – are the indirect band gap semiconductors, a large spectral range of their sensitivity is covered through the absorption processes involving phonons. Obviously, phonon-assisted photon absorption has much smaller probability than the direct valence band to conduction band transitions occurring in the direct band gap semiconductors. This explains the significantly smaller absorption coefficients and,

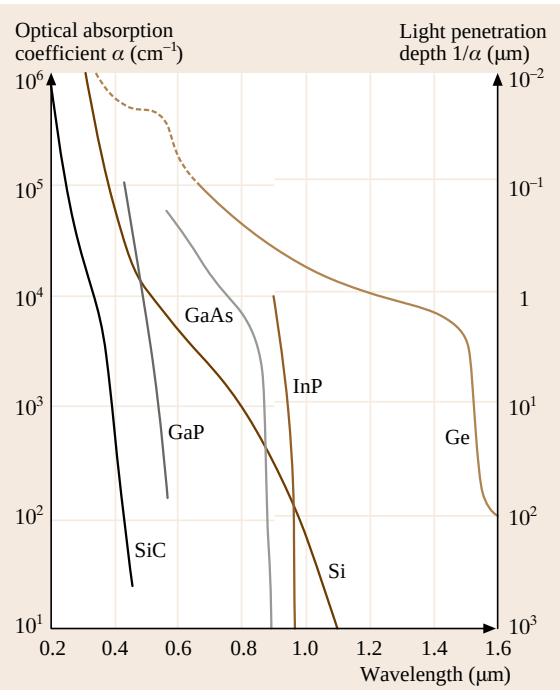

Fig. 9.11 Absorption versus wavelength of a several elemental and binary semiconductors

Table 9.1 Lowest energy gaps E_g and carriers mobility for a number of intrinsic semiconductors at room temperature [9.6, 14]

Material	E_g (eV)	μ_n ($cm^2/(V\,s)$)	μ_p ($cm^2/(V\,s)$)

correspondingly, larger absorption lengths for Si and Ge compared to many compound semiconductors. The values of band gap E_g for a number of important semiconductors are summarized in Table 9.1.

The other important photodiode parameter that is directly related to the absorption length is the time response. The time response is normally significantly shorter for the direct band gap semiconductors due to the much thinner absorption volume, which automatically translates into the shorter carrier collection time. However, specific structural features may greatly improve the response time and we will describe that in the following sections.

The photodiode rise time and time response is a complex function of several parameters, the carrier mobility being among the most important. Table 9.1 shows the carriers mobility values for various semiconductors.

Single Material Semiconductors

Because of the indirect character of photon absorption Si and Ge do not have a sharp absorption edge. Si is the main semiconductor material for the visible and near infrared (IR) spectral range. Si photodiodes have usually quantum efficiencies close to 100% at selected intervals within the spectral range from ≈ 400 to 1000 nm (Fig. 9.12). A typical spectral responsivity curve for Si photodiodes is also shown in Fig. 9.12. Special front surface treatment allows extending the high efficiency region of Si photodiodes below 400 nm. Among the other advantages of Si photodiodes are low noise currents (Fig. 9.10). The usual way to reduce the dark current in Si-based and other substrate photodiodes is to provide special structures like guard rings and surface leakage stoppers (channel stoppers) (Fig. 9.13).

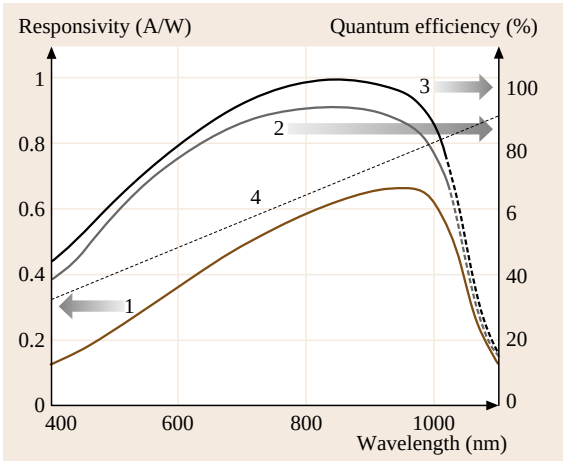

Fig. 9.12 An example of spectral response for a Si photodiode (*curve 1*). The quantum efficiency (QE) of the same photodiode is shown with the *curves 2* (external QE) and *3* (internal QE). *Curve 4* shows theoretical responsivity dependence for an imaginary photodiode with $\eta_{ex} = 100\%$

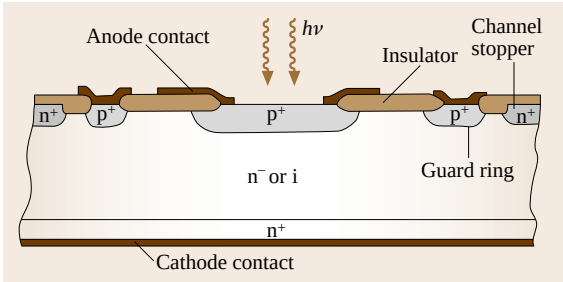

Fig. 9.13 Structure of a p-i-n photodiode (a cross sectional view). p^+ diffusion in the middle of the die forms the active area junction; p^+ diffusions close to the edges are the guard rings – the spacing from the main (anode) junction depends on the required breakdown and leakage performance; n^+ diffusions at the edges are the channel stoppers

Guard rings are usually designed to decrease the electric field strength in the depletion region, thus reducing the high-field ionization efficiency of the host and dopant atoms. The surface leakage stoppers are designed to prevent minority carriers from outside the active area from reaching the space-charge region.

The absorption edge of Ge extends beyond 1.6 μm, which is advantageous for the purposes of the wide spectral range applications but at the same time limits this material sensitivity to low photon fluxes because of the high levels of thermally generated dark current. An example of the p-i-n photodiode structure, typical for Si and Ge, is given in Fig. 9.13.

Binary III–V Semiconductor Photodiodes

III–V binary semiconductors allow designing the photodiodes operating in the wide spectral range from UV to mid-IR. The direct band gap III–V group semiconductors have a rather small absorption length, which assumes a relatively high probability of the non-equilibrium carrier recombination on surface defects. The latter effect is the main reason for the lower quantum efficiency values for the photodiodes based on III–V compounds in comparison with those for Si and Ge.

The photodiodes based on III–V compounds usually show increased dark current values, which limit the field of their application.

Binary II–VI Semiconductor Photodiodes

II–VI binary semiconductors have also found their application in photodiode design, although these materials are not as widely used as III–V compounds. Among those that have been explored are CdTe with a band gap of ≈ 1.48 eV [9.14] (some sources give a larger value of ≈ 1.6 eV [9.1] and HgTe, which is actually a semimetallic compound with a negative band gap of ≤ 0.25 eV. The ternary and quaternary compounds based on II–VI group semiconductors have found much wider application.

Table 9.2 Values of the κ parameter for various semiconductors [9.1]

Material	κ (eV)
$Al_xGa_{1-x}As$	0.27
$GaAs_{1-x}P_x$	0.21
$InAs_{1-x}P_x$	0.27
$InAs_xSb_{1-x}$	0.58
$In_{1-x}Ga_xAs$	0.32
$In_{1-x}Ga_xSb$	0.43

Ternary and Quaternary Semiconductor Photodiodes

Ternary $A_{1-x}B_xC$ and quaternary $A_{1-x}B_xC_{1-y}D_y$ compounds are used to build photodiodes with optimized spectral sensitivity range. Various formulae have been suggested to calculate the band gap as a function of the stoichiometry parameters x and y. For example, one of the ideas accounts for the second-order perturbation of the Schrödinger potential, which yields the following expression for the band gap change with x [9.15]

$$E_g(A_{1-x}B_xC) = E_g(AC) + \left[E_g(BC) - E_g(AC) - \kappa\right]x + \kappa x^2 , \quad (9.107)$$

where κ is a positive constant, specific for each compound. Note that some ternary and quaternary compounds can have both direct or indirect lowest band gap depending on the x and y values. Correspondingly, there will be two versions of (9.107) for materials that change from direct to indirect gap; AlGaAs is an example. To calculate the direct band gap value for $Al_{1-x}Ga_xAs$ ($0 < x < 0.44$), one should always take the direct band gap values of the corresponding binary compounds and vice versa. Table 9.2 shows the examples of calculated κ values for several (dired-gap) ternary compounds.

One of the main requirements in building ternary and quaternary structures is the lattice matching requirement. Figure 9.14 shows the variation of the lattice constant as a function of the band gap for some III–V ternary alloys. Note that the successful growth of heterostructures requires consideration of both the band gap and lattice constant. For example, $Al_{1-x}Ga_xAs$ can be grown on GaAs substrate for any value of x without lattice mismatch inducing defects. In contrast, for the $Ga_{1-x}As_xP$/GaAs structure there is a substantial mismatch in the lattice constant value for GaAs and GaP, which does not allow building simple quality structures within the whole range of x. However, in many cases this problem is overcome by providing a grading layer between the substrate and desired compound.

Instead of using grading layers, quaternary compounds can be built. Not all quaternary compounds can be ideally matched to the substrate. However, the case of $In_{1-x}Ga_xAs_{1-y}P_y$ provides the exciting exception. The diagram in Fig. 9.15 demonstrates the correlation between the band gap and lattice constant for this quaternary compound. The solid lines represent iso-band gap lines. Every band gap from 0.36 eV (InAs) to 2.2 eV ($In_{0.73}Ga_{0.27}P$) can be made in a direct gap semiconductor. The dashed lines in Fig. 9.15 represent iso-lattice

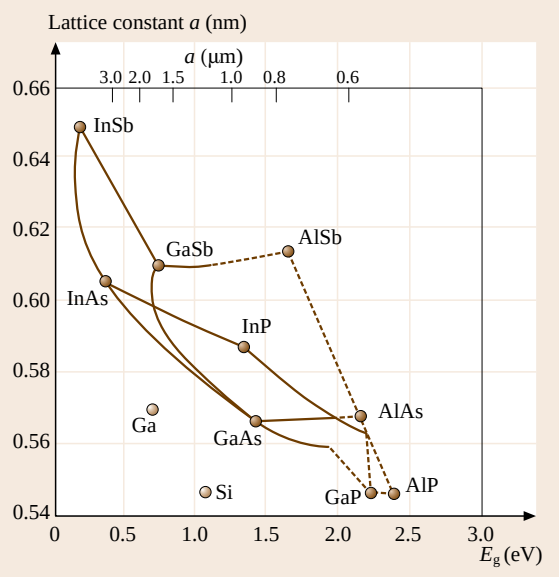

Fig. 9.14 The variation of lattice constant with band gap for the III–V ternary compounds. The direct gap materials are shown with the *solid line* and the indirect gap material – with the *dashed line*

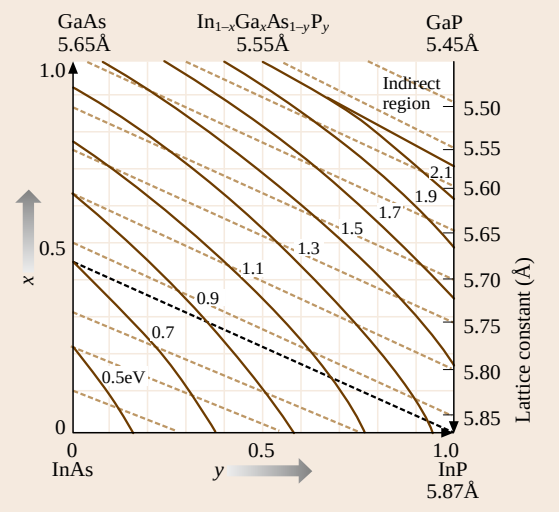

Fig. 9.15 The iso-band gap lines (*solid lines*) and iso-lattice constant lines for the $In_{1-x}Ga_xAs_{1-y}P_y$ quaternary alloy. The *bold dotted line* shows the continuous set of quaternary structures perfectly lattice-matched to InP

constant lines. The important feature of this diagram is presented with the bold dotted line that shows the continuous set of quaternary structures with band gap

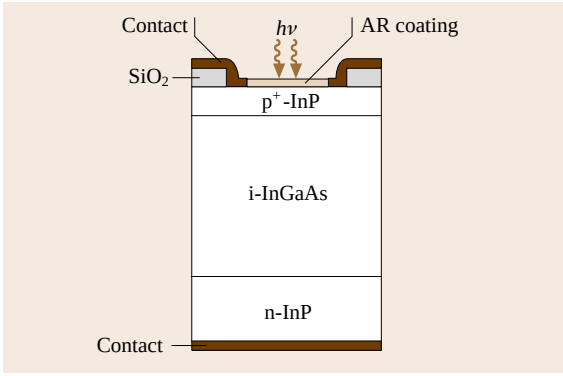

Fig. 9.16 An example of the structure of InGaAs/InP p-i-n photodiode

values from ≈ 1.33 eV to ≈ 0.7 eV and perfectly lattice-matched to InP.

Figure 9.16 shows a typical example of a p-i-n photodiode that employs the ternary III–V compounds. The intrinsic layer of $In_{1-x}Ga_xAs$ is grown on top of a n-type InP substrate. The ternary structure is sensitive up to ≈ 1.65 μm for $x = 0.47$. A top layer p-InP creates the junction and completes the structure. Since InP is transparent to the wavelengths above 0.92 μm, the device can be used as an efficient p-i-n, back-illuminated photodiode for the wavelength range from 0.92 through 1.65 μm, in which all absorption occurs within the intrinsic layer.

Another example of the quaternary structure p-i-n photodiode is shown in Fig. 9.17 along with the typical quantum efficiency curves for a number of stoichiometries.

As for the II–VI ternary compounds, the structures based around the $Hg_{1-x}Cd_xTe$ (mercury-cadmium-telluride, MCT) system had a virtual monopoly for the long-wavelength light detection (3–5 μm and 8–14 μm) until recently. Depending on x, this system provides tremendous flexibility in tuning the spectral sensitivity range from visible to far infrared. The band gap of the alloy $Hg_{1-x}Cd_xTe$ is zero at $x \approx 0.15$ and is only slightly non-linear over the whole range of x up to $E_g = 1.48$ eV at $x = 1$ [9.2]

$$E_g = -0.302 + 1.93x + 5.35 \times 10^{-4} T(1-2x) + -0.31x^2 + 0.832x^3 \,, \quad (9.108)$$

where T is an absolute temperature. Among the drawbacks of MCT photodiodes is a high leakage current, which requires cooling the device for noise-free operation.

Fast Response Photodiodes

Short carrier transit time is one of the determining parameters in designing photodiodes with short response time τ_r. To minimize carrier transit time, the carrier drift time should be reduced assuming that the photodiode bulk is fully depleted (9.100). However, for indirect-band gap semiconductors with low absorption coefficients, a thick absorption layer is required to achieve high quantum efficiency, and this condition is in conflict with the requirement to reduce the carrier transit time. There are several ways to overcome the conflict, one of which is to build resonantly enhanced structures, the other is to decouple the photodiode absorption length from the direction of non-equilibrium carrier drift.

A resonant cavity enhanced photodetector relies on the idea of constructive interference of a Fabry–Pérot cavity to enhance the optical field inside the photodetector bulk at specific wavelengths [9.16]. Such resonant cavities can be formed using a buried backside reflector and the air/semiconductor top interface. The backside reflector can be of various types; the scattering reflector [9.17] and distributed Bragg reflector [9.18] are common examples.

For indirect-band gap semiconductors, it is difficult to achieve both high bandwidth and high efficiency with a vertical design since the length of the absorption region is proportional to the carrier transit time. Decoupling of the absorption length from the motion of non-equilibrium carriers is another efficient method to improve the speed and quantum efficiency of Si-based and Ge-based photodiodes. Such decoupling is achieved in the lateral surface p-i-n photodiodes on silicon-on-insulator (SOI) substrates, which exploits the idea of a grating coupler on top of the photodiode [9.19, 20]. The coupler promotes the optical beam propagation in a thin, waveguide-type surface layer of Si (Fig. 9.18).

A different way to decouple absorption length and carrier motion is to incorporate alternating p^+ and n^+ fingers in Si substrate [9.21]. In the example of design shown in Fig. 9.19, the deep carriers are blocked by the junction between the n-well and p-substrate and the transit time is determined by a fast lateral motion of carriers between the fingers.

In top-illuminated, direct-band gap semiconductor photodiodes, a further reduction of the carriers' transit time is limited by the surface recombination processes, which decreases the responsivity. The side-illuminated photodiodes, in which the absorption length is decoupled from the carriers' transit time, overcome the efficiency-bandwidth tradeoff of top-illuminated photodiodes [9.22, 23]. However, they are not able to operate at high optical power levels, since carrier generation occurs in a very small volume at the diode input facet.

One of the solutions to that challenge is to design evanescently coupled photodiodes monolithically

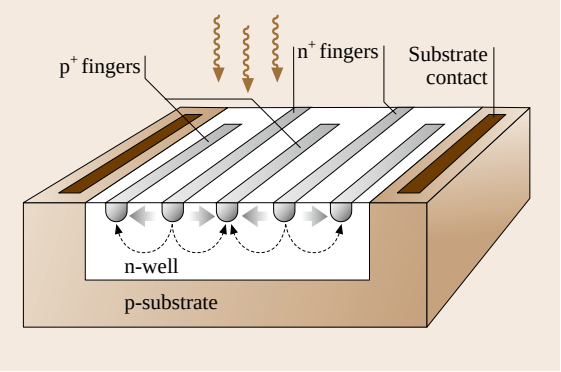

Fig. 9.19 A schematic example of the lateral p-i-n photodiode with alternating p^+ and n^+ fingers fabricated using CMOS technology

integrated with a waveguide [9.24–26]. The evanescent coupling optimizes the distribution of non-equilibrium carriers along the absorption layer. Due to more uniform light absorption, devices that utilize evanescent coupling can achieve several times higher saturation current than a traditional side-illuminated device. An example of an evanescently coupled photodiode is shown schematically in Fig. 9.20. The structure is usually based on a classical p-i-n photodiode with a very thin ($< 0.5\,\mu m$) undoped InGaAs absorbing layer of 20–30 μm length and a p^+-doped InP layer on the top. The n^+-doped layer is represented with InGaAsP structures that may consist of two optical matching layers. The light is delivered from the side and propagates along the undoped diluted waveguide layer, which

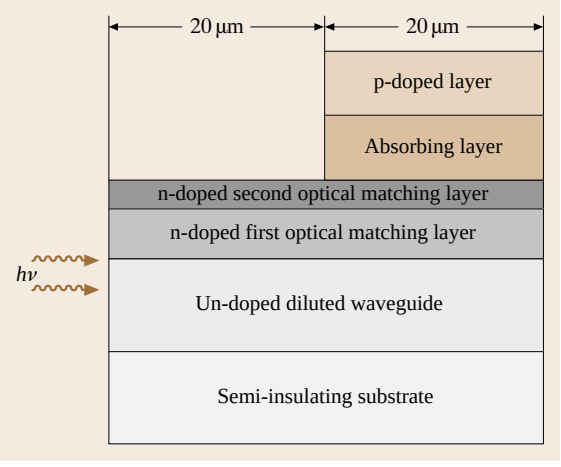

Fig. 9.20 A schematic cross section of the planar photodiode with short multimode waveguide coupler

is a stack of several InP/InGaAsP sandwiches. The band gaps and the thickness of optical matching layers are chosen in such a way that they provide a gradual increase of the refractive index from the diluted waveguide towards the thin absorbing layer. As a result of the evanescent wave coupling, when propagating along the waveguide the optical wave is gradually transferred through the optical matching layers to the absorbing layer. The quantum efficiency can be achieved higher than 95% with a bandwidth of over 50 GHz, which should be beneficial for many applications. However, the fabrication of such structures is rather complex.

Position-Sensitive Photodiodes

Resistive Charge Division Sensor. A silicon resistive charge division sensor, also known as a silicon position sensor consists of a segment of photodetective silicon (moderately doped p^+-layer on the top of n-type substrate) with either two or four terminals for signal output and a terminal for application of back-bias voltage (Fig. 9.21a). Position information in this device is derived by comparing the signal outputs from each terminal. For example, for the two-terminal device shown in Fig. 9.21a the position may be calculated from

$$x = \frac{I_2}{I_1 + I_2} d \,. \tag{9.109}$$

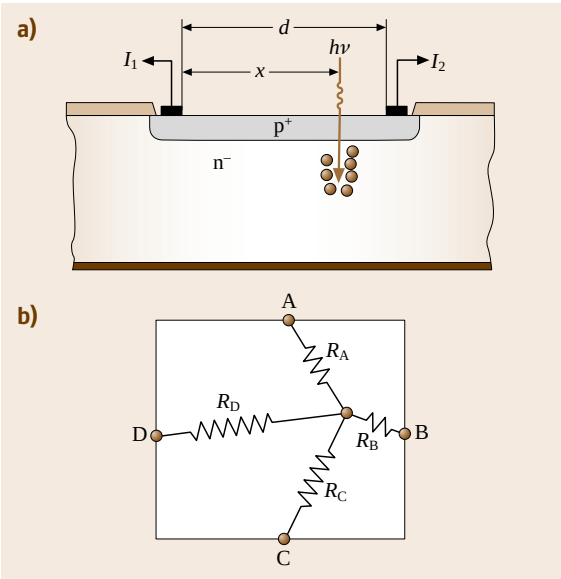

Fig. 9.21 (**a**) Cross section of the two terminal position sensitive detector. (**b**) Unequal resistance paths on the silicon four-terminal sensor

The focused image causes a photo current flow through the silicon to each terminal. Because the silicon has a given resistance per unit length, more current will flow to the closest terminals and less current to the terminals that are farthest from the focused image (Fig. 9.21b).

Position sensors of this type have several advantages over other similar devices. Because there is no gap in the active areas, the size of the image is not subject to constraints on minimum diameter. A second advantage is that position information is available as long as the image falls somewhere on the active area of the detector. One disadvantage is that frequency response of such detectors tends to be lower than for a conventional silicon detector of the same size, because of the series resistance that the photocurrent encounters at the detector surface.

Strip Detector. Another way to measure position is obtained by dividing the large-area photodiode into many small, strip-like regions and to read them out separately (Fig. 9.22). The method of producing the strip detectors is the same as that of planar photodiodes except for the more stringent requirements on the masks precision and alignment. The measurement precision depends mainly on the strip spacing and the readout method.

Quadrant Photodiode. A quadrant photodiode is variation of a strip detector, the segments of which are the four quadrants that have separate connectors for signal output. Each quadrant functions and behaves as a regular p-i-n or avalanche photodiode. Quadrant photodiodes are widely used in the tracking systems. Position information is derived from the relative signal output from each segment (Fig. 9.23). When the focused image is centered on the quadrant detector, each segment will receive the same amount of optical radiation, and all four signal outputs will be equal (Fig. 9.23, left). As the image moves on the detector surface (corresponding to an angular change of the object being tracked), more radiation falls on one of the segments and less on the opposite segment.

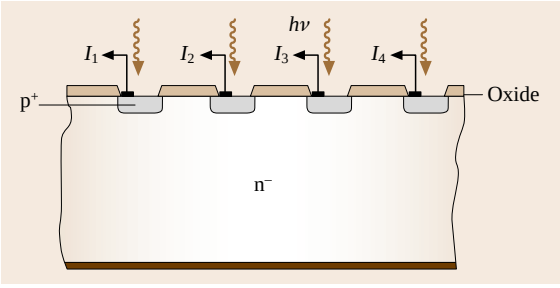

Fig. 9.22 Cross section of a silicon diode strip detector

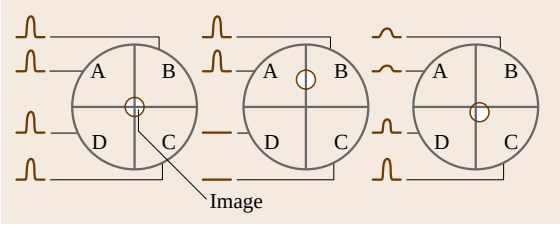

Fig. 9.23 Comparative output of the image falling in different positions on the quadrant detector

If more optical energy falls above the horizontal line (Fig. 9.23, middle), more photocurrent will flow through the upper segments (A and B) than through the lower segments (C and D). The up-down position of the spot is characterized with the relative amplitudes of $(A+B)-(C+D)$. Similarly, the term $(A+D)-(B+C)$ gives information about the left-right position.

In most tracking and alignment applications, a major parameter of concern is the ability of the detector to supply a very precise description of the location of the focused image on the face of the detector. In other words, the change in output signal in relation to a change in the position of the spot is imperative. In this case, sensitivity is used to describe the ratio

$$\text{Sensitivity} = \frac{\text{Change in output signal}}{\text{Change in position}} . \qquad (9.110)$$

The problem inherent in quadrant photodiodes is the finite width of the separation between segments. If the image is focused to a small spot size, erroneous information will result when the spot falls on the border between segments. This problem usually is avoided by defocusing the image or by using a long-focal-length objective that results in a larger image size and displacement. Additionally, some position information is lost when the entire image falls within one segment. This problem also can be avoided by defocusing or the use of longer-focal-length optics.

Color-Sensitive Detectors

The conventional way for detecting a color image relies on the idea that any color, as perceived by the human eye, is based on the three primary colors, red, green, and blue. Mixing light of these wavelengths in varying proportions can generate other colors. The main principle of operation of any color sensor is based, therefore, on impinging beam separation into three primary colors and detecting them separately. The variety of methods

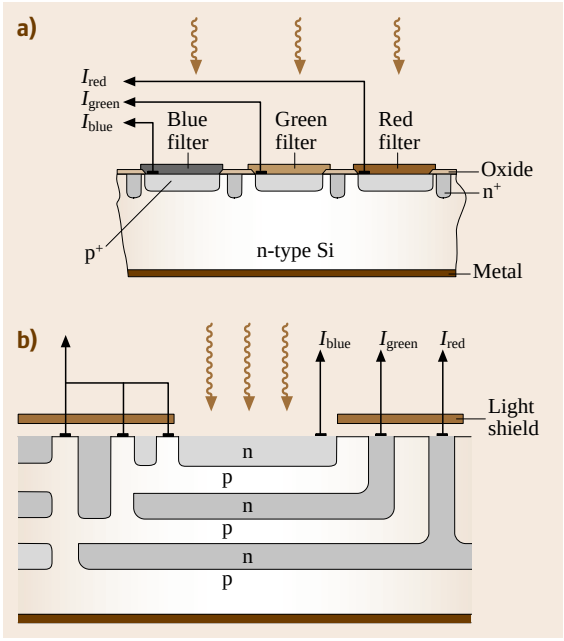

Fig. 9.24 **(a)** Typical structure of the color-sensitive element with three color filters overlaid over different photodiodes. **(b)** An example structure of the vertically arranged color detector; n-type regions are *hatched*

exploits two main principles: one uses color overlay filters on top of the photodetectors' active area, the other selects colors using the inherent property of the semiconductor to absorb light of different wavelength on a different depth. The Hue diagram is then used to infer the color of incident light [9.27].

In the first type of color sensors, color detection is performed by using three filters, one for each of the primary colors, and three photodetectors fabricated on the same substrate. A typical structure of this type is shown in Fig. 9.24a. p-n or p-i-n photodiodes are built on an n-type Si wafer with an n^+ guard ring. The filters allow transmission of one of the primary wavelengths, and the corresponding photodiode measures the intensity of the incident light at that wavelength. The responses of the photodetectors are then used to determine the relative contribution of each of the primary wavelengths to the incident light and hence to infer its color. A drawback of such methods is that the use of three sensors with their corresponding filters can become complicated and take up excessive space when forming a color sensing array.

Another type of multiple wavelength sensors employs more than one sensor in a vertically oriented arrangement. Different available designs include photodiodes formed in single-crystalline silicon and those formed in amorphous silicon. The operation of these devices is based on the intrinsic filtering property of semiconductors that results from the variation of absorption coefficient with the wavelength of light. An example of such a structure is shown in Fig. 9.24b [9.28]. The detector layers have different spectral sensitivities based on their different depths in the semiconductor substrate, doping levels, and biasing conditions. The three n-type regions are isolated vertically by p-regions. The blue, green, and red photodiode sensors are formed by the corresponding p/n junctions and are arranged one below the other underneath the sensor surface. The detector layers are individually connected to pixel sensor readout circuits.

Black Silicon Photodetectors

Silicon-based photodetectors are attractive due to their monolithic integratibility with low-cost complementary metal oxide semiconductor (CMOS) technology. Conventional Si photodetectors achieve high responsivity at wavelengths shorter than 850 nm. For longer wavelengths, the absorption coefficient of Si decreases dramatically. The band gap of Si limits operation to wavelengths of $\approx 1.07\,\mu m$, which makes it unsuitable for many near-infrared (NIR) applications. Recently, a laser-etched microstructured Si with enhanced near-IR absorption has been developed. This material exhibits low reflectance and high absorption across a broad wavelength spectrum extending to $2\,\mu m$ [9.29]. The photodetectors built using this material may have either a p/n junction or a Schottky barrier (Sect. 9.6) and exhibit high photoresponse (30–120 A/W) in a wide spectral range from 600 nm through 1100 nm operating in a photoconductive mode at a very low reverse bias [9.30, 31]. A pronounced photoresponse of over 0.02 A/W at wavelengths up to $2\,\mu m$ was observed as well.

The device structure is prepared by irradiating n-doped Si wafers with a Ti:sapphire laser that delivers a 1 kHz train of 100 fs laser pulses at normal incidence in a high pressure atmosphere of sulfur hexafluoride (SF_6). After irradiation, the surface layer is several hundred nanometers thick and is composed of polycrystalline silicon with a grain size of tens of nanometers. The specific surface morphology is formed by laser ablation; however, formation of the bead microstructure is not completely understood [9.32]. Figure 9.25 shows a scanning electron micrograph of the wafer surface after such laser treatment. Sulfur is known to create multiple energy levels in the middle of the Si

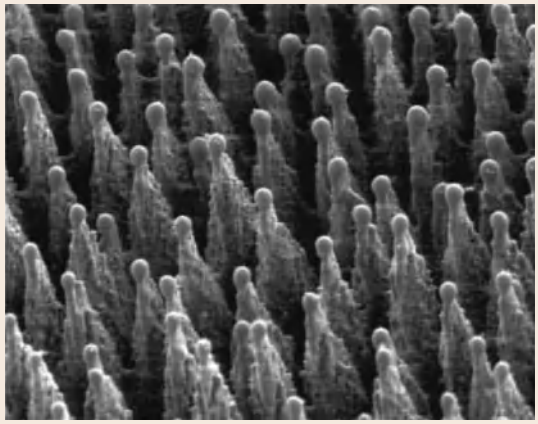

Fig. 9.25 Scanning electron micrographs of a silicon surface after irradiation with several hundreds of femtosecond laser pulses

forbidden zone and closer to the bottom of the conduction band [9.33]. Irradiating Si with ultra short laser pulses in saturated atmosphere of SF_6 allows Si doping with sulfur in a concentration higher than the thermodynamic solubility level, which promotes broadening of the sulfur energy states into a band underneath the bottom of the conduction zone of pure crystalline Si [9.29].

In addition to energy states introduced by sulfur impurities, the structural defects introduce infrared-absorbing states near the band edge. These energy states serve as trapping centers for photogenerated electron–hole pairs. Such band characteristics can explain the below-band-gap carrier generation observed in photodetectors made using black Si. In the microstructured photodetector, the photogenerated electrons and holes move in opposite directions under applied bias. For example, under reverse bias, photogenerated electrons move toward the microstructured Si surface and holes toward the Si substrate. The resulting photocurrent will persist until both carriers are collected at the electrodes, or until they recombine in the bulk of the semiconductor before reaching the respective contacts. In microstructured Si photodetectors operating in a photoconductive mode, the gain mechanism is most likely to be generation–recombination that originates from random carrier generation and recombination in the high density of impurities and structural defects in the microstructure layer. As for all photoconductors, high gain for black Si photodetectors is achieved at the cost of low bandwidth.

9.4 QWIP

QWIPs (quantum well infrared photodetectors) are efficient detectors for detection of infrared radiation. QWIP is a photoconductor and a unipolar device. QWIPs are fabricated by alternately growing thin layers of two different wide-band gap semiconductors. The band gap discontinuity of two materials creates quantized subbands in the potential wells associated with conduction bands or valence bands. Light absorption initiates electrons transition between the ground and first excited state subbands of multiquantum wells. The structure parameters are designed in the way that the photo-excited carriers can escape from the potential wells and be collected as photocurrent, which is facilitated by bending the bands in the external electric field. Depending on the QWIP structure, there can be three different types of electronic transitions: bound-to-bound, bound-to-continuum, and bound-to-miniband transitions (Fig. 9.26).

9.4.1 Structure and Fabrication of QWIPs

The lattice matched $GaAs/Al_xGa_{1-x}As$ material system is commonly used to create a QWIP structure such as that shown in Fig. 9.26. The quantum-well layers of GaAs have a typical thickness of 50–70 Å and are usually n-type doped to $\approx 10^{18}\,cm^{-3}$. The barrier layers AlGaAs are undoped and have a thickness in the range 300–500 Å. A typical number of periods is 20 through 50. By controlling the quantum well width and the barrier height (which depends on the Al molar ratio of $Al_xGa_{1-x}As$ alloy), the intersubband transition energy can be varied over a wide enough range to enable light detection at any wavelength range between 6–20 μm. The fabricated and experimentally investigated QWIPs can already cover a spectral range up to 35 μm. Other contemporary structures for QWIPs are InGaAs/InAlAs and InGaAs/InP

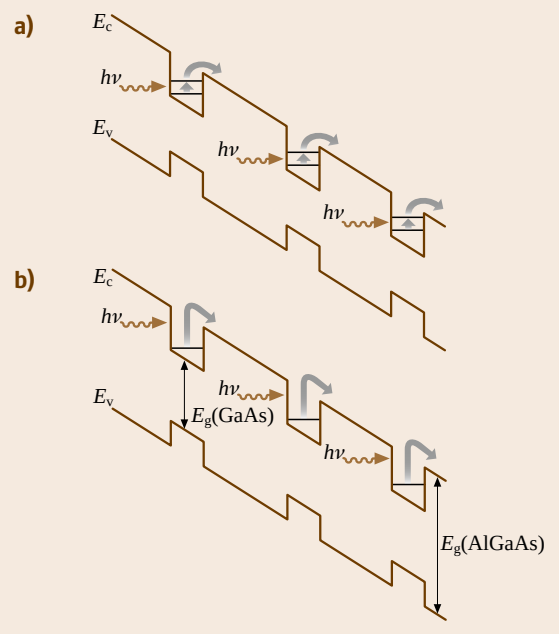

Fig. 9.26a,b Energy band diagram of QWIP under reverse bias showing **(a)** bound-to-bound transition and **(b)** bound-to-continuum transition

with the peak detection wavelengths of 4 and 8 μm, respectively.

9.4.2 QWIP Properties and Figures of Merit

Spectral Response

The spectral responsivity peak wavelength (λ_p) of a QWIP is determined by the energy difference between ground and excited states of the quantum well. Unlike the responsivity spectra of intrinsic infrared detectors, QWIPs spectra are much narrower and sharper due to their resonance inter-subband absorption. Typically, responsivity spectra of the bound and quasi-bound excited state QWIPs are much narrower ($\Delta\lambda/\lambda \approx 10\%$) than that the continuum QWIPs ($\Delta\lambda/\lambda = 24\%$). This is due to the fact that, when the excited state is placed in the continuum band above the barrier, the energy width associated with the state becomes wide. The spectral bandwidth of these QWIPs can be further increased by replacing single quantum wells with small superlattice structures (several quantum wells separated by thin barriers) in the multiquantum well structure. Such a scheme creates an excited state miniband due to overlap of the excited state wavefunctions of quantum wells.

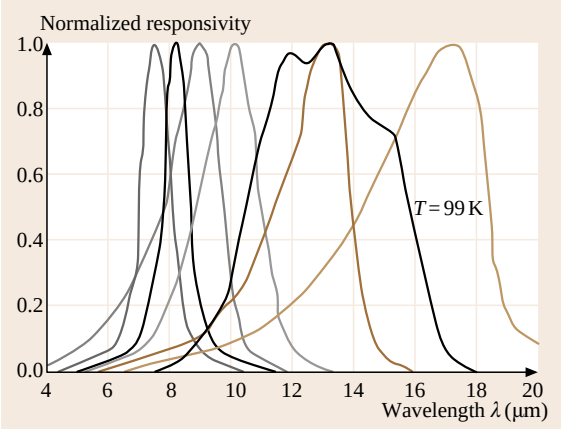

Fig. 9.27 Examples of the responsivity spectra for different GaAs/AlGaAs QWIP structures

Energy band calculations based on a two-band model shows excited state energy levels spreading greater than 30 meV. Figure 9.27 shows experimentally measured responsivity spectra with FWHM bandwidth $\Delta\lambda > 5$ μm. The broadest responsivity bandwidth demonstrated so far was $\Delta\lambda \approx 6$ μm.

Quantum Efficiency

The QWIPs photocurrent is given by the general expression used for photoconductors

$$I_p = q\Phi\eta_{ex}G\,, \tag{9.111}$$

where q is the elementary charge, Φ is the photon flux in reciprocal seconds, η_{ex} is the external quantum efficiency and G is the gain. The quantum efficiency is different from that of a regular photoconductor since in QWIPs, light absorption and carrier generation occurs only in the quantum wells, but not homogeneously throughout the structure [9.14]

$$\eta_{ex} = (1 - R_f)\left[1 - \exp\left(-N_p\alpha N_w L_w\right)\right] E_p P\,, \tag{9.112}$$

in which R_f is the front surface reflection, N_p is the number of optical passes, N_w is the number of quantum wells, L_w is the well length, E_p is the term that depends on the bias inside the quantum well, and P is the polarization correction factor.

The photoconductive gain G is similar to that of the standard photoconductor

$$G = \frac{\tau}{t} = \frac{(\tau\mu V)}{L^2}\,, \tag{9.113}$$

where V is the bias, τ is the minority carrier lifetime and t the transit time across the whole QWIP active length L, and μ is the minority carrier mobility. The right most part of (9.113) is written assuming the far from saturation field strength E, when the carrier drift velocity is given by $v_d = \mu E = \mu(V/L)$.

Photoconductive gain of QWIP depends on the device design. Typically it varies from 0.1 to 1. The photoconductive gain G higher than 1 is possible with QWIPs having fewer quantum wells.

Noise and Detectivity

The dominant noise in QWIP devices is due to the shot noise resulting from the total current in the device. There is no significant thermal noise in QWIPs because at the operating bias, the thermally assisted tunneling of carriers is not significant. To additionally decrease the thermal noise and limit the dark current, QWIP has to be operated at low temperature. In addition QWIP show remarkable noise stability, i. e. very low $1/f$ noise, enabling long integration times.

QWIP is a type of photodetector with the background-limited performance (BLIP), when the detector performance is limited by the photon generated noise. Signal-to-noise ratio, detectivity, etc. are independent of photoconductive gain when QWIPs operate under background limited condition.

9.4.3 QWIP Applications

There are many ground-based and space borne applications that require long-wavelength, large, uniform, reproducible, low cost, low $1/f$ noise, low power dissipation, and radiation hard infrared focal plane arrays built employing QWIPs [9.34]. For example, the absorption lines of many gas molecules, such as ozone, water, carbon monoxide, carbon dioxide, and nitrous oxide occur in the wavelength region from 3 to 18 μm. Thus, infrared imaging systems that operate in the long-wavelength IR (LWIR) region are required in many space applications such as monitoring global weather profiles, earth resource mapping, de-forestation, and the distribution of minor constituents in the atmosphere. In addition, there is a great astronomical interest in these very long-wavelengths due to the fact that this spectral region is rich in information vital to the understanding of composition, structure and the energy balance of molecular clouds and stars forming regions of galaxies.

9.5 QDIP

The quantum-dot infrared photodetector (QDIP) is similar to QWIP except that the potential well is created by a quantum dot instead of a quantum well. In QDIP, the active structure physical dimensions are reduced to the de Broglie wavelength, which enhances greatly the degree of carrier confinement. As a result, the spectral response can be controlled even more precisely than with QWIP structures. In addition, the noise characteristics and detectivity of QDIP can potentially be dramatically improved in comparison with those of QWIP structures.

9.5.1 Structure and Fabrication of QDIPs

There are two basic structures for QDIPs, one with photo-generated carriers traveling perpendicular to the quantum dot planes, the other parallel to the planes (Fig. 9.28). The technique for forming quantum dots

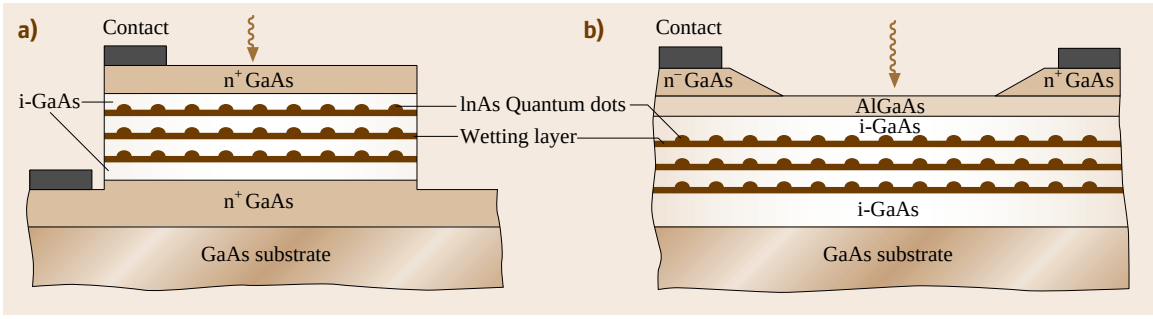

Fig. 9.28a,b Schematic cross sectional structure of QDIP. The photocurrent flows either **(a)** perpendicular or **(b)** parallel to the quantum dot planes

has been improved dramatically with an epitaxial synthesis process called the Stranski–Krastanow growth mode [9.35, 36]. The typical structures employ InAs dots on GaAs, InGaAs dots on GaAs, and SiGe dots on Si. As an example, the QDIP structure can be formed as a combination of InAs islands on GaAs substrate. With an optimum layer thickness of roughly two monolayers (≈ 6 Å), the InAs film nucleates into the array of islands (dots) to release the stress. The typical dimensions of dots are ≥ 150 Å at the base and ≥ 30 Å in height. The density of the array is in the range 10^{10}–$10^{11}\,\mathrm{cm}^{-2}$. An ultra thin residual wetting layer is usually left underneath the quantum dots.

The doping level in quantum dots is tuned to provide up to five electrons per dot. Alternatively, the dots can be intrinsic but electrons can be introduced by modulation doping of the incorporated delta-doped layer, from which electrons are injected and trapped within the potential well of the quantum dot. The delta-doped layers are fully depleted and they do not contribute to the dark current.

To improve light absorption, the quantum dot layers are repeated in many periods. The thickness of the intrinsic barrier layers is typically within the range from 100 to 500 Å.

The photocurrent of QDIP can be qualitatively described with (9.111) as QWIP photocurrent.

9.6 Metal–Semiconductor (Schottky Barrier) and Metal–Semiconductor–Metal Photodiodes

When metal contacts a semiconductor, a Schottky barrier results. Schottky-barrier photodiodes can operate in two different detection modes. In one of them electron–hole generation occurs from band-to-band excitation of the semiconductor, in the second mode the carriers are emitted from metal to the semiconductor over the Schottky barrier. In the front-illuminated version, which is advantageous for the first operation mode, the metal layer forming the Schottky barrier is very thin (less than ≈ 150 Å), thus allowing more photons to reach the semiconductor bulk. For detectors using the second operation mode, the backside (through the substrate) illumination is more efficient since the barrier height $q\varphi_{bn}$ is always smaller than the energy gap E_g and the infrared quanta with $q\varphi_{bn} < h\nu < E_g$ are not absorbed in the semiconductor.

9.6.1 Schottky-Barrier Photodiode Properties

Figure 9.29 shows the energy-band diagram for a Schottky diode schematically. The metal work function φ_m is usually different from the semiconductor work function φ_S. The necessary conditions to produce the useful barrier for the electrons in an n-type semiconductor–metal contact is $\varphi_m > \varphi_S$. The barrier height value

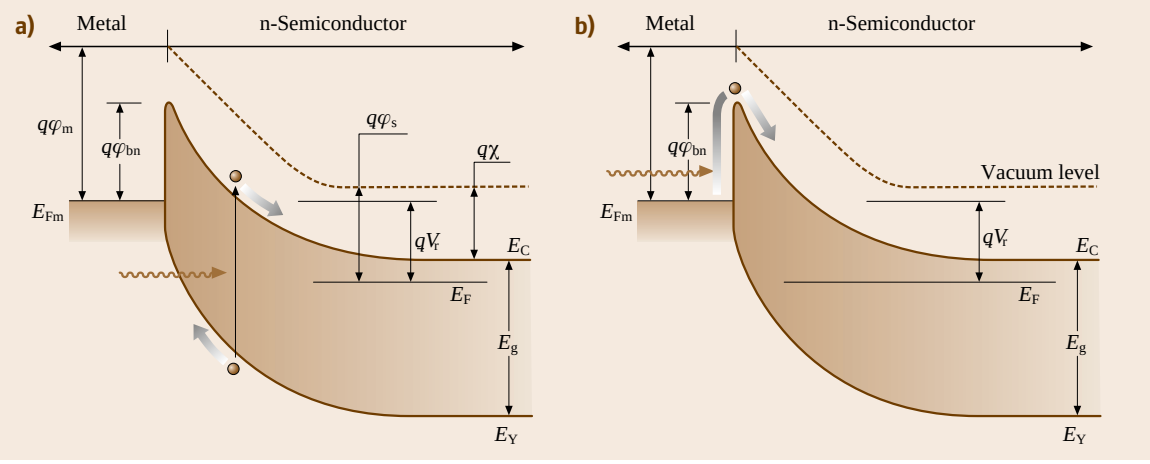

Fig. 9.29a,b Energy band diagram for the Schottky-barrier photodiode under reverse bias V_r with **(a)** band-to-band excitation and **(b)** intrinsic photoelectron emission

is

$$q\varphi_{bn} = q\,(\varphi_m - \chi)\ , \tag{9.114}$$

where $q\chi$ is the semiconductor electron affinity.

Dark Current and Photocurrent

Metal–semiconductor junctions have properties similar to those of the p-n junction. In particular, the dark conditions I–V characteristic follows the exponential dependence of I on V for forward bias, and saturates at a constant value on reverse bias

$$J_{dark} = J_s\left[\exp\left(\frac{qV}{kT}\right) - 1\right]\ , \tag{9.115}$$

in which the saturation current is

$$J_s = A_R T^2 \exp\left(\frac{-q\varphi_{bn}}{kT}\right)\ , \tag{9.116}$$

and A_R is the Richardson constant specific for each semiconductor. The major source of the dark current in Schottky-barrier photodiodes is known to be thermionic emission of majority carriers.

In either mode of operation, the photocurrent of a Schottky-barrier photodiode is given by

$$I_p = (1 - R_\Sigma)\, q\Phi\eta_{in}\ , \tag{9.117}$$

where R_Σ accounts for both the front side reflection of light and absorption by the metal film, η_{in} is the internal quantum efficiency, and Φ is the incident photon flux (in quanta per second).

Quantum Efficiency

For the case of band-to-band excitation, the internal quantum efficiency of an n-type Schottky-barrier photodiode is similar to that of the p-i-n photodiode and can be written as

$$\eta_{in} = 1 - \frac{\exp(-\alpha w)}{1 + \alpha L_p}\ , \tag{9.118}$$

where α is the absorption coefficient, w is the depletion width, and L_p is the holes diffusion length.

For the intrinsic photoemission, the process of photocurrent generation is dependent on the incident quantum energy $h\nu$ and the internal quantum efficiency is given by [9.14]

$$\eta_{in} = C_F \frac{(h\nu - q\varphi_{bn})^2}{h\nu}\ , \tag{9.119}$$

in which C_F is the so-called Fowler emission coefficient.

The Schottky-barrier photodiodes do not perform as well as p-n or p-i-n photodiodes; however, they can be advantageous for the wavelength range, where the semiconductor absorption coefficient is very high ($> 10^4\,cm^{-1}$) and most absorption of light occurs in a thin surface layer of the photodiode [9.37]. In a regular p/n structure, the non-equilibrium carrier collection efficiency is very low close to the surface because of a pronounced surface charge recombination. If a metal replaces the p semiconductor, the surface recombination–generation becomes much less pronounced or disappears completely, increasing the carrier collection efficiency in the metal–semiconductor depletion layer.

The Schottky-barrier photodiodes working in the second operation mode also proved to be very useful for the infrared light detection, which allowed building efficient Schottky-barrier focal plane arrays [9.38–40]. Another advantage of the Schottky-barrier photodiodes is their high speed of operation.

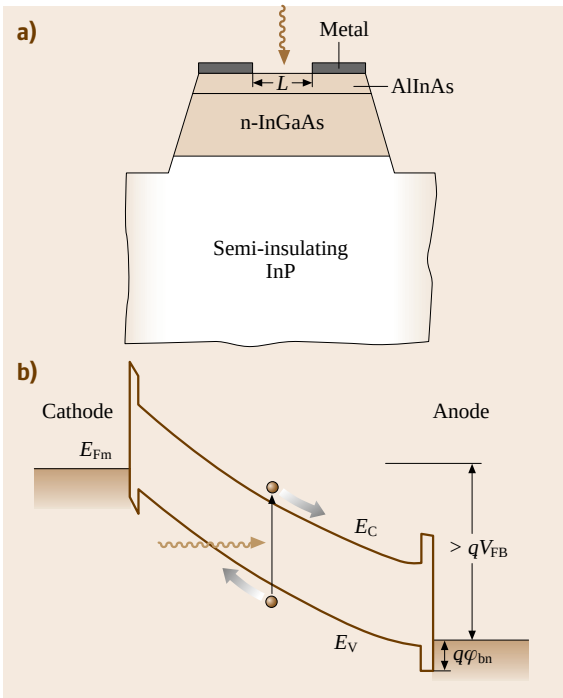

Fig. 9.30 (**a**) Cross section of the MSM mesa structure photodiode. (**b**) The energy-band diagram of the MSM photodiode under bias beyond flat-band. The barrier increase due to the barrier-enhancement layer is shown

9.6.2 Metal–Semiconductor–Metal (MSM) Photodiode

The MSM photodetector may be considered as two Schottky barriers connected back to back (Fig. 9.30a). For compound semiconductors, the thin light absorption layer (n-InGaAs in Fig. 9.30a) is deposited on a semi-insulating substrate. A barrier-enhancement layer AlInAs with a thickness of several tens of nanometers may be deposited between the metal and absorption layer to decrease the dark current of a narrow band gap semiconductor forming the absorption layer. The barrier enhancement layer fabricated with the wide energy gap semiconductor makes the barrier height much larger (Fig. 9.30b).

Applying bias of any polarity to an MSM photodetector puts one Schottky barrier in the forward direction and the other in the reverse direction. The dark current of MSM photodetector consists of both electron and hole current components and the saturation current has the form [9.41]

$$J_s = A_{Rn}T^2 \exp\left(\frac{-q\varphi_{bn}}{kT}\right) + A_{Rp}T^2 \exp\left(\frac{-q\varphi_{bp}}{kT}\right), \quad (9.120)$$

where A_{Rn}, A_{Rp} are the Richardson constants and φ_{bn}, φ_{bp} are the barrier heights at the cathode and anode side, respectively (Fig. 9.30b).

The photocurrent first rises with bias and then becomes saturated, indicating that the punch-through (complete depletion of the structure) is reached. The saturation voltage corresponds to the flat-band conditions, in which the electric field at the anode becomes zero.

The MSM photodetectors are advantageous in applications where a very low capacitance is required. The other important advantage of MSM structures is their compatibility with field effect transistor (FET) technology.

9.7 Detectors with Intrinsic Amplification

9.7.1 Avalanche Photodiodes (APD)

An APD can be considered as a family of p-n junction photodiode working in a photoconductive mode and capable of supporting high reverse bias. Upon generating electron–hole (e–h) pair by photon absorption, the electron and/or hole can accelerate in the electric field and gain sufficient kinetic energy to collide with the atoms of the crystal ionizing them. The primary carriers and the products of such impact ionization can accelerate again creating more non-equilibrium electron–hole pairs. Under favorable conditions, multiple collisions can create an avalanche-type increase of output current. Hence, the avalanche photodiode could be considered as a photoconductor. It can work in either a linear or non-linear mode.

In the avalanche regime, each absorbed photon creates on average a finite number M of e–h pairs. The typical internal gain is tens to hundreds in a linear mode when the photocurrent is proportional to the incident optical flux.

At high reverse bias, the rate of non-equilibrium carriers' extraction on the electrodes falls back the impact ionization rate, which produces a highly non-linear mode of APD operation – the avalanche breakdown. The population of non-equilibrium carriers in the high-field region and associated photocurrent grow exponentially in time. This growth continues until the voltage drop across the series resistance reduces the voltage drop across the photodiode high-field region, slowing down the avalanche and ultimately stopping it. Since the avalanche breakdown is not a destructive effect and is stable against thermal runaway, the above non-linear mode of operation has found many practical applications and has a specific name – the Geiger mode. High performance Geiger mode APDs can work in a single photon counting regime [9.42]. Recent advances in semiconductor technology led to development of a new type of solid state detector based on the Geiger mode avalanche effect in silicon–solid state photomultipliers, or silicon photomultipliers (SiPM) (Sect. 9.7.4).

The noise current of an APD has an additional term that goes beyond a simple scaling up by a factor of M of the photocurrent that would flow in a regular photodiode. The origin of the additional noise is in the statistic (and stochastic) nature of the multiplication process. The gain fluctuation produces excess noise, which becomes progressively worse as the average gain M of a diode is increased by raising the reverse bias. When the multiplication noise exceeds the noise introduced by downstream circuitry, a further increase in gain deteriorates the system signal-to-noise ratio.

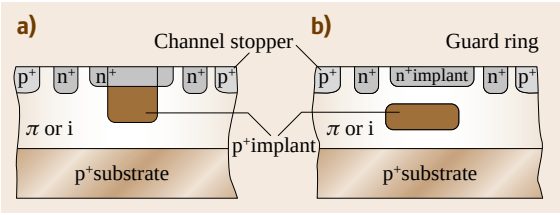

Fig. 9.31 (a) Cross section of a typical reach-through APD structures with separated absorption and multiplication regions. An intrinsic (or π) layer that separates n^+ implant and p^+ implant in the structure of panel (b) improves greatly the photo response uniformity and noise characteristics of APD

Figure 9.31 shows typical APD structures most commonly employed in practice. The starting material is chosen either n-type or p-type conductivity using the maximum value of the minority carrier impact ionization rate as a criteria. For Si, the electron ionization rate is much higher than that for the holes; hence, p-type material is used to build Si APDs.

The diode is fabricated by ion implantation of n-type and p-type dopants. The structure that results, rather than being a simple p-n diode, is either p-π-p-n (Fig. 9.31a) or p-π-p-π-n (Fig. 9.31b). Here π denotes very lightly – close to intrinsic – p-doped region. A thin layer of lightly π doped material between the top n electrode and highly doped p region in Fig. 9.31b improves the APD noise, response speed and uniformity, and quantum efficiency in comparison with the structure shown in Fig. 9.31a. Both structures in Fig. 9.31 have the absorption region separated from the multiplication layer. These structures are also called reach-through structures, because the electric field extends all the way from the n/p(π) junction and reaches the p layer. The lower π layer is where the photons are absorbed for either the front or back illuminated structures. Reverse biasing at the proper operating voltage establishes a modest electric field in this photon absorption layer that causes the photoelectron to drift up into the upper p layer. The field in that layer (sometimes it is called p-well) is much stronger, sufficient to cause impact ionization that initiates an avalanche. The photoelectron and the secondary electrons are collected at the top n layer, and the photohole and secondary holes are collected at the substrate.

Note that the p-well exists only in the central portion of the APD. Because of the absence of a p implant the diode's peripheral portion is a simple p-i-n structure, in which the field is intermediate in strength between the photon-absorption region and the avalanche region. This peripheral diode serves as a guard ring that performs two functions. First, it tailors the electric-field profile so that avalanche breakdown occurs in the central portion of the diode, not at the periphery. Second, it ensures that electrons generated outside the region directly under the p implant do not drift to the avalanche region, but are collected in the peripheral portion of the n layer without being able to start an avalanche. This collection minimizes the volume from which dark current is multiplied, and therefore minimizes the dark count rate.

9.7.2 Main Characteristics and Figures of Merit of APD

Ionization Rates

The electron and hole ionization rates, α_n and α_p, respectively, are defined as the number of ionizing collisions per unit distance. The ionization rates depend strongly (exponentially) on the threshold electric fields to overcome different carrier scattering effects. The examples of the experimental ionization rates (coefficients) at 300 K for Si, Ge, GaAs, and GaP versus electric field are given in Fig. 9.32. The ionization rates can be equal for electrons and holes, as for GaP, or can significantly differ from each other as for the case of Si, Ge, and most of the compound semiconductors.

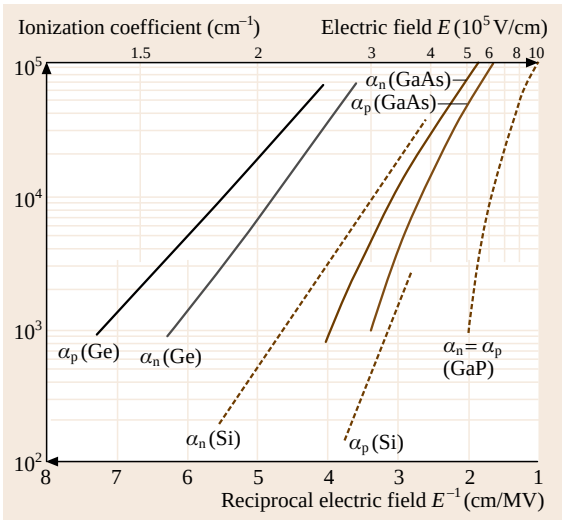

Fig. 9.32 Ionization coefficients for electrons and holes in a number of semiconductors

Avalanche Gain

The multiplication factor M is defined as the ratio of the number of carriers leaving the avalanche region to that entering it. Since the ionization rates are strongly dependent on the electric field, which is usually position-dependent, it appears to be almost impossible to explicitly calculate the avalanche gain for any real structure. However, the reasonable estimations may be made for some practically important cases [9.1, 6, 43].

The low-frequency gain for the electrons/holes is given by

$$M_{\mathrm{n,p}} = \left\{1 - \int_0^L \alpha_{\mathrm{n,p}} \exp\left[-\int_x^L (\alpha_{\mathrm{n,p}} - \alpha_{\mathrm{p,n}})\,\mathrm{d}x'\right]\mathrm{d}x\right\}^{-1}, \tag{9.121}$$

where L is the high-field layer width. This expression is simplified for position-independent ionization coefficients, which for the case of the electron current gain yields

$$M_{\mathrm{n}} = \frac{(1-\alpha_{\mathrm{p}}/\alpha_{\mathrm{n}})\exp\left[\alpha_{\mathrm{n}}L\,(1-\alpha_{\mathrm{p}}/\alpha_{\mathrm{n}})\right]}{1-(\alpha_{\mathrm{p}}/\alpha_{\mathrm{n}})\exp\left[\alpha_{\mathrm{n}}L\,(1-\alpha_{\mathrm{p}}/\alpha_{\mathrm{n}})\right]}\,. \tag{9.122}$$

For equal, position-dependent ionization rates ($\alpha_{\mathrm{n}} = \alpha_{\mathrm{p}} = \alpha(x)$)

$$M_{\mathrm{p}} = M_{\mathrm{n}} = \left(1 - \int_0^L \alpha(x)\,\mathrm{d}x\right)^{-1}, \tag{9.123}$$

from which we can conclude that the avalanche breakdown ($M_{\mathrm{n,p}} \to \infty$) corresponds to the case $\alpha_{\mathrm{n,p}}L \to 1$.

The maximum achievable multiplication is limited by the series resistance and space charge effect. Combining these two factors into a single equivalent series resistance R, the multiplication of photogenerated carriers' M_{ph} dependence on the reverse bias V and breakdown voltage V_{B} can be empirically described as [9.6]

$$M_{\mathrm{ph}} = \frac{I - I_{\mathrm{MD}}}{I_{\mathrm{p}} - I_{\mathrm{D}}} = \left[1 - \left(\frac{V - \mathrm{IR}}{V_{\mathrm{B}}}\right)^{\gamma}\right]^{-1}, \tag{9.124}$$

where I_{p} and I are the total primary and multiplied currents, and I_{D} and I_{MD} are the primary and multiplied dark currents, respectively. The exponent γ depends on the semiconductor material, doping profile, and wavelength, and it is usually in the range 3–6 [9.14]. For the relatively high light intensity $I_{\mathrm{p}} \gg I_{\mathrm{D}}$ and low parasitic losses $\mathrm{IR} \ll V_{\mathrm{B}}$, the maximum value of M_{ph} is given by

$$M_{\mathrm{ph}}^{\max} \approx \frac{V_{\mathrm{B}}}{\gamma I_{\mathrm{p}} R}\,. \tag{9.125}$$

For the case of small photocurrent, $I_{\mathrm{p}} \ll I_{\mathrm{D}}$, the maximum avalanche multiplication is

$$M_{\mathrm{ph}}^{\max} \approx \frac{V_{\mathrm{B}}}{\gamma I_{\mathrm{D}} R}\,, \tag{9.126}$$

which means that a high dark current limits the maximum multiplication.

Excess Noise Factor

Due to the statistical nature of the avalanche gain, the mean-square value $\overline{M^2}$ of the gain M is larger than the square M^2 of the mean value. The shot noise of any photodiode is determined by the statistics of the non-equilibrium carriers, electrons, and holes. For the p-i-n photodiode, each event of the non-equilibrium carrier generation creates one electron and one hole only, whereas for every incident photocarrier in the multiplying region of APD three non-equilibrium particles are present: one primary carrier and two newly created secondary carriers. If the noise spectral density in the total primary current I_{p} is $2qI_{\mathrm{p}}$, the noise spectral density in the total multiplied current $I = I_{\mathrm{p}}M$ can be written as

$$i_{\mathrm{sh}}^2 = 2qI_{\mathrm{p}}\overline{M^2} = 2qI_{\mathrm{p}}M^2F(M)\,, \tag{9.127}$$

where we put the frequency bandwidth $\Delta f = 1$ and introduced the *excess noise factor* $F(M) = \overline{M^2}/M^2$, which is the ratio of the actual noise to that which would exist if the multiplication process were noiseless.

Since the excess noise depends strongly on the total number of the secondary carriers, its value is large when the electron and hole ionization rates, α_{n} and α_{p}, are close to each other. In the case when either $\alpha_{\mathrm{n}} \gg \alpha_{\mathrm{p}}$ or $\alpha_{\mathrm{n}} \ll \alpha_{\mathrm{p}}$ the excess noise becomes smaller. For the constant throughout the avalanche region ratio $\alpha_{\mathrm{n}}/\alpha_{\mathrm{p}}$, the excess noise can be approximated with [9.44]

$$F(M) = k_{\mathrm{i}}M + \left(2 - \frac{1}{M}\right)(1 - k_{\mathrm{i}})\,, \tag{9.128}$$

in which $k_{\mathrm{i}} = \alpha_{\mathrm{p}}/\alpha_{\mathrm{n}}$ for the case of electron injection alone and $k_{\mathrm{i}} = \alpha_{\mathrm{n}}/\alpha_{\mathrm{p}}$ for the hole injection.

Signal-to-Noise Ratio

The thermal noise in an APD is the same as for the p-i-n photodiode and is given by (9.93). The APD's shot

noise spectral density is given by (9.127). The signal-to-noise ratio for avalanche photodiode is then

$$\mathrm{S/N} = \frac{I_\mathrm{s}}{i_\mathrm{n}} \equiv \frac{I - I_\mathrm{MD}}{i_\mathrm{n}} = \frac{1/\sqrt{2}\left(q\eta_\mathrm{ex}\Phi_\mathrm{p}/h\nu\right)M}{\left\{2q\left[I'_\mathrm{D} + I_\mathrm{p}F(M)M^2\Delta f\right] + 4kT\Delta f/R\right\}^{1/2}}, \tag{9.129}$$

where I_s and i_n are the average output photocurrent and rms noise current, respectively, I is the total multiplied current, I_MD is the multiplied dark current, I_p is the total primary current which is multiplied, I'_D is that component of the dark current (usually the surface leakage current) which is not multiplied, Δf is the noise bandwidth, Φ_p is the incident optical power, and η_ex is the external quantum efficiency.

Noise Equivalent Power

Equation (9.129) can be solved for the optical power required to produce the signal-to-noise ratio equal to 1,

$$\mathrm{NEP} = \frac{\sqrt{2}h\nu}{\eta_\mathrm{ex}}\left(\frac{I_\mathrm{p}F(M)\Delta f}{q} + \frac{2I_0\Delta f}{q}\right)^{1/2}, \tag{9.130}$$

in which

$$I_0 = I_\mathrm{D}F(M) + \frac{2kT}{qRM^2} \tag{9.131}$$

is an equivalent current, similar to that introduced in (9.17).

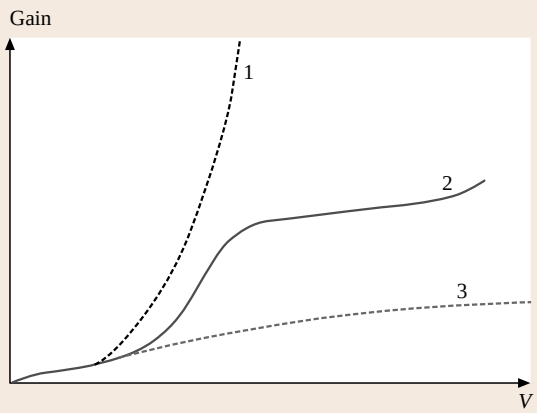

Fig. 9.33 Gain–voltage characteristics of APD at different stages of processing as described in the text

For the case when the thermal noise dominates, the APD sensitivity is determined by

$$S_0 = \mathrm{NEP} = \frac{2h\nu}{q\eta_\mathrm{ex}M}\sqrt{\frac{kT\Delta f}{R}}, \tag{9.132}$$

which indicates that the APD sensitivity threshold is substantially reduced (by the factor of M) due to the avalanche effect.

For the case of the photon-limited performance NEP value is given by

$$\mathrm{NEP}^{\mathrm{B,S}} = \sqrt{2}h\nu\sqrt{\frac{\Phi^{\mathrm{B,S}}\Delta f}{\eta_\mathrm{ex}}F(M)M^2}, \tag{9.133}$$

indicating that for the high signals the noise grows simultaneously with the signal thus limiting the APD performance. The superscripts B,S in (9.133) correspond to either the signal-limited or background-limited characteristics.

Gain–Voltage Characteristics

The three general gain-voltage characteristics that can occur are shown in Fig. 9.33. For example, for the APD structure of Fig. 9.30a, if the top diffusion (n-type implant in Fig. 9.31a) has not been adequately completed so that the implant concentration in the multiplication region (p-well) and the width of that region facilitate the avalanche breakdown prior reach-through is achieved, the case shown by curve 1 in Fig. 9.33 is realized. This case describes a non-optimal operating condition, because the avalanche breakdown is attained before the photodiode intrinsic layer is completely depleted. In this case, the gain becomes very high even at a relatively low bias, and the excess noise factor progressively increases with voltage. Curve 2 in Fig. 9.33 describes the desired conditions where reach-through occurs at the intermediate gain levels of 10 to 20. A further increase in the bias value increases gradually the gain without deteriorating the noise and detectivity performance. Curve 3 describes the other extreme case where the top implant (e.g. n-type implant in Fig. 9.31a) diffused too far, so that the useful gain would be achieved at excessively high voltages. Similar situations can occur for the APD structure shown in Fig. 9.31b; however, for that type of structure the p^+ implant parameters will control the APD behavior.

Figure 9.34 presents an example of the universal gain-voltage curves for the reach-through APD. For the constant bias, the lower the temperature the higher the ionization rates for electrons and holes; hence, the gain is also higher. The curves in Fig. 9.34 can be applied to

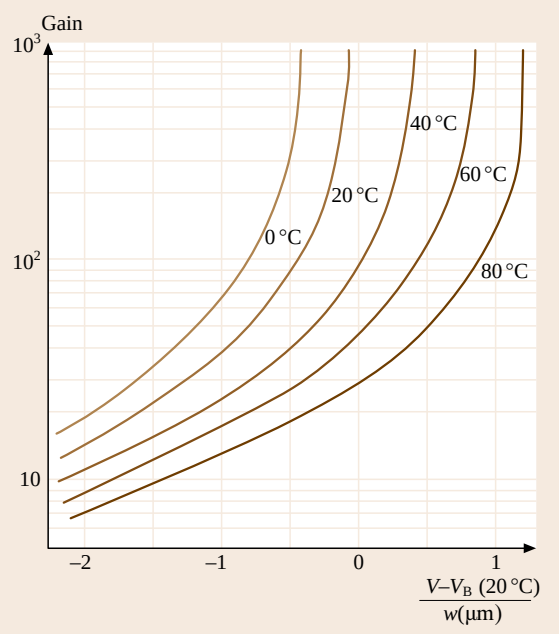

Fig. 9.34 Universal gain–voltage characteristics for the reach-through APD. The applied reverse bias V and breakdown voltage at 20 °C, V_B (20 °C) are in volts, the depletion width w is in microns

the given reach-through structure independently of the absorption and avalanche layers' thickness and room-temperature breakdown voltage V_B.

9.7.3 Materials to Fabricate APDs

The following materials have proved to be appropriate to fabricate high performance APDs.

- Silicon: for the spectral range 400 through 1100 nm. Both the front illuminated and backlit structures are employed. The electrons ionization rate is much higher than that for the holes ($\alpha_n \gg \alpha_p$).
- Germanium: for the wavelengths of up to 1.65 μm. However, since the band gap in Ge is lower than in Si, and the ionization rates for electrons and holes are approximately equal ($\alpha_n \approx \alpha_p$), the noise is considerably higher and limits the Ge-based APDs application.
- GaAs-based devices: most compound materials have $\alpha_n \approx \alpha_p$, so that the designers usually use the heterostructures like GaAs/$Al_{0.45}Ga_{0.55}As$, for which α_n(GaAs) $\gg \alpha_n$(AlGaAs). The large increase in gain occurs due to the avalanche effect in GaAs layers. GaAs/$Al_{0.45}Ga_{0.55}As$ structures are used below 0.9 μm. Applying InGaAs layers allows to extend the sensitivity range to ≈ 1.4 μm.
- InP-based devices: for the wavelength range 1.2–1.6 μm. The example is the double heterostructure with lattice matched layers n^+-InP/n-GaInAsP/p-GaInAsP/p^+-InP, in which either of carriers may be preferentially injected into the high field region, essential for low noise operation. The other example is APD with separated absorption and multiplication regions p^+-InP/n-InP/n-InGaAsP/n^+-InP, which is similar to the Si reach through devices shown in Fig. 9.31. The absorption occurs in the relatively wide InGaAsP layers and avalanche multiplication of the minority carriers proceeds in the n-InP layer (Fig. 9.35).

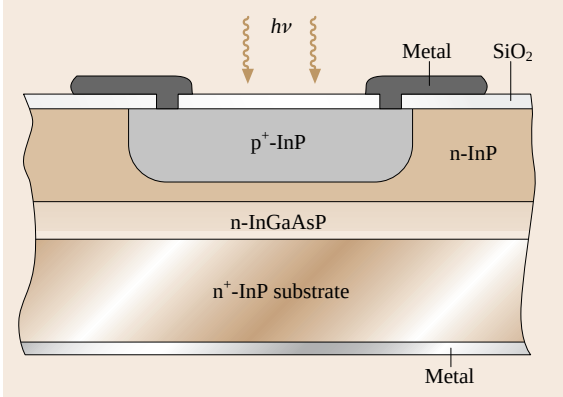

Fig. 9.35 Cross section of a typical APD structure based on III–V compounds

9.7.4 SiPM

A novel type of avalanche photodetector with Geiger mode operation, known as silicon photomultiplier (SiPM) or multipixel photon counter was developed recently by several groups [9.45–48]. A silicon photomultiplier is an array of microcell avalanche photodiodes operating in the Geiger mode. A typical SiPM may contain several hundred to thousands of microcells coupled to a common signal output terminal. The number of microcells defines the photon-counting dynamic range of SiPM. In each microcell, an arriving photon can trigger an avalanche flow of carriers, leaving the surrounding cells untriggered and ready to record other arriving photons. One possible way to quench the avalanche breakdown in the microcell is to use a resistor which

limits the current through the junction. This so-called passive quenching is applied in SiPMs. The quenching resistors are usually integrated in SiPM structure as either the regions of doped Si substrate or polysilicon layers. The output signal of the SiPM is the analog sum of all individual cell signals. In applications where the number of photons incident on the SiPM per event is much smaller than the number of microcells the output signal is proportional to the number of photons.

Typical Structure of SiPM

A typical SiPM consists up to 5000 Geiger-mode microcells located on a common silicon substrate having an area of 1–25 mm^2 with a common anode (Fig. 9.36). The front surface (aluminum layer) of each microcell is connected to the power supply that creates the electrical field inside the active p-n junction. The microcells are electrically decoupled from each other through individual polysilicon resistors (resistive layer). The voltage is adjusted to a value that operates each microcell in the Geiger mode when triggered by an incoming photon. In practice, the applied voltage is 15–20% higher than the breakdown voltage of the APD, which is typically in the range of several tens of volts at room temperature.

Crosstalk

An important feature of any SiPM is trenches blocking optical and partially electrical crosstalk between microcells. While the electrical crosstalk in SiPM has the same origin (carrier lateral diffusion and drift) as in any other multielement array, the optical crosstalk has a pronounced component that specific to arrays of APDs (including SiPM) only. Experimental and theoretical studies of photon emission from avalanche region at breakdown conditions in p/n junction devices proposed originally two mechanisms to explain this phenomenon: bremsstrahlung process, where the necessary momentum is supplied by a charged impurity center [9.49] and recombination of free electrons and holes in the avalanche region [9.50]. However, most recent comprehensive investigations ruled out the two above effects and suggested direct and phonon-assisted intra-conduction-band transitions as the main reasons for the observed emission of hot carriers in avalanche region [9.51–53].

Crosstalk is an inhibiting parameter in the performance of SiPMs. During the avalanche process in silicon, secondary photons are generated at a probability of around 10^{-5} photons/electron. These photons can be captured by neighboring microcells, which can then be triggered to fire as well. The triggering of neighboring cells can even spread in a chain reaction, degrading the amplitude resolution of a signal and contributing heavily to the noise figure of a SiPM (typically the noise figure is around 1.6 to 1.7). Currently available SiPM designs with blocking trenches between microcells allow efficient suppressing of optical crosstalk by several orders of magnitude.

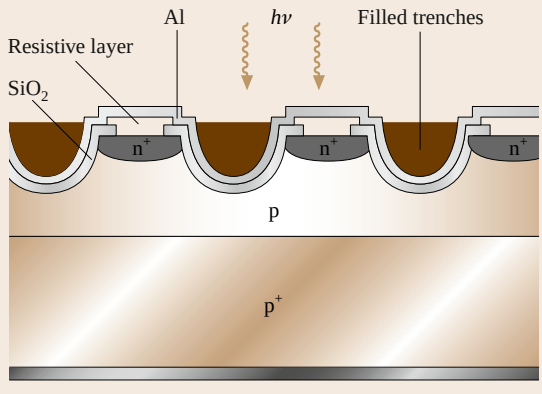

Fig. 9.36 Typical structure of SiPM with filled trenches between micropixels. The active region of each micropixel is shown with n^+ feature

Gain and Dark Current

The typical gain of a SiPM is 10^6, providing a signal of a few millivolts over a 50 Ω load resistor for a single photoelectron. One can consider single microcells as tiny charged capacitors (with a typical capacitance of 0.1–0.3 pF), which at the beginning are charged to the level of the power supply via the resistors. An incident photon initiates a Geiger avalanche process that starts to discharge the capacitor until it arrives at the breakdown voltage. Because all microcells have an identical topology, they have the same capacitance and therefore, for a given overvoltage, they provide the same fixed gain. This implies that, once fired, independent of the number of incident photons, any given microcell will produce the same charge at the anode. The charges produced from individual cells will instantly sum in the common anode. The total summed charge would be proportional to the number of fired cells. The waveform in Fig. 9.37 shows a typical SiPM single photoelectron spectrum from a low light level source. Well-resolved single peaks indicate a large signal-to-noise ratio of the SiPM used. The width of the single photoelectron peaks is a combination of the system noise, as represented by the pedestal, the statistical variation on the number of

electrons produced per avalanche (excess noise), which is very small, and the variations in the response of the different microcells. Any device instability would be indicated by decreased resolution.

The typical dark rate of a SiPM at room temperature is $1\,\mathrm{MHz/mm^2}$, which is at the same level as that for a single microcell. The electronics noise of SiPMs is negligibly small due to the very high gain, in contrast to standard APDs, where the gain is typically about 100. In SiPM, the level of electronics noise corresponds to less than 10% of the signal from one photoelectron. The main source of noise, which limits the SiPM's single photon resolution, is the dark rate, originating from charge carriers thermally created in the sensitive volume. The SiPM dark rate decreases with temperature from $\approx 1\,\mathrm{MHz/mm^2}$ (at room temperature) to $\approx 200\,\mathrm{Hz/mm^2}$ (at 100 K).

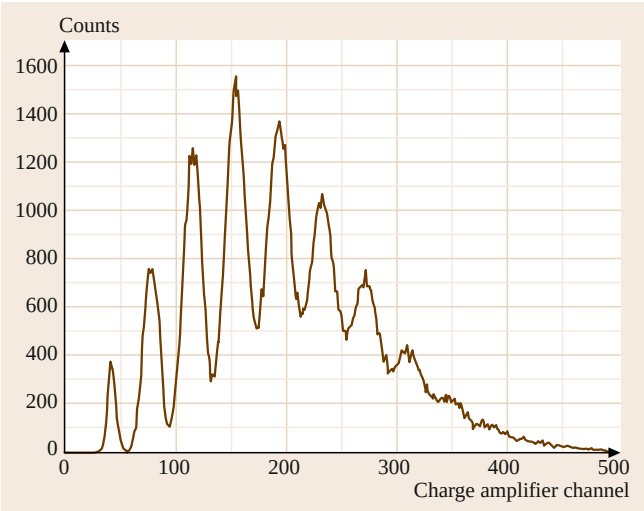

Fig. 9.37 Typical SiPM single photoelectron spectrum obtained using low intensity light source. The spectrum represents mean of four photoelectron. Each channel of the charge amplifier was equal to 0.1 pC

Detection Efficiency

As long as the number of instantly impinging photons is less than half the total number of microcells it can be assumed that a given microcell will be hit by one photon at a time only. Under this condition, the sensor output will depend linearly on the input light flux. The microcell recovery time is proportional to the product of the cell capacitance and the value of the individual decoupling resistor; this product is typically in the range of $0.1-1\,\mu\mathrm{s}$. While the cell is recovering (recharging), its Geiger efficiency increases toward its maximum value.

The overall conversion factor from impinging photons to the number of detectable photoelectrons is called photon detection efficiency (PDE). PDE is normally lower than quantum efficiency (QE) η. In addition, QE for SiPM is defined as a product of two factors: conventional quantum efficiency η and geometrical efficiency $\varepsilon_{\mathrm{Geom}}$, which is defined as a fraction of total SiPM area occupied by active pixels. The external QE of SiPM is

$$\eta_{\mathrm{ex}} = \varepsilon_{\mathrm{Geom}}\,(1-R_{\mathrm{F}})\left[1-\exp\left(-\alpha x\right)\right]\,, \qquad (9.134)$$

where α is the absorption coefficient, x the total absorption path length, and R_{F} the reflection coefficient.

The PDE of single photon detectors depends not only on the absorption efficiency and geometrical factor, but on a Geiger discharge triggering probability $\varepsilon_{\mathrm{Geiger}}$ as well

$$\mathrm{PDE} = \varepsilon_{\mathrm{Geiger}}\varepsilon_{\mathrm{Geom}}\,(1-R_{\mathrm{F}})\left[1-\exp\left(-\alpha x\right)\right]\,. \qquad (9.135)$$

In order to determine the PDE of SiPMs one should avoid commonly used methods in which a calibrated, monochromatic DC light source is compared with the sensor signal. The reason is because of the intrinsic features of the SiPM like rate effects, recovery time, and optical crosstalk.

The maximum achievable PDE of a SiPM is the product of the following factors: the geometrical efficiency, or the ratio of the light sensitive area of a single cell to its total area; the Geiger efficiency (this is a direct function of the applied overvoltage: 15–20% overvoltage can provide efficiencies in the range close to 100%); wavelength-dependent transport of impinging photons into the sensitive volume of the SiPM; and the intrinsic QE of Si. Typical SiPMs can achieve a peak PDE of 50–60% in both the yellow-to-green and the blue-to-near-UV ranges.

Applications

Molecular imaging is among the main applications driving the growth of the SiPM technology to higher volumes and to higher specification levels. One advantage of SiPMs for molecular imaging is their immunity to magnetic fields, allowing the concurrent application of magnetic resonance tomography in a single system. The other key advantages over conventional photon counting detectors include two to three times higher photon-detection efficiency, low excess noise factor (close to 1), better time and amplitude resolution, a compact size, and an overall reduced system complexity.

Possible additional applications for SiPMs include dosimetry of ionizing radiation; communications detectors, including those for quantum cryptography; and safety and security systems. In research, SiPMs are applicable to a wide range of applications in astronomy and astrophysics, in biology and biochemistry, and in high-energy and particle physics; they are ideal devices to detect photons from scintillators and fibers.

9.8 Detectors with Intrinsic Amplification: Phototransistors

Like diodes, all transistors are light-sensitive. Phototransistors are designed specifically to take advantage of this fact. Phototransistors could be considered as a device with intrinsic amplification and it operates as a photoconductor.

Early phototransistors were made of Si and Ge. Most recent devices include III–V compounds, especially heterostructures like AlGaAs/GaAs, InP/InGaAs, CdS/Si, Cu_2Se/Si, and PbS/Si.

9.8.1 Photosensitive Bipolar Transistor

The most-common variant is an NPN bipolar transistor with an exposed base region. Here, light striking the base replaces what would ordinarily be voltage applied to the base – so, a phototransistor amplifies variations in non-equilibrium carrier density created by incident light. To optimize the light collection, the base-collector junction (the light collecting element) of the bipolar transistor is made as large as possible. While not required for operation of the device as a photodetector, a base connection is often provided allowing using base current to bias the transistor. The typical gain of a phototransistor can range from 100 to over 100 000. In its mode of operation, a photoelectric transistor, corresponds to that of a photodiode with a built-in amplifier. The cross-section of a homojunction bipolar phototransistor and its simplified equivalent circuit is shown in Fig. 9.38. The emitter and base leads are affixed laterally to make the base diode most easily accessible to light. The large collector zone ensures that the most possible radiation quanta are absorbed and will contribute to the photocurrent.

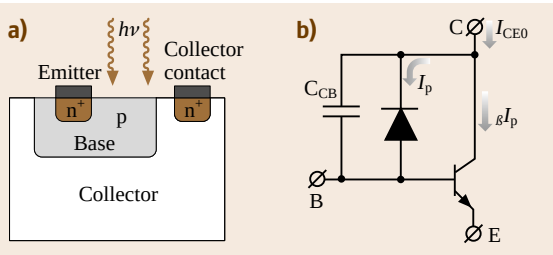

Fig. 9.38a,b The cross section **(a)** and simplifies equivalent circuit **(b)** of a homojunction bipolar phototransistor

Characteristics and Figures of Merit

In the dark, a small collector-emitter current flows due to the leakage current of the collector base junction I_{C0}. At illumination, the photogenerated carriers contribute to the photocurrent value I_p. In addition, the majority carriers generated in the base and those swept into the base region from the collector lower the base-emitter potential, allowing electrons to be injected across the base to the collector. Thus, the output (photo) current I of the phototransistor will be

$$I = I_{CEO} = (1 + h_{FE})\left(I_{C0} + I_p\right) , \tag{9.136}$$

with h_{FE} standing for the DC common-emitter current amplification (gain) and which indicates a photocurrent gain (and also the quantum efficiency gain) of $\beta = (1 + h_{FE})$. The output photocurrent I depends in a non-linear fashion on the incident radiation intensity, since the current gain β depends on the current. Figure 9.39 shows typical current-voltage characteristics of a phototransistor. These curves are similar to those of a conventional bipolar transistor with the base current replaced by photocurrent. Note that the photodiode dark current is also amplified by the same amount as the photocurrent.

Since the reverse current I_{C0} of the base diode is amplified in the same way as the photocurrent I_p the signal-to-noise ratio and noise equivalent power of the phototransistor is similar to that of the photodiode. For example, NEP can be written as

$$\mathrm{NEP} = \frac{\sqrt{2}h\nu}{\eta_{ex}}\sqrt{\frac{I_{eq}}{q}} , \tag{9.137}$$

with the equivalent current I_{eq}

$$I_{eq} = I_{CEO}\left(1 + \frac{2h_{fe}^2}{h_{FE}}\right) , \tag{9.138}$$

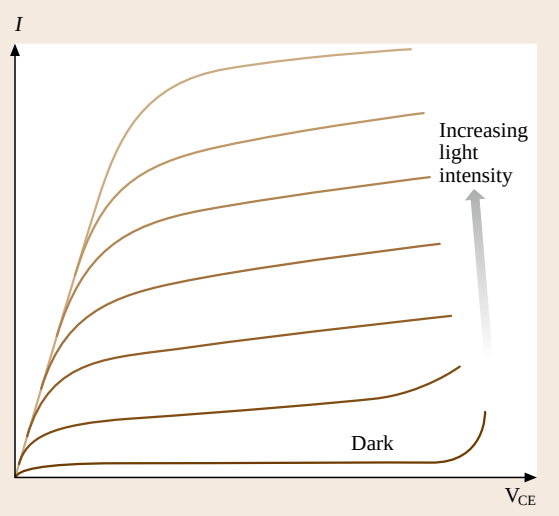

Fig. 9.39 *I–V* characteristics (output current versus collector–emitter bias) of a bipolar phototransistor under different level of the illumination intensity

where h_{fe} is the common-emitter AC current gain [9.6].

The operating point of the phototransistor may be preset by biasing the base leads, which controls both the speed and gain of the device. The speed of the phototransistor is limited by the base-to-emitter (C_{BE}) capacitance and is specified in terms of the rise time of the device. Since C_{BE} interacts mainly with the load resistor (R_L), the rise time is linearly dependent on R_L. Phototransistors are not as fast as photodiodes. A photodiode is, in fact, the input section of the phototransistor (collector-to-base section) without emitter and, therefore, does not suffer from the C_{BE} effect.

9.8.2 Darlington Phototransistor (Photo-Darlington)

Photo-Darlington is simply a cascaded pair of bipolar transistors (Fig. 9.40). One transistor in the pair serves as a primary photodetector while the other acts as an additional amplifier. The advantage of this design is higher amplification but the time response is pretty long (several tens of μs).

9.8.3 Field-Effect-Based Phototransistors

Examples of other types of phototransistors include the photosensitive field effect transistors like JFET, MESFET, and MOSFET. They employ different modes of operation, the simplest of which is based on photo-

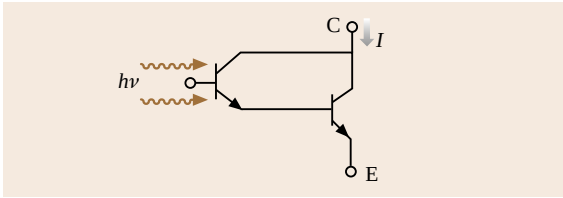

Fig. 9.40 A simplified schematic diagram of a Darlington phototransistor

conductivity, in which photo-generated excess carriers increase the conductivity of the channel. In the mode specific to JFET or MESFET the gate is not insulated and the gate-to-channel junction can be considered as a photodiode with the gate current as a primary photocurrent. For a MOSFET, the gate is insulated and different modes of operation can be suggested. For example, photo-generated carriers can be trapped at the surface of the semiconductor that changes the surface potential and induces a change in the channel current.

An interesting design uses the depleted field effect transistor structure (DEPFET) [9.10, 54]. It is based on the combination of the sideward depletion principle and the field effect transistor principle. In this structure, p-channel MOSFET is built on one side of the n-type wafer, whereas a p-n diode structure is created on the opposite side. Applying the reverse bias to the diode creates a depletion layer that propagates towards the MOSFET on the wafer front side. If the MOS gate is biased and an inversion layer is created on the oxide – semiconductor interface, then the potential minimum for the majority carriers (electrons) will be created in the bulk of the wafer, right underneath the MOSFET gate. Upon photo-generation of electron–hole pairs in the depleted bulk, the minority carriers (holes) will drift in the depleted region towards the diode p/n junction on the back surface of the structure while the majority carrier will be trapped in the potential well underneath the transistor p-channel. This trapped charge will induce the opposite polarity charge in the channel, thereby increasing its conductance and the transistor current.

The DEPFET structure is characterized with smaller overall capacitance thereby having potentially better noise performance than the photodiode coupled to the trans-impedance amplifier. The DEPFET structure allows controlling the amount of charge stored in the MOSFET gate region, thus providing the possibility of either multiple readouts of the stored information or clearing of that information.

9.9 Charge Transfer Detectors

The detectors described in the previous sections primarily operate as single-element detectors. In designing the multielement arrays, the simplest solution of adding a number of individual detectors together proved to be not very fruitful. This became even more evident in applications where high-resolution images with a large number of pixels and small element size were required. In the early 1970s a new concept for creating images using charge transfer devices was introduced [9.55–58]. The idea appeared to be very promising and triggered extensive research in this area.

The structure of all charge transfer devices – charge coupled devices (CCD), charge transfer image sensors (CTIS), or charge-coupled image sensor (CCIS), and more recent complementary metal–oxide–semiconductor detectors (CMOS) is based on a metal–insulator–semiconductor (MIS) capacitor. The most important is the metal–oxide–semiconductor (MOS) capacitor made from silicon and silicon dioxide as the insulator. The simplest version of CCD is an array of closely spaced MOS capacitors. Under the application of a proper sequence of clock voltage pulses, the charges accumulated in the capacitors of the array can be moved in a controlled manner across a semiconductor substrate. This basic mechanism was applied to build a variety of electronic and opto-electronic devices performing the function of image sensing, data storage, and signal processing.

9.9.1 MOS Capacitor

The MOS capacitor is a building block for the charge storage device. A cross section of such a capacitor is shown in Fig. 9.41a. First consider a MOS capacitor at thermal equilibrium conditions with no fixed or mobile charges in the oxide layer and zero probability for the charge carriers to cross that layer. In this case, the thermal equilibrium can be considered separately in two regions (oxide and semiconductor regions).

Modes of Operation

Flat-Band Conditions. A simplified band diagram of the ideal p-type MOS capacitor in thermal equilibrium and at the so-called flat-band conditions is given in Fig. 9.41b. Under this condition, semiconductor band bending is absent (the electric field strength throughout the semiconductor is zero) and the electrode voltage V_{FB} applied to the gate corresponds to the difference in the metal and semiconductor work functions

$$V_{FB} = \varphi_m - \varphi_s \,. \tag{9.139}$$

Note that for Si, the barrier height at the Si–SiO_2 interface is 3.2 eV for electrons and 4.3 eV for holes. The Fermi level E_F shifted down from the intrinsic level E_i^p by

$$q\psi_{Bp} = E_i^p - E_F = kT \ln \frac{N_A}{n_i} \,, \tag{9.140}$$

where N_A is the acceptor concentration and n_i is the intrinsic carrier concentration.

Applying a bias to the gate electrode $V_g \neq V_{FB}$ allows shifting the potential level ψ_S of the oxide-semiconductor interface, which drives the MOS capacitor into different regimes. There can be three distinctly different modes of operation depending on the gate voltage polarity and amplitude: (a) accumulation, (b) depletion, and (c) inversion. These three modes are shown schematically with the band diagrams of Fig. 9.42a through Fig. 9.42c. The Fermi level remains flat at any regime of operation because of zero current flow.

Accumulation Mode. Applying a more negative voltage than V_{FB} to the gate of p-type MOS capacitor, holes will be attracted to the semiconductor–oxide interface

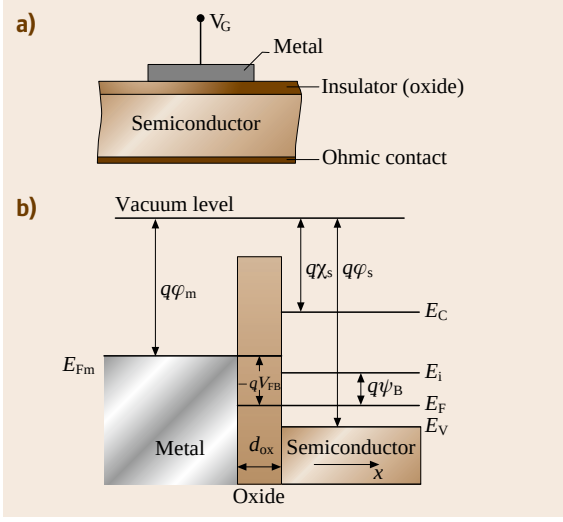

Fig. 9.41 **(a)** Cross section of a MOS capacitor. **(b)** Simplified energy-band diagram of the ideal MOS capacitor biased at $V_g = V_{FB}$

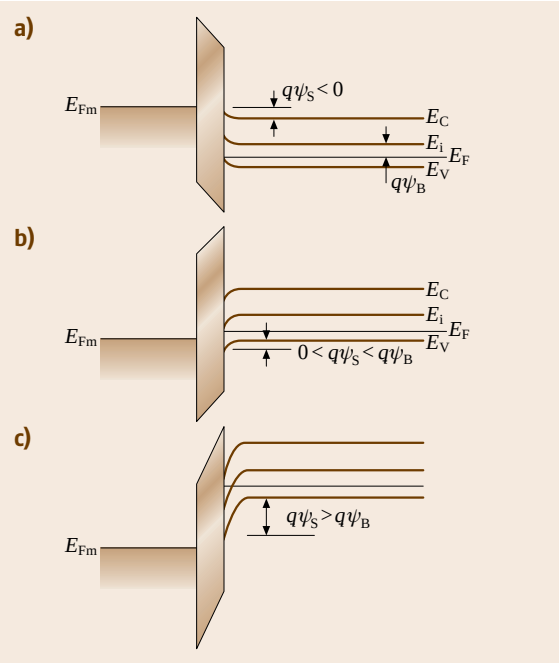

Fig. 9.42a–c Different modes of MOS capacitor operation: **(a)** accumulation, **(b)** depletion, and **(c)** inversion

and a thin layer of positive charge (majority carriers) will form in the semiconductor at the boundary. The bands bend upwards near the semiconductor–oxide interface and the valence band edge gets closer to the Fermi level, thereby facilitating filling the potential well at the boundary with free holes. The surface potential energy $q\psi_S$ is negative in this case. Since these free holes are concentrated in a very thin interfacial layer, the surface charge density can be written as

$$Q_{acc} = -\varepsilon_{ox}\varepsilon_0 \frac{V_g - V_{FB}}{d_{ox}} = -C_{ox}\left(V_g - V_{FB}\right) , \tag{9.141}$$

where ε_{ox} and ε_0 are the oxide dielectric constant and vacuum permittivity, respectively, d_{ox} is the oxide layer thickness, and C_{ox} is oxide layer capacitance per unit area.

Depletion Mode. When a small positive excess voltage $V_g > V_{FB}$ is applied, the majority carriers are repelled from the semiconductor–oxide interface, the bands bend downwards at the interface, and a relatively small positive surface potential $\psi_S(0 < q\psi_S < q\psi_{Bp}$, Fig. 9.42b) is formed.

To find the potential distribution inside the semiconductor, depletion approximation is usually used, which assumes that the edge of the depletion region is abrupt and no mobile majority carrier exist in this depletion region. The potential ψ in the depletion region for the thermal equilibrium case (no photoexcitation, no imperfections in the oxide and interface layers) is described by the Poisson equation

$$\nabla^2\psi = \frac{\partial^2\psi}{\partial x^2} = -\frac{\rho}{\varepsilon_S\varepsilon_0} = \frac{qN_A}{\varepsilon_S\varepsilon_0} , \tag{9.142}$$

where ρ is the charge density, N_A is the acceptor concentration in a uniformly doped p-type semiconductor, and ε_S is the semiconductor dielectric constant. The electric field $E = -\nabla\psi$ can be found by integrating (9.142) assuming a constant electric field E_{ox} in the insulator layer as the boundary condition. One more integration provides the potential distribution as a function of depth x inside the semiconductor

$$\psi = \int_0^x E(x)\,\mathrm{d}x = \int_0^x \frac{qN_A x}{\varepsilon_S\varepsilon_0}\,\mathrm{d}x = \frac{qN_A x^2}{2\varepsilon_S\varepsilon_0} , \tag{9.143}$$

where the potential was assumed to be zero throughout the semiconductor outside the depletion region. The potential varies linearly with distance across the insulator and quadratically in the depletion region. The potential minimum at the interface has the value

$$\psi_S = \frac{qN_A}{2\varepsilon_S\varepsilon_0} w^2 , \tag{9.144}$$

where w is the semiconductor depletion layer width.

The gate voltage V_g is distributed between the voltage drop V_{ox} that charges the oxide capacitance, the work-function difference (9.139), and the semiconductor surface potential ψ_S,

$$V_g = V_{FB} + V_{ox} + \psi_S . \tag{9.145}$$

The potential drop across the oxide is given by

$$V_{ox} = E_{ox}d_{ox} = \frac{qN_A w}{\varepsilon_S\varepsilon_0} d_{ox} \equiv \frac{qN_A w}{C_{ox}} = \frac{\sqrt{2qN_A\varepsilon_S\varepsilon_0\psi_S}}{C_{ox}} , \tag{9.146}$$

where in the right-hand side we substituted w from (9.144). Solving (9.145) and (9.146) for the surface potential at thermally equilibrium conditions yields

$$\psi_S = V_g - V_{FB} + \frac{qN_A\varepsilon_S\varepsilon_0}{C_{ox}^2} - \frac{1}{C_{ox}}\sqrt{2qN_A\varepsilon_S\varepsilon_0\left(V_g - V_{FB}\right) + \left(\frac{qN_A\varepsilon_S\varepsilon_0}{C_{ox}}\right)^2} . \tag{9.147}$$

The surface layer depletion width w is given by [9.10]

$$w = \sqrt{\frac{\varepsilon_S \varepsilon_0}{qN_A}\left(V_g - V_{FB}\right) + \left(\frac{\varepsilon_S}{\varepsilon_{ox}} d_{ox}\right)^2} - \frac{\varepsilon_S}{\varepsilon_{ox}} d_{ox} \,. \tag{9.148}$$

The capacitance of the MOS structure in the depletion mode can be described as a series capacitance of the insulator and semiconductor layer capacitance

$$C = \left(\frac{d_{ox0}}{\varepsilon_{ox}\varepsilon_0} + \frac{w}{\varepsilon_S \varepsilon_0}\right)^{-1} . \tag{9.149}$$

Inversion Mode. When a larger positive voltage is applied, the bands bend even more so that the intrinsic level E_i at the semiconductor–oxide interface crosses over the Fermi level E_F (Fig. 9.42c). For this mode the surface potential becomes large ($q\psi_S > q\psi_{Bp}$) and the number of minority carriers (electrons) at the surface may become larger than that of majority carriers (holes). A thin conducting layer of minority carriers forms close to the semiconductor–insulator interface and the surface becomes inverted.

If the gate voltage increases further, the minority carrier concentration at the surface surpasses the majority carrier bulk concentration. This situation is called strong inversion and it begins at a surface potential [9.6]

$$\psi_S(\text{inv}) \approx 2\psi_{Bp} = \frac{2kT}{q} \ln\left(\frac{N_A}{n_i}\right) . \tag{9.150}$$

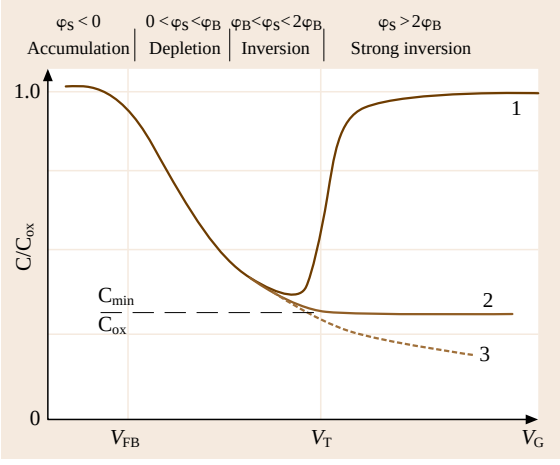

Fig. 9.43 Typical C–V characteristics of a MOS capacitor for the low frequency (*curve 1*) and high frequency (*curve 2*). *Curve 3* shows drop in the capacitance value in accord with the depletion approximation

The depletion width reaches its maximum value

$$w_{max} = \sqrt{\frac{4\varepsilon_S \varepsilon_0 \psi_{Bp}}{qN_A}} = \sqrt{\frac{4\varepsilon_S \varepsilon_0 kT \ln\left(N_A/n_i\right)}{q^2 N_A}} \,, \tag{9.151}$$

and the gate threshold (turn on) voltage, at which strong inversion occurs, is given by

$$V_T = V_{FB} + 2\psi_{Bp} + \frac{d_{ox}}{\varepsilon_{ox}\varepsilon_0}\sqrt{4qN_A\varepsilon_S\varepsilon_0\psi_{Bp}} \,. \tag{9.152}$$

A further increase above the threshold voltage will only increase the strength of the inversion layer remaining the depletion depth constant at w_{max}.

MOS Capacitor Characteristics

C–V Characteristics. The capacitance dependence on gate voltage for MOS structure is shown schematically in Fig. 9.43. Capacitance stays high in the accumulation mode and starts decreasing in the depletion operation mode due to increase in the depletion layer width with voltage. When inversion is reached, capacitance continues to drop until the minimum value

$$C_{min} = \left(\frac{d_{ox}}{\varepsilon_{ox}\varepsilon_0} + \frac{w_{max}}{\varepsilon_S \varepsilon_0}\right)^{-1} \tag{9.153}$$

is reached at maximum depletion width w_{max}. At strong inversion, the capacitance behavior is different for low and high frequencies.

At low frequencies, minority carriers can follow the AC signal to modulate the inversion layer, and capacitance rises to C_{ox} at $V_g > V_T$ (curve 1, Fig. 9.43). At high AC frequencies, minority carriers are not generated fast enough to follow the AC signal. The depletion width either saturates at w_{max} (with a slow ramp of the gate voltage V_g) or becomes even wider (at fast V_g ramp), so the overall MOS structure capacitance either saturates at C_{min} level (curve 2, Fig. 9.43) or continues to drop in accord with the depletion layer approximation similar to the abrupt p/n junction approximation (curve 3, Fig. 9.43).

For the case of light-induced generation of minority carriers, the equilibrium high frequency curve (curves 2 or 3, Fig. 9.43) can be obtained with either slow or fast V_g ramp.

Concept of Charge Storage

Under illumination and either in the depletion or inversion mode, the photogenerated minority carriers (electrons for the p-type semiconductor) will tend to collect

in the potential well ψ_S close to the semiconductor–oxide interface. As the electrons accumulate at the semiconductor interface, the field across the insulator starts to increase, and the surface potential and the depletion width begin to shrink [9.14]

$$\psi_S = V_g - V_{FB} + \frac{qN_A\varepsilon_S\varepsilon_0}{C_{ox}^2} - \frac{Q_{sig}}{C_{ox}} - \frac{1}{C_{ox}} \times \sqrt{2qN_A\varepsilon_S\varepsilon_0\left(V_g - V_{FB} - \frac{Q_{sig}}{C_{ox}}\right) + \left(\frac{qN_A\varepsilon_S\varepsilon_0}{C_{ox}}\right)^2}\,, \tag{9.154}$$

where Q_{sig} is a signal charge density. The maximum charge density that can be collected in ideal case is estimated from the condition $\psi_S = 0$,

$$Q_{sig}^{max} = C_{ox}V_g\,, \tag{9.155}$$

which is to be avoided. In practice, the maximum achievable charge density is $\approx 10^{11}\,\mathrm{cm}^{-3}$, which limits the dynamic range of MOS detectors to $\approx 10^4$.

Effects of Dark Currents, Interface Traps, and Oxide Charges

Various imperfections deteriorate MOS capacitor performance. For example, mobile oxide charges, oxide trapped charges, and fixed oxide charges near oxide-semiconductor interface cause a parallel shift of the *C*–*V* curve of Fig. 9.43 in the V_g direction, yet main performance parameters do not suffer significantly from these imperfections. Special attention is usually paid to the interface charge traps, which are among the major limitations of MOS capacitor performance. If the charge traps are empty prior to illumination of the MOS capacitor, they are able to capture the non-equilibrium carriers created by light and then release them so slowly that the readout electronics will not detect them correctly.

The effect of interface traps can be substantially reduced by passing a constant background charge to MOS capacitors. Then to first order, the interface traps remain permanently filled and interact with the signal charges to a minimal extent. However, the drawback of this method is a reduction in the dynamic range value by approximately 10 to 20%.

In addition to light generation, various sources for generation of dark current also supply charge to the interface and act as background noise. The dark current density can be expressed with the sum of generation current in the depletion region, generation in the neutral bulk, and generation at the surface [9.14]

$$J_{dark} = \frac{qn_i w}{2\tau} + \frac{qD_n n_i^2}{L_n N_A} + \frac{qS_r n_i}{2}\,, \tag{9.156}$$

where τ is the minority carrier lifetime, D_n the diffusion constant, L_n the diffusion length, and S_r the surface recombination rate. The dark current limits the accumulation time of MOS detector to its maximum value

$$t_s = \frac{Q_{sig}^{max}}{J_{dark}}\,. \tag{9.157}$$

If the gate voltage remains fixed, thermally generated minority carriers will gradually fill the surface potential well and the MOS capacitance will increase toward its low-frequency asymptotic inversion condition C_{ox}.

Buried Channel MOS Capacitor

In the previous sections the surface-channel MOS capacitor was described. One of the major limitations of this type of MOS structure is the effect of interface traps. To circumvent this problem, the potential well can be buried more deeply in the semiconductor bulk producing the so-called buried-channel MOS structure [9.59]. In this structure, the non-equilibrium minor carriers' accumulation is confined to a valley underneath the surface.

Figure 9.44a shows the schematic structure of the buried-channel MOS capacitor built on a p-type semiconductor. The structure has a thin layer ($< 0.5\,\mu\mathrm{m}$) of opposite type (n-type) dopant at the semiconductor surface. This layer is fully depleted when the gate pulse is applied. The potential well in this case is formed close the p/n junction and photo-generated carriers are kept away from the interface. The energy-band diagram

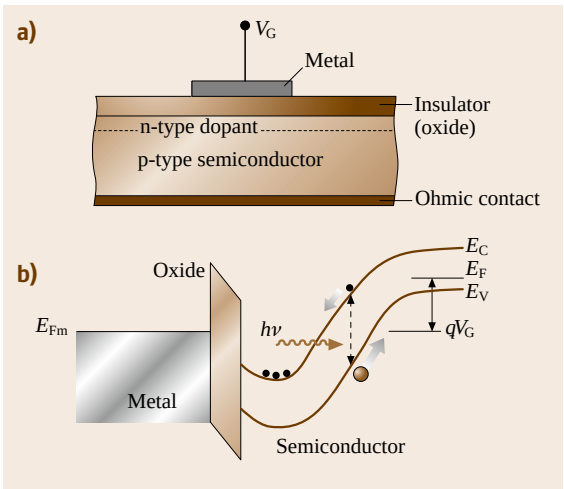

Fig. 9.44 **(a)** Schematic structure and **(b)** energy band-diagram of the buried-channel MOS capacitor under a large positive gate bias V_g

for this capacitor under a high gate pulse is shown in Fig. 9.44b.

9.9.2 CCD as Charge Coupled Image Sensors (CCIS)

A charge coupled device is an array of MOS capacitors placed close together. The gates are made semitransparent for the front-illuminated devices or they can be opaque if the device is back-illuminated. Illumination with light creates non-equilibrium charge carriers through photoelectric effect under each gate electrode. Applying the proper sequence of gate voltages allows transferring minority carriers across the array thereby delivering electrical signal proportional to the amount of photons absorbed by each pixel to the output register.

Basic CCD Structure

The process of photodetection by CCD can be described as a four-step process: charge generation, charge collection, charge transfer, and charge measurement. In a CCD array sensor, each pixel's charge is transferred through a limited number (often one) of output nodes to be converted to voltage, buffered, and sent off-chip as an analog signal. A cross section of a simple, typical back-illuminated CCD sensor is shown in Fig. 9.45. The device in Fig. 9.45 is a three-phase CCD that consists of a number of n-channel MOS capacitors connected to the φ_1, φ_2, and φ_3 clock lines. Those capacitors participate in charge generation, charge collection, and charge transfer steps. The output gate OG and output diode OD are the structures necessary to detect output charge packets. The input gate IG is a part of a structure that blocks charges against flowing outside the main CCD array. The surface channel stoppers p^+ at the edges of the structure provide the unidirectional transfer of

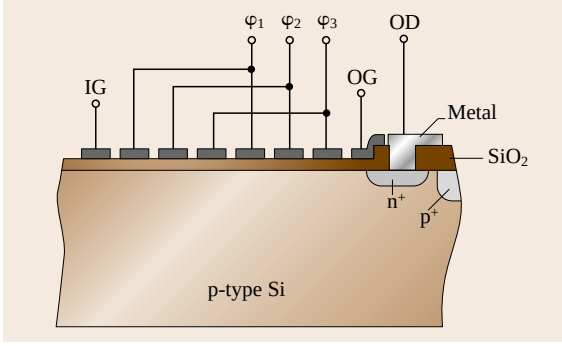

Fig. 9.45 A simplified cross sectional diagram of an n-channel charge-coupled device

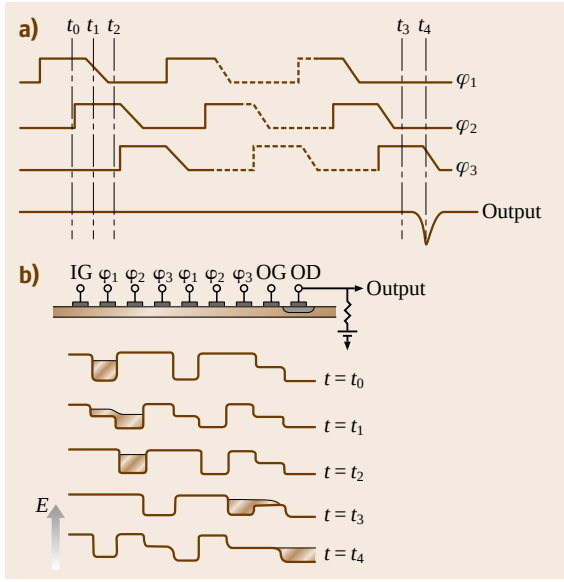

Fig. 9.46 **(a)** Clock waveforms and the output signal of an example CCD structure shown in Fig. 9.45. **(b)** Energy levels and charge distribution of the same device with the clock from the panel **(a)**

charges. For the efficient charge generation and collection, CCDs are usually made using a high resistivity material to deplete up to 10 μm of the semiconductor bulk underneath the gate of each MOS capacitor.

Assuming that the charge was generated and collected in the left-hand side MOS capacitor only, the charge transfer mechanism can be described using the following scheme. Figure 9.46a shows the clock waveforms and Fig. 9.46b illustrates the corresponding potential wells and charge distribution for the structure in Fig. 9.45 with charge collected by the left-hand side capacitor only.

At $t = t_0$, clock line φ_1 is at high voltage and φ_2 and φ_3 are at low gate voltages. The output diode (OD) is biased with a high positive voltage to prevent inversion of the surface under the output gate. Thus the surface under OG is in deep depletion and OD cannot supply electrons into the main CCD array. If the first MOS capacitor was illuminated, the charges are collected in the well under the first capacitor gate as shown in Fig. 9.46b for $t = t_0$. At $t = t_1$, the voltage applied to φ_1 is returning to the low value while the φ_2 electrodes have high voltage applied to them. The second MOS capacitor becomes depleted and electrons stored under the first gate are then transferred to the well under the second gate. The voltage on φ_1 has a slowly falling edge because the

charge carriers require a finite time to transport across the width of the gate. At $t = t_2$, the charge-transfer process is completed and the original charge packet is stored under the second gate. This process is repeated until the charge packet reaches the output terminal. At $t = t_4$ the voltage of the φ_3 electrodes returns to the low value pushing the electrons to the output diode OD.

Charge Transfer Mechanisms

Charge is transferred from one gate to another by three mechanisms: (1) self-induced drift (repulsion of like charge); (2) thermal diffusion; and (3) fringe field drift. These mechanisms operate with a free charge transfer model and the charge transfer process is governed by the continuity equation

$$\frac{\partial n}{\partial t} = \frac{1}{q}\frac{\partial J}{\partial x} , \tag{9.158}$$

where n is the charge carrier concentration, J is the current density, and x is distance in the transfer direction. As a rule, self-induced drift account for $\approx 95\%$ of the charge transfer and two other mechanisms account for the rest. The expression for the decay of the initial charge packet Q_0 due to the self-induced drift can be expressed via the decay process given by [9.60, 61]

$$Q(t) = Q_0\left(1 + \frac{\tau_{si}}{t}\right) , \tag{9.159}$$

with

$$\tau_{si} = \frac{\pi L^3 HC}{2\mu_n Q_0} \tag{9.160}$$

standing for the decay time constant, L is the gate length, H is the gate electrode width, C the insulator and semiconductor layer total capacitance, and μ_n is the minority carrier mobility.

However, for a small amount of signal charge, thermal diffusion is the dominant transfer mechanism. The total stored charge decreases exponentially with time, and the time constant is [9.6]

$$\tau_{th} = \frac{4L^2}{\pi^2 D_n} , \tag{9.161}$$

where D_n is the minority carrier diffusion constant.

Fringe field drift originates due to the two-dimensional coupling of the electrostatic field from the biased adjacent electrodes. Because the fringing field is present even at very low charge concentration, the last bit of the signal charge will be transferred by the fringing field.

CCD Figures of Merit

Spectral Response. Spectral response of CCIS (CCD) is determined by the same relationships as spectral response of semiconductor photodiodes. Since for CCIS manufacturing a relatively high resistivity material is appropriate, the efficient non-equilibrium charge collection occurs from the charge-space (depletion) region, which may be up to 10 μm thick. That is why CCIS have high sensitivity and quantum efficiency in the broad spectral range. For example, for Si-based CCIS, a spectral sensitivity range from 300–1000 nm is typical.

Besides traditional detectors figures of merit, charge transfer detectors can be characterized with a number of specific parameters discussed below.

Transfer Efficiency. The transfer efficiency η_{tr} is the ratio of charge Q transferred to the initial charge Q_0 stored

$$\eta_{tr} = \frac{Q}{Q_0} . \tag{9.162}$$

The related figure of merit is the transfer inefficiency ε_{tr}, defined as

$$\varepsilon_{tr} \equiv 1 - \eta_{tr} . \tag{9.163}$$

The charge transfer efficiency for m charge transfer steps can be approximated with [9.3]

$$(\eta_{tr})^m = \frac{V_m - \Delta V}{V_m} , \tag{9.164}$$

where V_m is the maximum signal packet voltage and ΔV is the voltage loss for a lead pulse in a packet. From (9.164), by rearranging terms and taking the first two terms of a binomial expansion one can obtain for a large number m of the transfer steps

$$\eta_{tr} \cong 1 - \frac{\Delta V}{nV_m} . \tag{9.165}$$

For the case of incomplete free charge transfer in a clock period, the charge transfer efficiency can be written as [9.6]

$$\eta_{tr} \cong \frac{Q_0 - Q(t)}{Q_0} = 1 - \frac{8}{\pi^2}\exp\left(-\frac{t}{\tau_{th}}\right) . \tag{9.166}$$

Time Response. Charge collection inside the depletion region is a relatively fast process, which usually does not limit the operation frequency of CCIS. Consider other factors that influence time response and frequency range of charge coupled devices.

The pixel charge density is given by the sum of various sources of dark current and photocurrent,

$$\frac{dQ}{dt} = J_{dark} + J_{ph} = \frac{qn_i w}{2\tau} + \frac{qD_n n_i^2}{L_n N_A} + \frac{qS_r n_i}{2} + \eta_{ex} q\Phi \,, \quad (9.167)$$

where the first three terms in the right-hand side are described by (9.156), Φ is the pixel incident optical photon flux, and η_{ex} is the external quantum efficiency. Note that the overall detection efficiency of CCIS can be thought of as a convolution of the quantum efficiency term with the terms that determine the charge transfer efficiency.

For different frequency ranges, the charge transfer efficiency is influenced by different terms from (9.167). The transfer efficiency at high frequencies can be described by the free charge transfer model of (9.158) and is limited by the clock rates for a given device.

At medium frequencies trapping the signal charge at the interface traps determines the transfer efficiency. The methods to overcome the problems due to the interface traps have been discussed above.

At low clock frequencies, the time response is determined by the dark current (9.167). The low-frequency degradation of frequency response is due to the buildup of dark current in the charge packets, which distorts the shape and size of the signal charge. To improve the low-frequency response, one must reduce all the dark current components in (9.167) by minimizing the gate length, choosing the material with high minority carrier mobility, long carrier lifetime, large diffusion length, and low surface recombination velocity. As was mentioned previously, the low limit frequency response is limited to the inverse of the maximum integration time given by (9.157).

Noise

The most important noise sources in CCIS are the following. [9.61, 62]:

1. The photon shot noise, which is the basic limitation for the device sensitivity
$$N_{sh} = \sqrt{2\eta_{ex}\Phi\Delta f} \,, \quad (9.168)$$
where N_{sh} is in rms electrons.
2. Dark current shot noise N_{sh_DC}, which can be expressed in rms electrons by
$$N_{sh_DC} = \sqrt{\frac{2J_{dark}\Delta f}{q}} \,, \quad (9.169)$$
where J_{dark} is given by (9.156).
3. Charge transfer noise, which is nowadays negligible due to the use of buried channels.
4. Readout diffusion reset noise, which is usually added after the step of charge/voltage conversion.

Thermal noise for CCD has the same origin as for photodiodes and can be greatly reduced by cooling the detector. Contemporary cooled CCIS can show the photon-limited performance and operate in a single photon counting mode.

9.9.3 Complementary Metal Oxide Semiconductor (CMOS) Detectors

Many of the newer imaging devices use a different chip, one known as a CMOS chip. CMOS technology is the standard computer chip technology that has been around for years. Originally, CCD technology gave better images than CMOS detectors. Recently, CMOS image detectors have been developed to the stage where they give images comparable to or better than those made with CCD chips. In addition, CMOS chips are simpler and require fewer external supporting devices for their operation.

In a CMOS sensor, each pixel has its own charge-to-voltage conversion, includes MOS transistors providing buffering and addressing capability, and may also include the digitizing circuit. The price that the designers pay for these additional functions is the reduced area available for front-side light collection.

Basic CMOS Structure and Properties

Similar to CCD, CMOS detectors also have a four-step process: charge generation, charge collection, charge transfer, and charge measurement. However, unlike CCD, the first three steps in CMOS sensor are performed within each individual pixel.

To convert two-dimensional spatial information into the serial stream of electrical signals, electronic scan circuits of CMOS photodetector read out each pixel sequentially. First, the vertical scan circuit selects a row of pixels by setting a high DC voltage on all gates of the MOS switches for that row. Next, the horizontal scan circuit selects the pixels in one particular column using the same technique. As a result, only one pixel in the two-dimensional matrix has a high DC voltage on both the row and the column switch, which electronically selects it for readout. After the pixel dumps its information into the output stage, it is reset to begin a new integration, and the readout process progresses to the next pixel in the row. Such organization, in contrast to

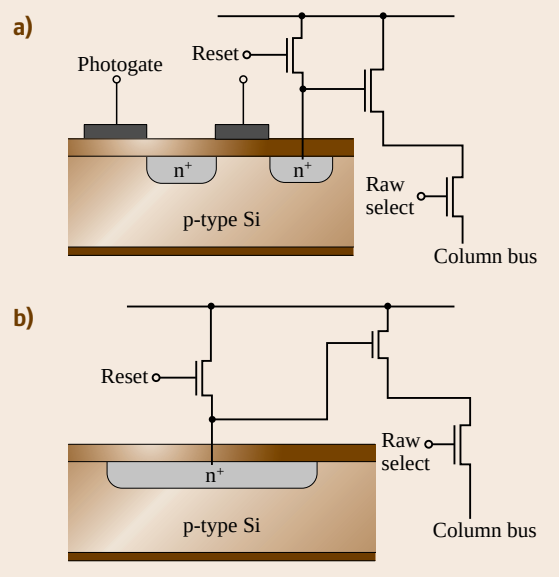

Fig. 9.47a,b Two designs of CMOS sensor pixels: **(a)** photogate architecture and **(b)** photodiode architecture

CCD architecture, provides random access to each pixel and avoids multiple charge transfers over long distances of semiconductor material.

The most common pixel architectures for CMOS sensor pixels are photo gate conversion and photodiode conversion (Fig. 9.47). The photosensitive element of the photo gate design is a MOS capacitor that performs the functions of charge generation and collection. Once the scan circuitry has selected a pixel, a pulse on the transfer gate triggers the charge transport from the photosensitive area toward the potential well of a sense node, created by n^+ diffusion area at the semiconductor interface (Fig. 9.47a). This node is a part of the floating-diffusion amplifier, which performs the function of charge-to-voltage conversion. The charge-to-voltage conversion in this case is independent of the active area size, which allows producing high conversion gain.

The photodiode pixel looks very similar to the photo gate pixel. However, the additional transfer gate is not required since the photodiode capacitance performs the function of charge storage and n^+ diffusion operates as the output diffusion of the floating-diffusion amplifier (Fig. 9.47b). For the photodiode pixel, the conversion gain depends on the photodiode active area and is usually several times smaller than for the case of the photo gate pixel. To allow detection of a low flux level, most of CMOS sensors operate in charge integration mode for both photo gate and photodiode design.

Quantum Efficiency and Spectral Sensitivity. The quantum efficiency of CMOS detectors is not as high as that of CCD sensors because the CMOS fabrication process requires low resistivity wafers and relatively low power supply levels, which limits the depletion width of the semiconductor bulk to 1–3 μm. The spectral sensitivity range of CMOS sensors is usually narrower than that of CCIS detectors since the absorption length increases towards the red spectral range.

Noise. The noise of CMOS sensors consists of photon shot noise, dark current shot noise, reset noise, and thermal noise. The noise properties are the same as described above for CCD photodetectors. However, there is an important difference in the noise properties of CCD and CMOS detector arrays. In CCD, the noise is captured at the highest bandwidth at the output, whereas due to the column-parallel organization of CMOS arrays, the noise bandwidth is set to the row readout bandwidth by the column sampling circuitry that filters the in-pixel noise [9.61].

9.10 Photoemissive Detectors

The operational principle underlying photoemissive detectors is the external photoelectric effect, which is the emission of electrons from a surface upon exposure to electromagnetic radiation. To amplify the signal detectors with multiple electrodes have been developed.

9.10.1 Photoemissive Cell

In their simplest form photoemissive detectors consist of a metal anode–cathode pair in a vacuum tube. When photons strike a cathode, electrons in the valence band become excited, moving to the cathode surface. If the diffused electrons have enough energy to overcome the vacuum level barrier, they are emitted as photoelectrons. Electrons emitted from the cathode are accelerated towards the anode. The photo signal is directly proportional to the intensity of the incident radiation. One method to improve the sensitivity of a photoemissive cell is adding an inert gas resulting in subsequent ionization.

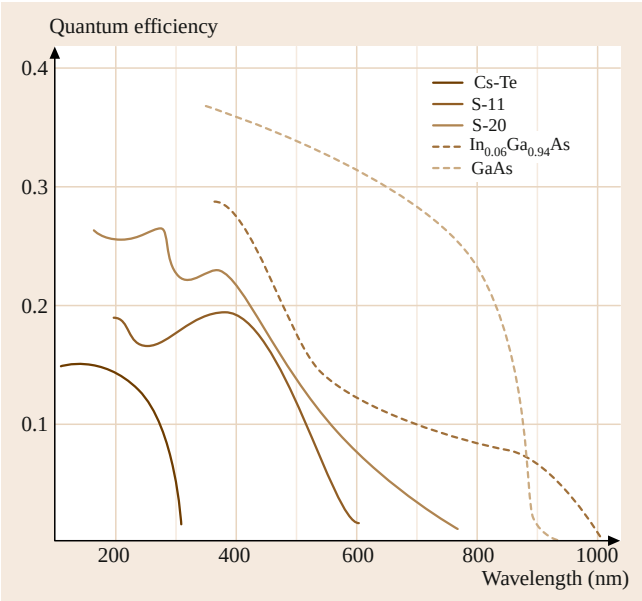

Fig. 9.48 Spectral response of some representative photocathodes. *Solid lines* correspond to material with positive electron affinity, whereas *dotted lines* are for negative electron affinity materials

The cathode is made of a material with a very low work function, usually a combination of alkali and other metals. Some common photocathode materials (with positive electron affinity ψ) are Ag-CsO-Cs (S-1), Ag-Rb (S-3), Sb_3Cs (S-4), Cs_3Sb-O (S-11), and Na_2KSb-Cs (S-20) that are sensitive between 300–1200 nm, 300–1000 nm, 350–600 nm, 200–600 nm, and 180–800 nm, respectively. The photocathode with negative electron affinity ψ could be expected to have potentially very high quantum efficiency; however, their quantum efficiency is limited by a non-zero escape length for the excited electrons. The quantum efficiency of some representative conventional and negative affinity photocathodes is shown in Fig. 9.48.

Figures of Merit

Quantum Efficiency. The quantum efficiency η of a photocathode can be expressed in terms of a probability process that depends on the reflection coefficient R_f of the light entering surface, material absorption coefficient α, a probability for absorbed photons to excite the valance band electrons beyond the vacuum level, a mean escape length of excited electrons, and a probability for electrons reaching the surface to be released into vacuum.

Signal Current. Assuming the quantum efficiency of a photocathode is η and the incoming photon flux is Φ the current signal I_s is equal to

$$I_s = q\eta\Phi \,, \tag{9.170}$$

where q is the elementary charge.

Current Responsivity. The current responsivity of a photoemissive cell is given by the general expression

$$\Re_I = \frac{q\eta\lambda}{hc} \,, \tag{9.171}$$

in which λ is the wavelength, c is the speed of light, and h is Planck's constant.

Noise Current. The noise current

$$i_n = \sqrt{i^2_{\text{sh-phot}} + i^2_{\text{sh-dark}}} \tag{9.172}$$

of a photoemissive cell consists of the two main parts: (1) the shot noise $i^2_{\text{sh-phot}} = 2q^2\Phi\eta\,(\Delta f)$ of the photocurrent caused by the photon flux Φ and (2) the shot noise $i^2_{\text{sh-dark}} = 2q^2 I_D\,(\Delta f)$ due to the dark current $I_D = q\left[(4\pi m_e)/h^3\right](kT)^2\,A_{\text{det}}\exp(-\varphi/kT)$, which is of a thermionic origin. In the above expression for I_D, A_{det} is the photocathode area, m_e the electron mass, and φ the photoemissive cell material work function.

Noise Equivalent Power. For the case of the dark-current-limited conditions, the noise equivalent power of the photoemissive cell is determined by I_D

$$\text{NEP} = \frac{hc}{\eta\lambda}\left(\frac{2I_D}{q}\right)^{1/2} \,. \tag{9.173}$$

9.10.2 Photomultiplier

A common way to increase the sensitivity of a photoemissive detector is to implement multiple anodes. This kind of device is called a photomultiplier tube (PMT). Like in a photoemissive cell, light causes the emission of electrons from a photosensitive cathode. Instead of just one anode a sequence of electron absorbers with enhanced secondary emission, called dynodes, is used in a PMT.

Figure 9.49 shows the PMT schematics. The dynodes are connected along a series of resistors that divide the high voltage, which is applied between the photocathode and the anode. For a typical gain of 200 eV in kinetic energy between adjacent dynodes each electron is able to set free four to eight secondary electrons. With

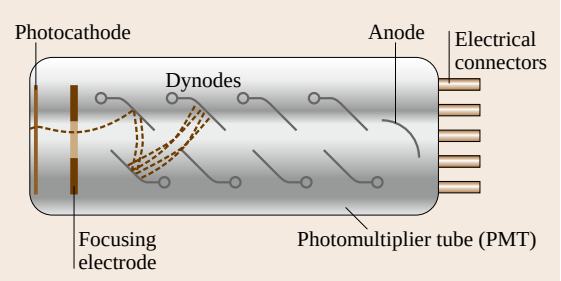

Fig. 9.49 Cross section of a photomultiplier tube

typically 10 dynodes in the device a total multiplication factor of about $10^6 \approx 10^8$ can be achieved.

The dynamic range of PMT is limited for low signals by the dark current. The biggest contribution to the dark current is the thermal emission of electrons, which can be effectively suppressed by cooling the tube to $-40\,^{\circ}\mathrm{C}$. Other contributions are leakage currents inside the tube and noise generated by incoming ionizing radiation. At the high-end space charge effects are the reason for the photo current to level off with increasing photon flux on the cathode. A cloud of electrons starts building up behind the last dynode, thus effectively shielding the anode from additional charge carriers.

Photomultipliers are extremely sensitive and can be used for single photon counting purposes [9.63–65]. In this mode the PMT has to be operated such that a single photon generates an electron cloud resulting in an anode pulse of several millivolts into a $50\,\Omega$ load. Due to the statistical nature of the amplification process the signal pulses show a height variation. A fast discriminator is used to set a threshold that only accepts analog signal above the noise level and transforms those into logic pulses. These pulses are subsequently counted. Setting the proper threshold can further reduce the thermal noise of a cooled PMT since noise pulses from dynode thermionic emission have a lower mean height distribution than pulses triggered by an incoming photon.

Figures of Merit

Gain. The PMT gain is

$$G = P_\mathrm{d} V^{k_1 m} \,, \tag{9.174}$$

where m is the number of dynodes, V voltage, P_d the dynode collection efficiency, and k_1 a constant depending on geometry and dynode material.

Dark Current. Thermionic emission characterizes the PMT dark current I_D

$$I_\mathrm{D} = C_1 T^2 \, \mathrm{e}^{-C_2 \varphi / kT} \,, \tag{9.175}$$

where φ is the photocathode work function, k the Boltzmann constant, and T the absolute temperature. C_1 and C_2 are constant factors.

Noise Equivalent Power (NEP). In the dark-current-limited condition the noise equivalent power of a photomultiplier is

$$\mathrm{NEP} = \frac{hc}{\eta\lambda}\sqrt{\frac{2I_\mathrm{D}}{q}} \,. \tag{9.176}$$

Signal-to-Noise Ratio. The signal-to-noise ratio for a photomultiplier having the secondary emission ratio δ identical for the dynodes of each stage and operating in shot-noise-limited conditions is

$$\mathrm{S/N} \approx \frac{I_\mathrm{c}}{\sqrt{2q\Delta f \frac{\delta}{\delta-1}(I_\mathrm{c}+2I_\mathrm{D})+I_\mathrm{A}^2}} \,, \tag{9.177}$$

where I_c is the cathode (photo)current, Δf the bandwidth, I_D the dark current, and I_A the amplifier noise current.

9.10.3 Single-Channel Electron Multipliers and Microchannel Plate

If the discrete dynode structure for photomultipliers described in the previous section is replaced by a single continuous dynode, the resulting light detector can be much smaller than a PMT with similar detection characteristics. These devices are usually referred to as *single-channel electron multipliers*, by their trade name *Channeltrons* [9.66] or, if combined to arrays, as *microchannel plates* (MCP) [9.67].

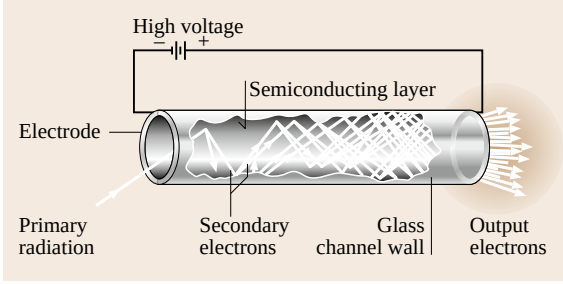

Fig. 9.50 Single-channel electron multipliers (microchannel). Electrodes are deposited on the entrance and output surfaces

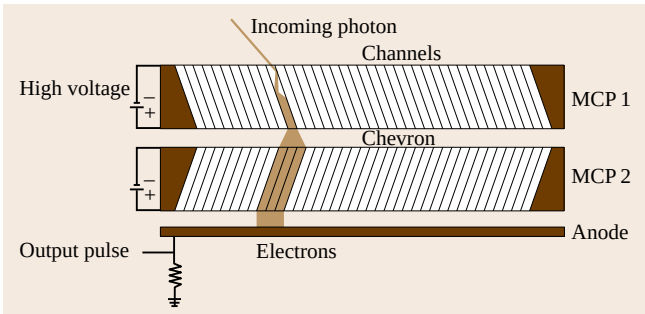

Fig. 9.51 Two microchannel plates in chevron configuration

Typically a single-channel is made of a glass tube that has been coated on the inside first by a conductive and subsequently by an emissive layer (Fig. 9.50). A high voltage (1000–3000 V) is applied across the length of the tube that accelerates electrons emitted by impinging photons at the negative end. If the tube is straight the maximum gain of the device is generally limited to about 10^5. The reason is that the high electron density near the anode is desorbing ions from the tube walls or ionizing residual gas ions. These positive ions are accelerated back to the cathode were unwanted secondary electron pulses are created (ion feedback). Therefore, a curvature is often introduced into the tube design. With this modification there will still be positive ions created in the tube, but due to the short distance of travel and their large mass compared to that of electrons they will not gain enough kinetic energy to set free secondary electrons when impacting the inner tube wall. Depending on the voltage and the resistivity of the conductive material ($\approx 10^{15}\ \Omega$ cm) the gain can be tuned as high as 10^8 for such a device.

Microchannels as described above can be manufactured as small as 10–100 µm in diameter. A combination of many of these minute detectors into an array is called a microchannel plate (Fig. 9.51). These plates are very thin, typically around 0.5 mm. Curved channels like those for the single device are difficult to manufacture. Therefore, a different design is used to suppress the ion feedback. The detector in Fig. 9.51 is made of two similar plates that have straight channels under a slight bias angle. The plates are combined in a way that requires the charge carriers to change the direction when leaving the first plate before entering the second. This so-called chevron configuration denies positive ions to travel from the output of the rear plate all the way to the input of the front plate [9.68].

9.11 Thermal Detectors

A wide extent of the electromagnetic spectrum from UV to far infrared can be covered by thermal detectors. In most cases they are a combination of two components. The first one is an absorber in contact with a heat sink and the second is a temperature sensitive element (Fig. 9.52). The optical absorbance of the material that converts incoming photons into heat determines their spectral response. By choosing the appropriate material photons within a broad wavelength band are absorbed causing some other physical parameter to change as well. This change is the signal registered by the temperature sensitive element.

Detector Response

Independent from the material of the absorber and the type of temperature sensor, the sensitivity and the response time of thermal detectors are limited by some general constraints. The temperature change of a thermal detector, due to the change in incident light, can be calculated as follows. The heat balance equation for a detector with a heat capacity C_{th} that is linked to a heat reservoir by a thermal resistor R_{th} is

$$C_{\mathrm{th}}\frac{\mathrm{d}}{\mathrm{d}t}(\Delta T)+\frac{1}{R_{\mathrm{th}}}\Delta T=\eta_{\mathrm{S}}\Phi_{\mathrm{p}}\,. \tag{9.178}$$

The parameter η_{S} is the surface emissivity of the detector, which is mainly given by the surface finish of

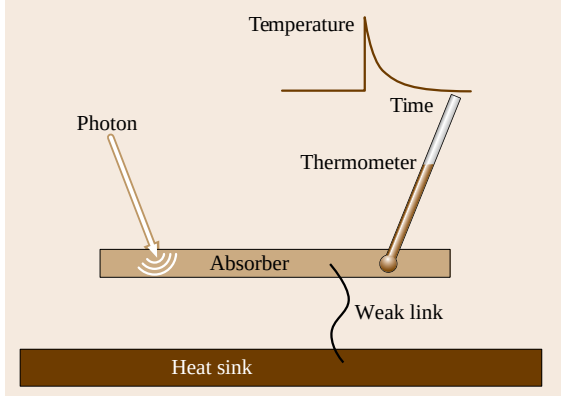

Fig. 9.52 Schematics of a thermal detector

the absorber. In general the change in temperature ΔT and the incident radiant power Φ_p are functions of time. For simplicity the latter is assumed to be a sinusoidal excitation

$$\Phi_p = \Phi_{p0}\, e^{i\omega t} \,. \tag{9.179}$$

Solving and introducing the thermal time constant τ_{th}

$$\tau_{th} = R_{th} C_{th} \tag{9.180}$$

gives for the temperature change

$$\Delta T = \left| \frac{\eta_S \Phi_{p0} R_{th}}{1 + i\omega\tau_{th}}\, e^{i\omega t} \right| = \frac{\eta_S \Phi_{p0} R_{th}}{\sqrt{1+\omega^2\tau_{th}^2}} \,. \tag{9.181}$$

To achieve high sensitivity the optically induced temperature change can be increased by choosing good thermal insulation. The price to be paid for this improvement is a lower response speed due to a larger τ_{th}. Another option is to decrease the heat capacitance. However, this usually means a smaller detector size, which also reduces the signal amplitude.

The temperature sensitive element that records the change in temperature caused by the irradiation of the absorber can be based on a variety of physical processes discussed below. These also contribute to the overall time response of the system.

9.11.1 Mechanical Displacement-Sensitive Detectors

Thermal expansion of a solid or liquid is a common method to detect radiation induced temperature changes. *Bimetal springs* or alcohol filled *glass thermometers* are examples of devices commonly used for temperature monitoring and control.

A radiation detector based on the expansion of a gas is the *Golay cell* [9.69]. Golay cells are broadband and extremely sensitive, which makes them suitable for wavelengths very far in the infrared part of the spectrum ($> 300\,\mu m$). Another advantage is that the operation is mostly independent of the ambient temperature, thus eliminating the need for cooling.

Golay cells consist of a gas reservoir that is being heated by the incoming radiation. The heat causes minute pressure changes to deflect a membrane, which is registered by an optical system. The sensitivity can reach $10^{-10} \approx 10^{-11}\,W/Hz^{1/2}$. A variation of this pneumatic detector is the gas filled *capacitor microphone*.

Advances in microfabrication technology make it possible to create smaller and more sensitive thermal detectors. A good example is the *microcantilever* that is based on a bimetal strip combined with piezoelectric resistance readout, a laser and position-sensitive photo detector or capacitance meter.

9.11.2 Voltage-Sensitive Detectors

If two wires or thin films made of different metal are brought into contact with each other a difference in the Fermi levels leads to an electro motive force. This so-called Seebeck effect is the origin of a voltage drop across the metal/metal junction, which depends on the temperature. Thermal detectors based on this principle are labeled *thermocouples* or *thermoelectric elements*. The measured voltage ΔV is directly proportional to the temperature difference ΔT

$$\Delta V = \alpha_S \Delta T \,, \tag{9.182}$$

where a_S is the so-called Seebeck coefficient (Table 9.3). With the help of (9.179) and the last equation the voltage responsivity of a thermocouple is easily de-

Table 9.3 Seebeck coefficients α_S for different materials at 0 °C

Material	Seebeck coefficient (μV/°C)	Material	Seebeck coefficient (μV/°C)	Material	Seebeck coefficient (μV/°C)
Aluminum	3.5	Gold	6.5	Rhodium	6.0
Antimony	47	Iron	19	Selenium	900
Bismuth	−72	Lead	4.0	Silicon	440
Cadmium	7.5	Mercury	0.6	Silver	6.5
Carbon	3.0	Nichrome	25	Sodium	−2.0
Constantan	−35	Nickel	−15	Tantalum	4.5
Copper	6.5	Platinum	0	Tellurium	500
Germanium	300	Potassium	−9.0	Tungsten	7.5

termined

$$\Re_v = \frac{\Delta V}{\Phi_{p0}} = \frac{\alpha_s \eta_S R_{th}}{\sqrt{1+\omega^2\tau_{th}^2}} \,. \tag{9.183}$$

For low frequencies ($\omega \ll 1/\tau_{th}$) the voltage response becomes a constant

$$\Re_v = \alpha_s \eta_S R_{th} \,. \tag{9.184}$$

In many applications two metal junctions are combined in series. The first one is thermally linked to the absorber that is exposed to the radiation, whereas the second is kept at a constant reference temperature. To increase the voltage signal additional junction can be added (*thermopile*). The voltage response of a thermopile is the right-hand side of (9.184) multiplied by the number of junctions.

With the help of (9.25) and (9.183) the noise equivalent power of a thermocouple can be written as

$$\mathrm{NEP} = \frac{\sqrt{4kT\Delta f}}{\Re_v \sqrt{R_{el}}} = \frac{\sqrt{4kT\Delta f}}{\alpha_s \eta_S} \times \frac{\sqrt{1+\omega^2\tau_{th}^2}}{R_{th}\sqrt{R_{el}}} \,, \tag{9.185}$$

where R_{el} is the ohmic resistance of the detector.

9.11.3 Capacitance-Sensitive Detectors – Pyrometers

Some dielectric materials like tourmaline, lithium tantalate ($LiTaO_3$), or triglycerine sulfate (TGS) exhibit a spontaneous electrical polarization without an external electrical field being present. The magnitude of the polarization and therefore the dielectric constant are a function of the temperature [9.72]. Thermal detectors operating on the basis of this effect are called *pyroelectric detectors* .

Pyroelectric Effect

A measure of the pyroelectric effect for a material is the pyroelectric coefficient γ_p. For a given electric field E and constant elastic stress σ the pyroelectric coefficient is defined as

$$\gamma_p = \left(\frac{\partial P}{\partial T}\right)_{E,\sigma} \,, \tag{9.186}$$

where P is the polarization and T the temperature. There are two effects contributing to its magnitude. The *primary pyroelectric effect* is due to constant strain on the material. The *secondary effect* is the piezoelectric contribution due to thermal expansion. The total pyroelectric coefficient for various materials is shown in Table 9.4.

In general the effect vanishes completely above a certain temperature (Curie temperature).

Responsivity

A simple pyroelectrical detector consists of a crystal between to metal electrodes. If the temperature of the device is held constant leakage currents eventually redistribute charges between the two surfaces facing the electrodes. Thus any internal electric field is canceled out and under steady state conditions no current or voltage signal can be observed between the electrodes. Therefore, a pyroelectric detector is AC coupled. It has to be operated at a frequency high enough to prevent the leakage current from playing a role. A temperature change, however, cause charges to move to accommodate for the change of the internal field. The magnitude of the electrical readout depends on the frequency of the input signal. In a crude analysis one can identify two major contributions that determine this frequency dependence, the thermal response and the electrical response of the system. A more rigorous treatment of the problem is given, for example, in [9.2, 73].

A temperature change ΔT can generate a pyroelectric charge Q that is proportional to the surface area of the electrodes A,

$$Q = \gamma_p A \Delta T \,, \tag{9.187}$$

where γ_p is the pyroelectric constant. The temperature change can be calculated by applying solution of the heat balance equation (9.181).

Table 9.4 Total pyroelectric coefficient for different materials at room temperature [9.70, 71]

Material	Pyroelectric coefficient ($\mu C/(m^2\,K)$)
Ferroelectric crystals	
$LiNbO_3$	−83
$LiTaO_3$	−176
$Pb_3Ge_3O_{11}$	−95
$NaNO_2$	−135
$LiNbO_3$	−200
Ferroelectric ceramics	
$BaTiO_3$	−200
$PbZr_{0.95}Ti_{0.05}O_3$	−268
Nonferroelectric crystals	
Tourmaline	−4.0
CdSe	−3.5
CdS	−4.0
ZnO	−9.4
BeO	−3.39

Taking the time derivative and calculating the absolute value yield the temperature change with time

$$\frac{\mathrm{d}}{\mathrm{d}t}(\Delta T) = \left|\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\eta_S \Phi_{p0} R_{th}}{1+\mathrm{i}\omega R_{th} C_{th}}\,\mathrm{e}^{\mathrm{i}\omega t}\right)\right| = \frac{\eta_S \Phi_{p0} R_{th}\omega}{\sqrt{1+\omega^2\tau_{th}^2}}\,. \tag{9.188}$$

Combining the last result with the derivative of (9.187) gives the electric current induced by a sinusoidal temperature change

$$I_{el} = \frac{\mathrm{d}Q}{\mathrm{d}t} = \gamma_p A \frac{\mathrm{d}}{\mathrm{d}t}(\Delta T) = \frac{\gamma_p \eta_S A \Phi_{p0} R_{th}\omega}{\sqrt{1+\omega^2\tau_{th}^2}}\,. \tag{9.189}$$

With this expression the current responsivity $\Re_I$ can be written as

$$\Re_I = \left|\frac{I_{el}}{\Phi_p}\right| = \frac{\gamma_p \eta_S A R_{th}\omega}{\sqrt{1+\omega^2\tau_{th}^2}}\,. \tag{9.190}$$

For the voltage responsivity $\Re_V$ the electrical capacitance C_{el} and the ohmic resistance R_{el} of the detector must be taken into consideration (Fig. 9.53). The voltage V_{el} across the output terminals is then

$$V_{el} = \left|\frac{R_{el} I_{el}}{1+\mathrm{i}\omega\tau_{el}}\right| \tag{9.191}$$

with $\tau_{el} = R_{el} C_{el}$ as the electrical time constant. The resulting voltage responsivity is

$$\Re_V = \left|\frac{V_{el}}{\Phi_p}\right| = \gamma_p \eta_S A R_{th} R_{el} \frac{\omega}{\sqrt{1+\omega^2\tau_{th}^2}\sqrt{1+\omega^2\tau_{el}^2}}\,. \tag{9.192}$$

The frequency response of the system is determined by the values for the thermal and electrical time constants. Usually the thermal response is much slower than the electrical one. At low frequencies the current signal generated by the periodic temperature change increases

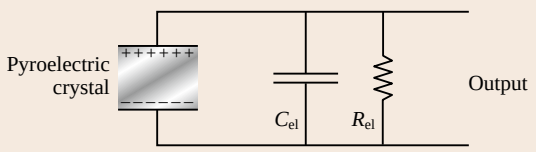

Fig. 9.53 Electrical equivalent circuit for a pyroelectric detector

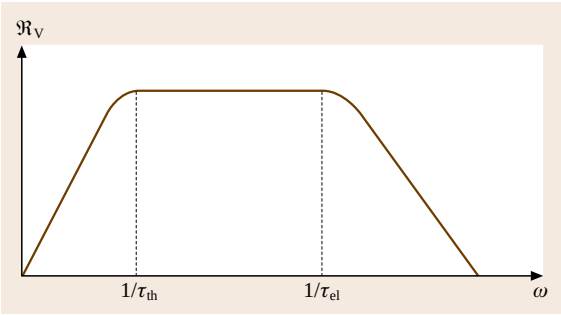

Fig. 9.54 Frequency response of a pyroelectric detector

until it levels off at a threshold of about $1/\tau_{th}$. This behavior is also seen for the voltage response. At higher frequencies ($1/\tau_{el}$), however, the electrical capacitance and ohmic resistance of the detector begin to dominate and the voltage starts dropping (Fig. 9.54).

Specific Detectivity

In the common case that the noise performance of a pyroelectric detector is limited by Johnson noise, the specific detectivity D^* can be obtained using the result for the voltage responsivity (9.192), as well as (9.25) and (9.28)

$$D^* = \frac{\gamma_p \eta_S}{\sqrt{4kT}} A R_{th} \sqrt{A R_{el}} \frac{\omega}{\sqrt{1+\omega^2\tau_{th}^2}\sqrt{1+\omega^2\tau_{el}^2}}\,. \tag{9.193}$$

It is notable that the performance of the system improves linearly with the product of the detector area and thermal resistance and with the square root of the product of the area and shunt resistance.

Detector Design

Depending on the application there are various designs for passive infrared detectors (PIR) using pyroelectric sensors. Figure 9.55 shows a typical single-element detector. Main components are the window, the sensing element, and electronics to read the signal.

Since a pyroelectric detector is a thermal detector the response is mostly flat over the wavelength range. Therefore, in many cases the window material is coated to serve as a filter blocking unwanted parts of the spectrum. To improve the sensitivity it is common to cover the sensing elements with an absorbing layer. Typical materials for this layer are metal blocks or thin metallic films of NiCr, Ti, or Al [9.70].

As sensing elements thin wafers of single crystal or ceramics are common. Recent progress in microfabrication led to the use of thin pyroelectric films on

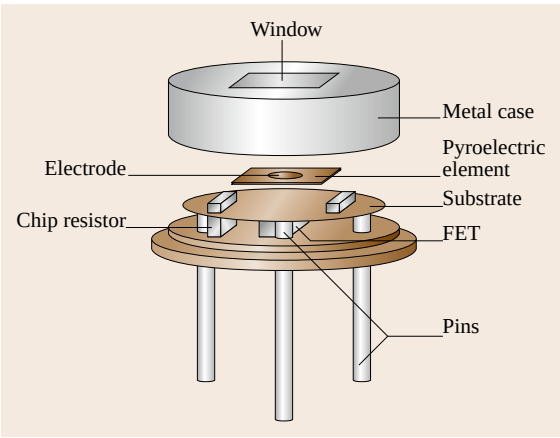

Fig. 9.55 Single-element pyroelectric detector

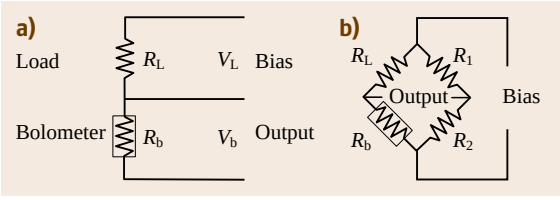

Fig. 9.56a,b Circuit diagram for biasing a bolometer. **(a)** Single load resistor, **(b)** Wheatstone bridge

micromachined substrates [9.74]. To compensate for a drift in ambient temperature two pyroelectric elements are used connected with opposite polarity exposing only one of them to the incoming radiation. Since most pyroelectrical materials are susceptible to microphonics for many of these differential sensors both elements are air-suspended from the substrate in order to decouple from noise sources.

Often the detector is housed in a hermetically sealed transistor outline package (e.g. TO-5, TO-39, or TO-8) to protect it from the environment and to RF shield integrated FETs or operational amplifiers.

Applications

The use of pyroelectrical material to detect infrared radiation is very attractive for many applications because of the following five factors:

- Wide spectral sensitivity
- Availability of pyroelectrical materials covering the temperature range from mK to hundreds of K
- Low power operation
- Fast response
- Low cost.

Combined with a Fresnel lens in a cheap plastic housing millions of PIR detectors are used worldwide for intruder alarms and flame and fire detectors. Other applications are gas analysis and IR spectroscopy, pollution monitoring, laser detectors, and thermal imaging [9.74].

9.11.4 Electrical Resistance-Sensitive Detectors – Bolometers

If the heat generated by the optical flux is changing the electric resistance of the detector the device is commonly called a *bolometer*. In first order approximation the temperature dependence of the resistance R_B of a conductor can be written as

$$R_B = R_0 \left[1 + \alpha_{th}(T - T_0)\right] , \tag{9.194}$$

where R_0 is the conductor resistance value at reference temperature T_0.

In this equation α_{th} denotes the temperature coefficient of the resistance. It is a material constant and can be either positive (e.g. metals) or negative (e.g. semiconductors). In order to detect the resistance change an electrical current must flow through the bolometer. Figure 9.56 shows a simple diagram using only one load resistor (panel a) and a Wheatstone bridge (panel b).

Since the operating current leads to energy dissipation in the detector and the connecting wires, a detailed calculation of the responsivity must take into account a contribution by Joule-heating. Furthermore, depending on the temperature range of operation heating by background radiation may play a role also. In the case of semiconductor bolometers the electrical resistance is not a linear function of the temperature and (9.194) is not valid. The following estimation of the responsivity of a bolometer neglects all these corrections. For this reason it is only a very crude and general description.

The voltage change across the bolometer is assumed to be proportional to the resistance change under illumination

$$\mathrm{d}V_b = I\,\mathrm{d}R_b , \tag{9.195}$$

where R_b is the electrical resistance of the bolometer. Assuming that the approximation (9.194) is valid ($R_b \equiv R_B$), from (9.194) and (9.195) one obtains

$$\mathrm{d}V_b = I\alpha_{th} R_b\,\mathrm{d}T . \tag{9.196}$$

The current through the bolometer and load resistor R_L is $I = V_b/(R_L + R_b)$, which together with (9.190) yields

$$\Re_V = \frac{R_b V_b}{R_L + R_b} \frac{\alpha_{th} \cdot \eta_S \cdot R_{th}}{\sqrt{1 + \omega^2 \tau_{th}^2}} . \tag{9.197}$$

Table 9.5 Resistivity and temperature coefficient of resistivity for different materials at room temperature

Material	Resistivity (10^{-8} Ω m)	Temperature coefficient (10^{-3} °C^{-1})
Silver	1.6	4.1
Copper	1.7	4.3
Aluminum	2.7	4.3
Tungsten	5.4	4.8
Iron	10.1	6.5

Metal Strip Bolometer

In 1880 the bolometer was invented by Langley, who measured the change of resistance of platinum strips due to changes in illumination. Later different metals were used. A typical value for the temperature coefficient α_{th} is +0.5%/°C (Table 9.5).

Thermistors

For many industrial applications, where ruggedness and performance under challenging environmental conditions are mandatory, thermistors are the detectors of choice. Metal oxides, pressed into a small bead, disc, wafer, or other shape, which have been sintered at high temperatures, serve as radiation sensitive elements. The assembly is coated with epoxy or glass and mounted to an electrically insulating thermally conductive material like sapphire. The temperature coefficient is typically around 5%/°C.

Johnson noise is the primary contribution to the noise budget of thermistors. Collecting more light on the detector surface can therefore improve the signal-to-noise ratio. To achieve better light collection many thermistors have a lens added to the detector surface. These devices have a NEP of $10^{-10}\,\mathrm{W/Hz^{1/2}}$ in the spectral range of 1–40 μm for uncooled operation [9.2, 75, 76].

Semiconductor Bolometers

For applications that demand high performance detectors a variety of low temperature semiconductor bolometers have been developed [9.77, 78]. At cryogenic temperatures phonon modes of the bulk material freeze out and the specific heat becomes very small while the temperature coefficient for the resistance increases. Therefore, detectors with very small heat capacitance and high sensitivity are feasible. A good example of such a detector is the Germanium bolometer operated at liquid helium temperatures [9.77]. It can be operated near the theoretical limit between 5 μm and 100 μm. Due to the low heat capacity Germanium bolometers are very fast thermal detectors with a typical response time of 400 μs. The voltage responsivity of such a device is around $5 \times 10^{-3}\,\mathrm{V/W}$.

An even better time response than for the simple semiconductor bolometer can be realized if germanium is just used for the temperature sensor but the large area absorber (typically bismuth) is placed on a sapphire or diamond substrate that is in thermal contact with the semiconductor. The heat capacity of the electrically non-conducting substrate is orders of magnitudes smaller than it would be if the whole assembly were made of germanium [9.77].

Superconductive Bolometers

The dramatic change of the electrical resistance of a superconductor makes these devices very sensitive to small temperature changes. However, for metallic superconductors the transition from a superconducting to a normal conducting state occurs within a narrow

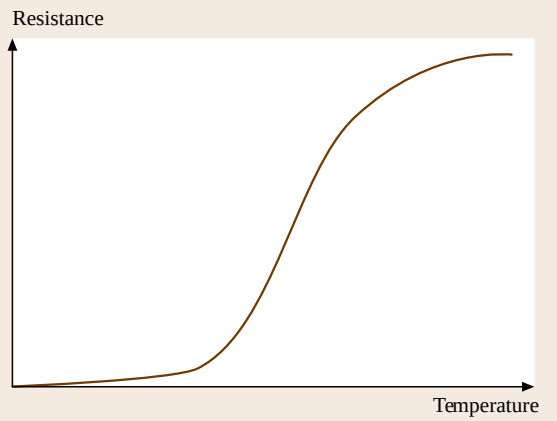

Fig. 9.57 Transition region of a superconductor

transition region at very low temperatures (≈ 4 K). Therefore, liquid helium cooling and a temperature control with milli-kelvin resolution are required for proper operation. Thermometers made of high temperature superconducting material e.g. niobium nitride or yttrium barium copper oxide are much easier to handle. With a more gradual transition at about 77 K, only liquid nitrogen is required for cooling. Figure 9.57 shows a typical *R–T* characteristic for the superconductive bolometer.

Beside the bolometric mode superconducting detectors can also be operated beyond the transition temperature (non-equilibrium mode) and in the so-called photon-assisted tunneling mode. In the latter case a change in the *I–V* characteristics of the junction has been detected.

9.12 Imaging Systems

Imaging arrays are usually built by combining photoconductors or photodiodes described above with electronic readouts. Imaging systems are very often referred to as focal plane arrays (FPA) – an assembly of individual detector picture elements (pixels) located at the focal plane of the imaging system. In general, the architectures of FPAs may be classified as monolithic and hybrid.

In the monolithic approach, some of the multiplexing is done in the detector material itself rather than in an external readout circuit. The basic element of a monolithic array is a MIS (MOS) capacitor. There are a few obvious advantages to the monolithic structure, principally in the simplicity and lower cost associated with a directly integrated structure. For visible and infrared detection, monolithic structures like CCD and CMOS arrays can be built in silicon to form arrays with millions of high performance pixels [9.79].

Ultraviolet and infrared imagers are most commonly built with a hybrid structure. Visible hybrids have also been built for specific applications (e.g. p-i-n photodiode arrays). Hybrid FPAs detectors and multiplexers are fabricated on different substrates and mated with each other by flip-chip bonding or loophole interconnection. In this case, the detector material and multiplexer can be optimized independently. Indium bump, solder bump, or gold stud bump bonding of readout electronics provides for multiplexing the signals from thousands of pixels onto a few output lines, greatly simplifying the interface between the sensor and the system electronics. In infrared, the large dimension, multiple elements hybrid arrays with number of pixels over several millions are commonly used. Each element of IR array performs near the fundamental photon noise limit within the spectral range between 1 and 40 μm. Materials used to build IR FPAs include PtSi (Schottky-barrier array), InSb, QWIP-based arrays ($GaAs/Al_xGa_{1-x}As$, $In_{0.53}Ga_{0.47}As/In_{0.52}Al_{0.48}As$, $In_{0.53}Ga_{0.47}As/InP$, InGaAsP-based quaternary QWIPs, etc. [9.34], and HgCdTe.

9.12.1 CCD Arrays and CMOS Arrays

In Sect. 9.9 we described the principles of operation and main properties of charge transfer sensors. Here a comparison of CCD and CMOS arrays is presented.

CCD technology has been able to provide top-level performances for detection, but at the cost of several drawbacks for the user. For the best thinned and backside illuminated products, which have a risk associated with the limited number of procurement sources, it remains the first choice technology for very high-end applications. On the other hand, CMOS detectors have intrinsic advantages (low power consumption, readout rate, noise, radiation hardness, integration capability) that make them well suited for several applications. Due to recent efforts in developing optimized detectors compatible with CMOS core process, CMOS can provide enhanced quantum efficiency (although it still remains weaker than CCD for that aspect) [9.61]. Table 9.6 compares some of the important features and properties of CCD and CMOS imaging systems.

9.12.2 p–i–n Photodiode Arrays

Multiple elements, 2-D p-i-n and avalanche photodiode arrays have a virtual monopoly in some fields of medical imaging, light detection and ranging (LIDAR), 3-D laser radar (LADAR) systems, laser vibrometers, etc. What makes p-i-n and avalanche photodiode arrays unique is their ability to provide a fast access to any single pixel of the array, high dynamic range, high frequency bandwidth (up to 1 GHz and even more), and possibility to provide a high-speed parallel readout regime.

Table 9.6 CCD versus CMOS feature and performance comparison

Feature and performance	CCD	CMOS
Signal out of pixel	Electron packet	Voltage
Signal out of chip	Voltage (analog)	Bits (digital)
Signal out of camera	Bits (digital)	Bits (digital)
Fill factor	High	Moderate
Amplifier mismatch	N/A	Moderate
System noise	Low	Moderate to high
System complexity	High	Low
Camera components	PCB + multiple chips + lens	Chip + lens
Responsivity	Moderate	Slightly better
PlaceNameDynamic range	High	Moderate
Uniformity	High	Low to moderate
Speed	Moderate to high	Higher
Antiblooming	High to none	High
Biasing and clocking	Multiple, higher voltage	Single, low-voltage

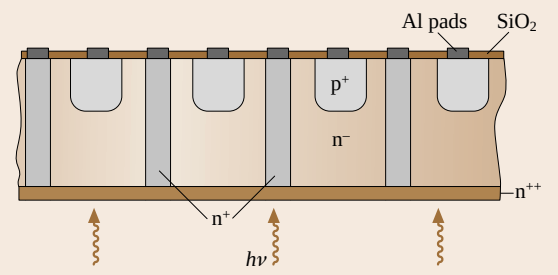

Fig. 9.58 Cross section of the p-i-n photodiode array manufactured on a thin Si wafer (after [9.80])

State of the art p-i-n photodiode arrays with very high quantum efficiency in virtually the whole visible and near infrared spectral range were designed on thin (30–100 μm) Si wafers with back-illumination capability [9.80–82]. The features of the structure shown in Fig. 9.58 – a narrow neutral region width, isolation n^+ diffusion between adjacent pixels, and possibility to control the gaps width – provide unique properties that make arrays promising for many applications. In particular, the rise and fall time of ≈ 1 ns with a small reverse bias of few volts is characteristic for the pixels of such photodiode arrays. The other important feature of the design shown in Fig. 9.58 is a very low DC and AC crosstalk between adjacent elements.

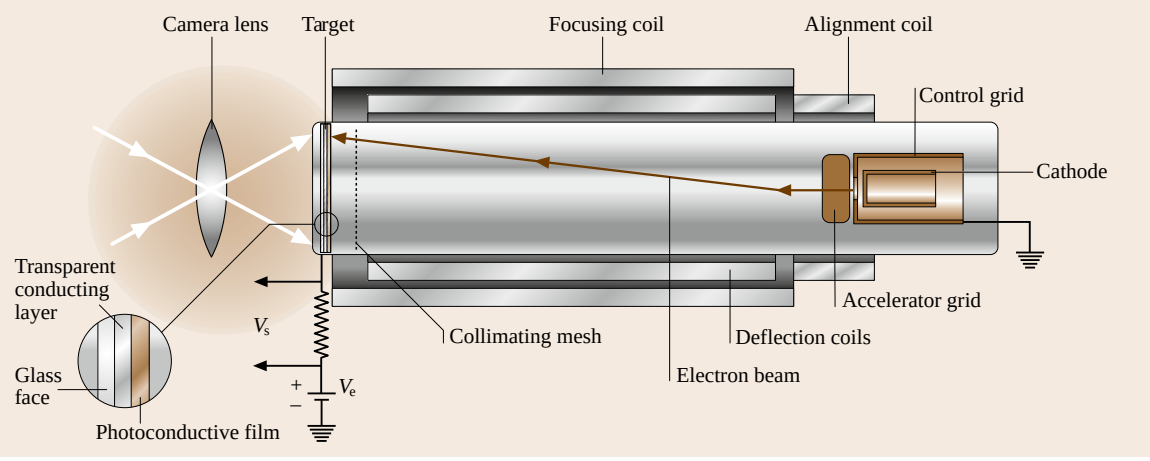

Fig. 9.59 Cross section of a vidicon

9.12.3 Vidicon

A vidicon is a photoconductive detector that was used in the first TV cameras. It consists of a light sensor and an electron beam as readout inside a vacuum tube (Fig. 9.59). The photoconductive material, typically antimony sulfide (Sb_2S_3), is suspended in the form of little beads inside a dielectric matrix (mica). The image is focused through a light entry window and a transparent and conductive layer (signal plate) held at positive potential onto the photoconductive material (cathode) at near-ground potential. There electron hole pairs are generated and the negative charge carriers are removed by the field towards the anode. An electron beam scans the backside of the cathode thus depositing electrons to the illuminated positive areas. This generates a capacitively coupled signal in the signal pate.

9.13 Photography

Photography is undoubtedly one of the oldest known methods to detect light and create images. The major streams of photography development include black-and-white photography, color photography, and holography. This section describes black-and-white and color photographic detectors, leaving the detailed description of optical holography methods for a separate chapter.

Photography is a process based on chemical changes triggered by a photoexcited electron in certain kinds of semiconductors and dye molecules. These changes accumulate during exposure of photographic film to light forming a latent image. The following chemical processing amplifies the image making it visible.

The composition of photographic films and developing chemicals depends on whether one wants to create a negative or positive image on the transparent film, or whether the positive image on a solid substrate is required. Below we will consider some basic processes and associated physics of the photographic images formation.

9.13.1 Black-and-White Photography

Basics and Image Creation

Common photographic materials are based mainly on silver halide grains (microcrystals of AgBr, AgCl, and AgI), which are the active parts of the photographic detectors. Photographic films consist of multiple layers, each performing its specific functions [9.83]. The silver halide grains are suspended in a gelatin binder (creating the emulsion) and coated onto a glass or plastic film for mechanical stability. The interface layer is used to improve bonding of gelatin to glass, and the protective gelatin layer is usually applied on the top to protect grains. The backside of the glass or plastic film is covered with an absorptive layer to avoid light reflection from the rear surface.

The photographic process is centered on the silver halide grains. Photon absorption in the silver halide results in creation of the electron–hole pair with an electron in the conduction band and hole in the valence band. The process may be described with the following equation (assuming Br as a halide atom)

$$h\nu + \mathrm{Br}^- \rightarrow \mathrm{Br} + \mathrm{e}^- , \tag{9.198}$$

in which we took into account that silver halides are the ionic crystals and negative charge is associated with Br, and the right-hand side means that the photoexcited electron can move freely in the conduction band across the AgBr crystal structure. The photo-induced hole at the bromine atom can migrate to the grain surface and react with the gelatin, or it can couple with another hole forming a bromine molecule. In either case the bromine atom is excluded from the further reactions.

At the same time, photoelectrons may be trapped by silver atoms

$$\mathrm{e}^- + \mathrm{Ag}^+ \Leftrightarrow \mathrm{Ag} , \tag{9.199}$$

which can act as a trap for a second electron,

$$\mathrm{Ag} + \mathrm{e}^- \rightarrow \mathrm{Ag}^- . \tag{9.200}$$

The resulting negative ion combines with a positive silver ion from the crystal structure producing a stable two-atom silver molecule

$$\mathrm{Ag}^- + \mathrm{Ag}^+ \rightarrow \mathrm{Ag}_2 . \tag{9.201}$$

This cluster is still not developable. In further reactions, a silver molecule (9.201) can trap additional positive silver ions from the crystal and photoexcited electrons forming thereby the cluster with either three or four Ag atoms. The center with a critical size of three or four silver atoms can catalyze the further reduction of silver ions to silver in the subsequent chemical pro-

Table 9.7 Experimental E_g values (in eV) for AgF, AgCl, AgBr, and AgI crystals

Halide	Indirect transition $\Gamma \leftarrow L$	Direct transition at Γ
AgF	2.8 ± 0.3 [9.84]	4.63 [9.84]
AgCl	3.25 [9.85]	5.15 [9.86]
AgBr	2.69 [9.85]	4.29 [9.86]
AgI	2.0 ± 0.3	3.0 ± 0.2

cessing, thus providing the nucleation for the latent image.

Visualization (amplification) of a latent image is accomplished by immersing the exposed film in a chemical reducing agent – the so-called developer. The aggregates of silver atoms serve as electrodes and conduct electrons from the reducing agent to the grain, promoting growth of the silver atom aggregate. The final amount of silver atoms in the aggregate is over 10^7, which makes them visible and remaining silver ions are washed away.

Spectral Response

The primary events in photography are the light absorption by the semiconductor microcrystals of silver halides. Silver halides form face centric cubic crystals with the indirect lowest energy band gap [9.87]. Table 9.7 summarizes the energies for the lowest indirect and direct band gap transitions for a few silver halide crystals.

Indirect absorption provides a reasonably high photoexcitation rate in the short wavelength spectral range below 500 nm. The overall efficiency of films in the UV spectral range is reduced due to strong gelatin absorption at $\lambda < 250$ nm. Response can be extended farther into the ultraviolet by using extremely thin gelatin coating on top of the film.

The extension of films' response to red is achieved by dye sensitization [9.83]. In sensitized films, photons photo-excite the dye molecule, which is attached closely to the silver halide grain. There are two possibilities for the photoexcited dye molecule to create conduction electron in the halide crystal grain. One is through a direct electron transfer process from dye molecule to the grain [9.88, 89], the other is through the resonant and non-resonant energy transfer processes between the photoexcited dye molecule and silver halide microcrystal [9.90–92]. In the spectral region of dye sensitization, only the grain surface, as opposed to the entire grain volume, takes part in the initial photon detection.

9.13.2 Color Photography

Additive and Subtractive Processes

Additive and subtractive processes relate the properties of light to color. The additive process is based on the production of color by the combination of two or more primary colors. Thus, red, green, and blue colors variously combined produce all colors of the visible spectrum.

However, the additive process cannot be used in dye superimposed systems because one layer of an additive primary colored dye removes the whole complementary portion of the light spectrum and a superposition of two different primary-color dyes will always produce a black color.

The subtractive process is based on the production of color by either subtraction or absorption of primary colors. The three primary subtractive colors are yellow, magenta, and cyan, and they are complementary to the additive colors. They each absorb only one primary color. Yellow color absorbs blue light, cyan absorbs red light, and magenta absorbs green light. A superposition of two layers with different complimentary dies will always produce a single primary color. Like the majority of photographic film processes, the concept of subtractive color is utilized in the dye-coupled process.

Basics and Image Creation

A variety of methods has been used for color photography, but most modern approaches are based on stacking of a number of emulsion layers with color couplers [9.83, 93]. Figure 9.60 exemplifies a process of color image creation using a positive film. Assume that all layers forming the film are uniform and the left-hand side of the film is exposed to the red light, the center is illuminated with green light, and the right-hand side is illuminated with blue light. The top layer of the structure is an emulsion with bare silver halide grains, which respond to blue light only. A yellow filter removes the blue light protecting the underlying emulsion layers against their exposure to blue light. This means that those two underlying layers can be exposed to light containing green and red photons only. One of the underlying layers is sensitized with a dye that responds to green only, whereas the other emulsion layer is sensitized with the red-sensitive dye. Thus, the three primary colors are recorded separately in the three layers of emulsion (Fig. 9.60a).

When being developed, the yellow filter is removed and latent image sites are reduced by color developing agents. The reaction of oxidized color developing

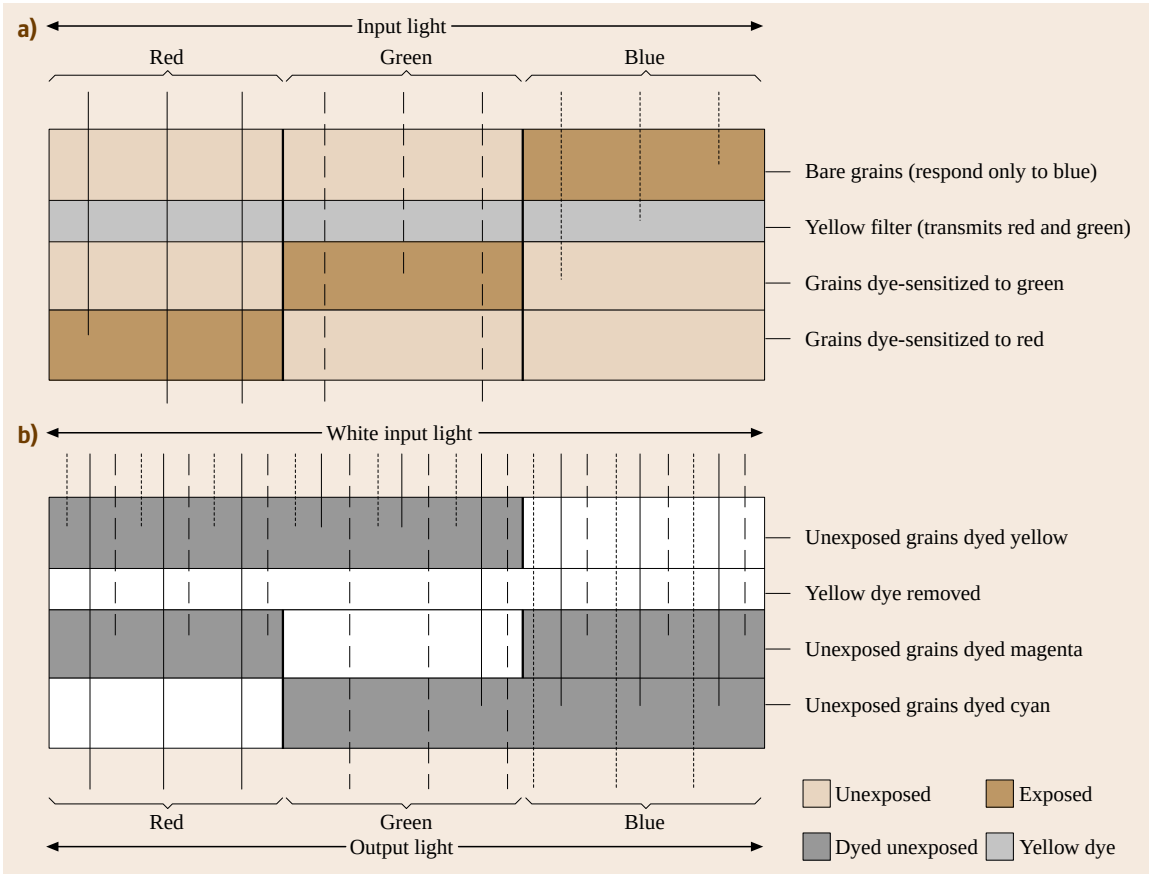

Fig. 9.60a,b Example of forming a color image using a positive film: **(a)** exposure of a film to the three primary colors; **(b)** development of positive film

agents with color couplers in the emulsion produces a color dye in the way described by Fig. 9.60b. First, a development of the exposed silver halide grains amplifies the latent image. After that a development with color couplers forms the complementary dye in the unexposed grains in each layer. The yellow dye is produced in the unexposed grains of the top, blue-sensitive emulsion layer. Magenta dye is produced in the unexposed grains of the middle, green-sensitive layer, and cyan dye is produced in the unexposed areas of the bottom, red-sensitive layer. At the end of the process, all silver has been washed out and only the image color dyes remain. As a result, the areas of the film containing stacked yellow and magenta dye layers will transmit or reflect red light (left-hand side of Fig. 9.60b) – the same color that originally illuminated this portion of the film, compare with the left-hand side of Fig. 9.60a. In a similar way, the middle portion of the film in Fig. 9.60b will transmit or reflect green light, whereas the right-hand side of the film will be transparent and reflective to the blue light. Thus, the colors of the illumination will be reproduced directly.

9.13.3 Properties and Figures of Merit

The properties of photographic films and images are usually described using qualities that have been historically proved to be adequate for the characterization of photographic images. Below we summarize some of the most important properties and figures of merit.

Detective Quantum Efficiency (DQE)

The latent image formation and development process usually introduce some degradation to the input signal producing either loss of information or addition of noise. The detective quantum efficiency describes this

degradation in terms of a ratio of the number of imaginary signal photons N_{out} that, with a perfect detector system, would produce the same information content in the output signal as is received from the real system to the actual number N_{in} of input signal photons [9.64]

$$\mathrm{DQE} = \frac{N_{out}}{N_{in}} = \frac{(\mathrm{S/N})^2_{out}}{(\mathrm{S/N})^2_{in}} , \qquad (9.202)$$

in which the right-hand side assumes the Poisson photon statistics. It is obvious from (9.202) that DQE is just the external absorptive quantum efficiency η_{ex}, defined above in Sect. 9.1.4 (9.22) as a probability that the photoelectron is produced when the photon is incident on the detector, if there is no subsequent degradation of the signal-to-noise ratio.

In reality, the DQE of photographic materials is much lower than the absorptive quantum efficiency η. In average, up to 20 photons have to be absorbed by a grain in a short period of time to provide 50% grain developing probability. This cause alone reduces the quantum efficiency by a factor of 20 at least. Two other effects that reduce DQE are the non-uniform distribution of grains in the emulsion film and variations in grain properties. These two effects may be expressed quantitatively as the granularity of the film, which refers to the variations in response measured through a tiny fixed aperture for a film with uniform exposure. As a result of the combination of all effects, the real DQE for the photographic plate is usually well below 5%.

Some of the methods to improve the quantum efficiency of the photoinduced silver cluster formation in silver halide microcrystals are based on doping of silver halide crystals with the dopants that inhibit holes activity suppressing the electron–hole recombination [9.94].

Optical Density and Spectral Sensitivity

The optical density D of the image in the photographic film characterizes the capability of the emulsion layers to transmit light

$$D = -\log T , \qquad (9.203)$$

where T is the transmittance defined as the amount of light that passes through the developed film to the incident amount of light. The density in photography can be measured as either the diffuse density (measured over a hemisphere from an incident collimated beam) or specular density, which refers to density measured over a certain solid angle only. Diffused density is usually used to compare different photographic films.

In photography, sensitivity may be measured as an absolute value or as a relative value as the ratio of the energy required to expose a material compared with some reference. Sensitivity may be measured as the reciprocal of exposure, expressed in radiant energy flux per unit area Φ_p during the exposure time t, required to produce a certain density D_0. The definition of the spectral sensitivity of photographic emulsion is [9.83]

$$S(\lambda) = \frac{1}{H(\lambda)} , \qquad (9.204)$$

in which $H = \Phi_p t$.

Characteristic Curve

The photographic film response is usually non-linear with the light level, which is described by the characteristic curve shown in Fig. 9.61. The center portion 3 of the curve describes the condition in which the net response of the film depends only on the total number of photons received (reciprocity law). In the two non-linear regions, the reciprocity law fails.

At low exposure (underexposure levels, see portion 2 of the characteristic curve), which occurs either at very low exposure time or at very low photon arrival rates, electrons may escape from the trapping centers before a stable development center forms. Note that the characteristic curve usually exhibits a non-zero density even at zero exposure, arising from both the background radiation from different sources and chemical development without receiving any light. This region of exposure levels is called the gross fog level – see portion 1 of the characteristic curve in Fig. 9.61.

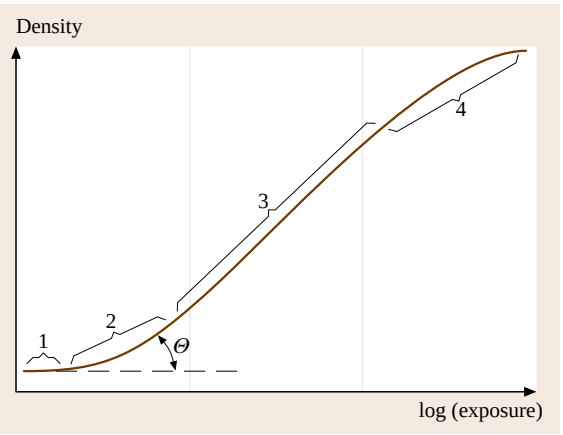

Fig. 9.61 Typical characteristic curve of the film. Portions of the curve describe different exposure levels: (1) gross fog level; (2) underexposure level; (3) level of normal exposures; (4) level of saturation

High photon rates and long exposure times produce saturation and non-linearity – see region 4, overexposure in Fig. 9.61.

Speed

The speed of photographic films can be characterized assuming that the grain must absorb a certain number of photons to become developable [9.64]. The referred number of photons depends on the grain size. Thus, there is a correlation between the speed and the grain size. For bare silver halide emulsions (which are sensitive below 500 nm), the whole volume of the grain absorbs and the speed of the film is the grain volume times the absorption coefficient. In the case of dye-sensitized grains, only the surface is effective at absorbing photons, so the speed is proportional to the grain surface. For very small grains with the diameter close to the wavelength, diffraction effects reduce the absorption efficiency and hence, the emulsion speed.

To improve film speed at low light levels special efforts in emulsion sensitization and illumination optics improvements must be applied.

Contrast and Noise

The slope $\gamma = \tan\theta$ of the linear portion of the characteristic curve in Fig. 9.61 characterizes the contrast of the film. The higher the contrast of the film, the larger the separation between the signal and noise. The achievable contrast is generally higher for emulsions with smaller grains, partially because small-grained emulsions are more homogeneous in grain size.

Random variations in the number of grains per resolution element, variations in the grain properties itself, and the stochastic nature of the processes of light absorption, electron transfer, and silver aggregate growth lead to density non-uniformities and the detection process noise.

Assuming that for each given exposure the density is defined, the output signal-to-noise ratio can be written as the ratio of exposure H to exposure uncertainty (noise) σ_H, $(S/N)_{out} = H/\sigma_H$ [9.64]. Noting that for any small exposure and density variations, the relationship between the exposure uncertainty σ_H and density uncertainty σ_D can be expressed as $\sigma_H/\sigma_D \approx dH/dD$, and taking into account that from Fig. 9.61 the contrast $\gamma = dD/d(\log H)$, the signal-to-noise ratio yields

$$(S/N)_{out} = \frac{H}{\sigma_H} = \frac{H}{\sigma_D}\frac{dD}{dH} = \frac{H}{\sigma_D}\frac{dD}{d(\log H)} = \frac{H}{\sigma_D}\gamma\,, \tag{9.205}$$

where we have taken into account that $d(\log H) = dH/H$.

For Poisson photon statistics, the signal-to-noise ratio for the incident information content is

$$(S/N)_{in} = \frac{\Phi_p t}{\sqrt{\Phi_p t}} = \sqrt{\Phi_p t} \equiv \sqrt{H}\,, \tag{9.206}$$

where Φ_p is the radiant energy flux per unit area during the exposure time t. Hence, the detective quantum efficiency can be written as

$$DQE = \frac{H\gamma^2}{\sigma_D^2}\,. \tag{9.207}$$

Resolution and Modulation Transfer Function (MTF)

Exposing the photographic film to a pattern of alternating black and white lines and determining the minimum distinguishable spacing of the line pairs provides the measure of the film resolution. This method has its shortcomings since the film is usually a part of the imaging system that includes image-forming optics, and it is difficult to separate effects from different components of the whole system.

A more general concept is to use the modulation transfer function (MTF) for characterization of the quality of each component of the imaging system. More specifically, MTF is the magnitude response of the optical system to a variety of spatial frequencies $\{x\}$ [9.95]. Performance-wise, MTF characterizes the modulation depth of the image $M_{out}(x)$ relative to that of the incident information packet $M_{in}(x)$,

$$MTF(x) = \frac{M_{out}(x)}{M_{in}(x)}\,. \tag{9.208}$$

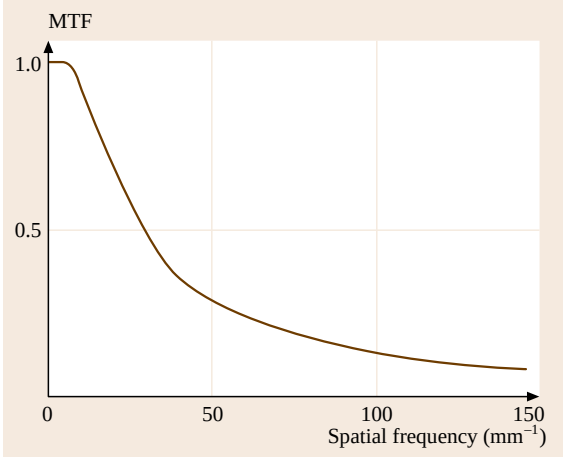

Fig. 9.62 MTF of a typical photographic film

A typical example of MTF for a photographic emulsion is presented in Fig. 9.62. It is possible to enhance the detector sensitivity to some particular spatial frequencies, resulting in MTF of more complex shape than that shown in Fig. 9.62.

MTF can be calculated as a Fourier transform function (FTF) of the source object. For example, for a single ideal, rectangular-shaped photodetector pixel, where the one-dimensional spatial response is described with a π-function, the theoretical limit for MFT is a sinc function ($\mathrm{sinc}(x) = \sin(x)/x$). In practice, the closer the FTF of a photodetector spatial response is to the sinc function, the better are the imaging properties (resolution, etc.) of the photodetector. Zeros of the FTF functions correspond to the harmonics of the fundamental frequency, which is the active area physical size in the case of the photodetector.

Using MTF is advantageous because the MTF of an entire linear optical system can be determined by a simple multiplication of MTFs of its components. The overall resolution capability of complex optical system can be easily determined in this way.

9.14 Recent Advances in Optical Detectors

Recent development in device technologies as well as in fundamental sciences facilitated designing of new types of photodetectors as well as critical improvements to already existing ones. This section briefly reviews some of the most important recent advances in the field of optical detectors.

9.14.1 Polymer-Based Optical Detectors

Organic photovoltaic diodes based on semiconducting conjugated polymers have been studied for many years but recently their development received an additional stimulus caused by demands of the solar cells industry [9.96].

Conducting polymers generally exhibit an alternating single bond–double bond structure (conjugation) based on sp^2-hybridized carbon atoms, which leads to a highly delocalized π-electron system with large electronic polarizability. This enables both absorption within the visible light region, due to π–π^* transitions between the bonding and anti-bonding p_z orbitals, and transport of non-equilibrium charges – two requirements necessary for a semiconductor to work as a photodiode/photoconductor. The π–π^* transition corresponds to the optical excitation from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). The optical band gaps of most conjugated polymers are around 2 eV. Charge carrier mobilities in organic semiconductors are generally lower than those of their inorganic counterparts. This drawback is partly balanced by high absorption coefficients and long carrier lifetimes, for example in polymer–fullerene blends.

The structures of three conjugated polymers commonly used in polymer-based photodetectors are shown in Fig. 9.63. They are hole-conducting, donor-type polymers MDMO-PPV (poly[2-methoxy-5-(3,7-dimethyloctyloxy)]-1,4-phenylenevinylene), P3HT (poly(3-hexylthiophene-2,5-diyl)), and PFB (poly[9,9′-dioctylfluorene-*co*-bis-*N*,*N*′-(4-butylphenyl)-bis-*N*,*N*′-phenyl-1,4-phenylenediamine]). Typical electron-conducting, acceptor-type polymers are CN-MEHPPV (poly[2-methoxy-5-(2′-ethylhexyloxy)]-1,4-(1-cyanovinylene)-phenylene) and F8BT (poly(9,9′-dioctylfluorene-*co*-benzothiadiazole)).

Basic Principles and Device Architectures

The basic principle of photodetection using conjugated polymers relies on photo-induced formation of excited states – excitons – followed by charge separation and

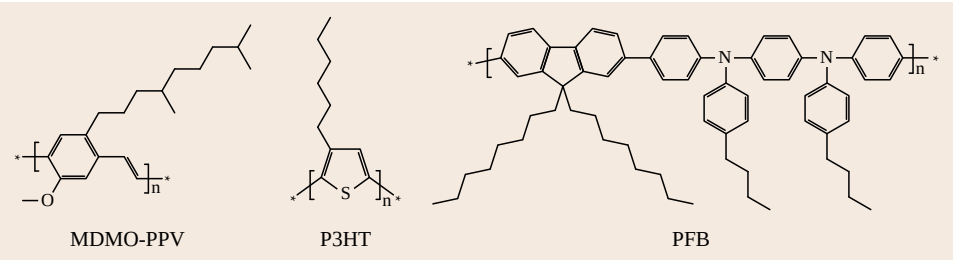

Fig. 9.63 Structures of conjugated polymers used in polymer-based photodetector technology

transfer of non-equilibrium electrons and holes over the chain of acceptors and donors, respectively, to the electrodes. Exciton binding energies range between 0.1 and 1 eV; therefore the dissociation mechanism requires up to ≈ 1 eV to separate charges. In single layer organic solar cells this may be achieved by the strong electric field present within the depletion region of a Schottky contact. In polymer photodetectors, exciton dissociation relies on gradients of the potential across a donor/acceptor interface, which results in the photoinduced charge transfer between these materials [9.97]. The driving force required for this charge transfer is the difference in ionization potential of the excited donor and the electron affinity ψ of the acceptor, minus the Coulomb correlations. As a result of the photoinduced charge transfer, the positively charged hole remains on the donor material whereas the electron is located on the acceptor.

When holes and electrons are separately transported within physically different regions, the probability of charge recombination is reduced considerably, leading to long charge carrier lifetimes. Since charge carrier mobilities in conjugated polymers are around $10^{-4}\,\mathrm{cm}^2/(\mathrm{V\,s})$, long carrier lifetimes are required for the extraction of all photoexcited charge carriers from the photoactive layer. The charge carrier extraction is driven by internal electric fields across the photoactive layer caused by the different work function electrodes for holes and electrons.

In most cases the operation of a photodetector based on conjugated polymers may be explained using the simplified model of a Schottky or metal–insulator–metal diode, in which a thin layer of polymer is sandwiched between two metals with different work functions (Fig. 9.64). The selectivity of charge injection/extraction into/from the molecular HOMO or LUMO levels ensures the rectifying diode behavior of these organic devices. When external bias is applied, different working regimes of these devices may be obtained [9.96].

The simplest schematic of a polymer-based photodetector is presented in Fig. 9.65a. The photoactive layer is sandwiched between a transparent indium tin oxide (ITO) covered substrate and a reflective aluminum back electrode. Illumination takes place from the ITO side of the device. The two electrodes may be further modified by the introduction of a PEDOT:PSS (poly[3,4-(ethylenedioxy)thiophene]:poly(styrene sulfonate)) coating on the ITO side and a lithium fluoride (LiF) underlayer on the aluminum side, thereby improving the charge injection. In single layer (single polymer material) devices, only excitations generated close to the depletion region W of the Schottky contact formed by the aluminum electrode and polymer layer may lead to separated charge carriers as a result of the limited exciton diffusion length (Fig. 9.65b). Therefore, only a narrow active region contributes to photocurrent generation.

Bilayer polymer (polymer–polymer) devices apply the donor–acceptor concept, in which the exciton is dissociated at the interface between the donor and acceptor polymers, leading to holes on the donor and electrons

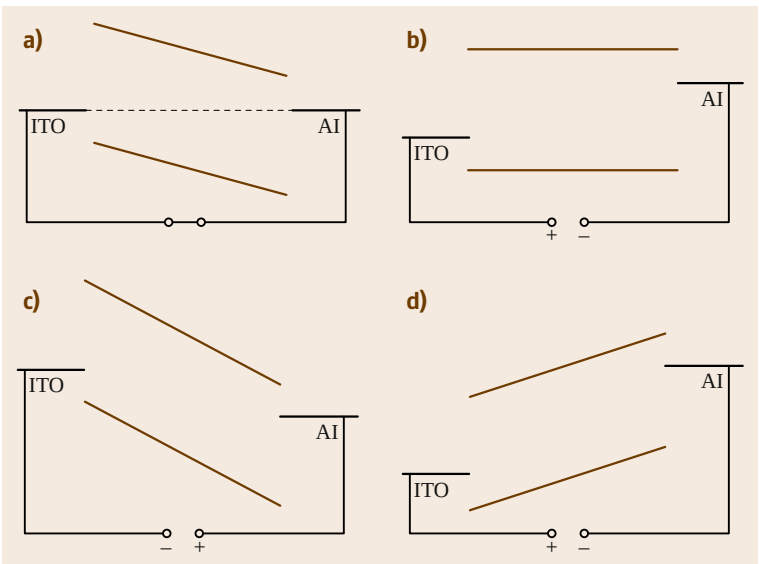

Fig. 9.64a–d Schematic band diagram for organic semiconducting layers sandwiched between two metallic electrodes (indium–tin oxide (ITO) and aluminum (Al)). **(a)** Short circuit condition, **(b)** flat band condition, **(c)** reverse bias, and **(d)** forward bias

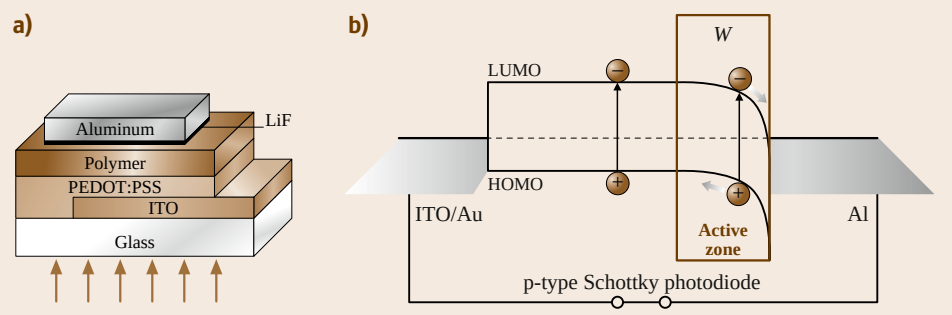

Fig. 9.65 **(a)** Simplest schematic design structure of a polymer-based photodetector. **(b)** Schematic band diagram of a single-layer polymer photodiode in short-circuit mode

on the acceptor. Thus, the different types of charge carriers may travel independently within separate materials, bimolecular recombination is suppressed, and the photocurrent in such devices exhibited a rather linear behavior with light intensity. However, bilayer devices also suffer from a limited width of an active zone.

Polymer-based photodetectors with a bulk heterojunction overcome the above limitation. In these devices, the donor and acceptor materials are thoroughly blended throughout the bulk. This way, photogenerated excitons do not need to travel long distances to reach the donor/acceptor interface, and charge separation occurs throughout the whole depth of the photoactive layer, extending the active zone throughout the volume. The bulk heterojunction concept has led to major improvements of the quantum efficiency.

Polymer–Polymer Optical Detectors

Polymer–polymer photodetectors employ two different polymers as donor and acceptor components in the photoactive layer. These two polymers require a molecular energy level offset between their HOMO and LUMO levels to enable a photoinduced charge transfer. Since their molecular levels are close to each other, polymer–polymer devices allow high open circuit voltages to be reached. Such devices may be built using either the bilayer or bulk heterojunction design. For example, the bulk heterojunction devices may be prepared from blends of two poly(*para*-phenylenevinylene) (PPV) derivatives: MEH-PPV (poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene]) as the donor component and cyano-PPV (CN-PPV) as the acceptor component. In the other example, the active region consists of alternating thin layers of donor–like polymer copper phthalocyanine (CuPc) and acceptor-like polymer 3,4,9,10-perylenetetracarboxylic bis-benzimidazole (PTCBI), with the first CuPc layer in contact with the anode [9.98]. Such blends show largely increased photocurrent and quantum efficiency in comparison with single component devices. Comprehensive reviews of the state-of-the art in polymer–polymer optical detectors is given in [9.96, 98, 99].

Polymer–Fullerene Optical Detectors

Both the bilayer and bulk heterojunction structures of polymer-based photodetectors were realized using a conjugated polymer as one component and fullerene (C_{60}) or its derivatives as the other component [9.100–102]. In these devices, C_{60} is an electron acceptor, whereas various conjugated polymers can be used as electron donors – for example, MEH-PPV or PPV. In the next step of development a side group was attached to the C_{60} to allow for solution processing due to increased solubility in common organic solvents. This new compound – PCBM – currently provides the best performances in polymer–fullerene photovoltaic devices.

A further improvement of MDMO-PPV-based bulk heterojunctions was achieved by the application of a new C_{70} fullerene derivative, which was substituted with the same side chains as PCBM and is therefore called [70]PCBM. Due to the reduced symmetry of C_{70} as compared to the icosahedral symmetry of C_{60}, more optical transitions are allowed and thus the visible light absorption is considerably increased for [70]PCBM. This led to an improved external quantum efficiency (EQE) of MDMO-PPV-based photodetectors reaching up to 66%.

Multiple studies showed that a large scale phase separation as well as the difference in the material's phase percolation and thus charge transport properties influence the photovoltaic performance of polymer–fullerene photodetectors (see [9.96] for a review). As such, it becomes evident that the charge carrier mobility measured in these devices must be a function of the blend morphology. Furthermore, the electron and hole carrier mobilities strongly depend on the

polymer–fullerene blending ratio. Moreover, the hole mobility of the donor polymer is increased considerably in blends with fullerenes. The polymer–fullerene devices represent the most widely studied concept of polymer-molecule organic/inorganic hybrid photovoltaic detectors to date. More information on hybrid organic/inorganic photodetector is given in the following section.

9.14.2 Hybrid Organic/Inorganic Optical Detectors

Hybrid photodetectors are currently designed using a mix of nanostructures of both organic and inorganic materials, combining unique properties of inorganic semiconductor nanoparticles with properties of organic/polymeric materials. Due to high absorption coefficients and the optical band gap tunability by particle size confinement effect in inorganic semiconductor nanoparticles, such detectors have proved their advantages for photovoltaics applications. In addition, low cost synthesis, processability and versatile manufacturing of thin film devices make them attractive for other large-scale applications. Hybrid photovoltaic detectors are manufactured using different concepts such as solution-based and solid state dye-sensitized optical detectors, as well as hybrid detectors using the bulk heterojunction concept with different nanoparticles such as TiO_x, ZnO, ZnSe, ZnTe, CdSe, CdS, PbS, PbSe, $CuInS_2$, and other compounds [9.103, 104].

Solution-Processed, Dye-Sensitized Optical Detectors

The realization of solution-processed photodetectors based on conjugated polymers was first reported in 1994 [9.105]. The photodiodes were built using composite MEH-PPV-C_{60} (fullerenes), spin-coated on an ITO covered glass substrate followed by metal evaporation of the cathode. The devices were sensitive to visible and ultraviolet light and demonstrated responsivity of 0.3 A/W across this spectral range. C_{60} allowed extending the sensitivity to 700 nm. The required applied bias of the device was 10 V.

A different approach to build near infrared detectors was based on dye-sensitized photovoltaic detectors [9.106]. The device consisted of a nanoporous TiO_2 layer infiltrated with various anionic dyes that acted as the light-absorbing material. The heterojunction was formed at the interface of the dye with TiO_2; upon illumination, the electrons were extracted through the TiO_2 and holes via a CuSCN overlayer used as a hole transport layer. The nanoporous TiO_2 was chosen to increase the interface area of the heterojunction, thereby leading to higher external quantum efficiency. The sensitivity of the device was extended to 950 nm. The reported responsivity was limited to ≈ 2 mA/W; the specific detectivity of the device was reported as $D^* \propto 10^{10}$ Jones.

To overcome the carrier mobility bottleneck in conjugated polymers that limits their temporal response to several tens of microseconds, another class of hybrid thin-film photodetectors has also been proposed. These organic-based photodetectors consist of small organic molecule layers evaporated onto ITO substrates; the alternating layers of CuPC and PTCBI to form a thin film of 32 nm in thickness were used [9.107]. The resultant performance includes a responsivity of 0.3 A/W, dark current on the order of 10^2 nA/cm^2, and a frequency response of ≈ 400 MHz.

Solution-Processed, Colloidal Quantum Dot Optical Detectors

The solution processability and spectral tunability of colloidal quantum dots render them attractive for application in photodetectors. Their compatibility with conjugated polymers allows for their integration to form nanocomposites with high interface area. These bulk heterojunctions provide high photon absorption and efficient exciton formation followed by dissociation and charge separation. Upon illumination, excitons dissociate and electrons and holes are transported to the contacts through separate paths within different physical environments (polymer and nanocrystals), reducing recombination, and thereby increasing charge collection efficiency.

A polymer-nanocrystal composite photodetector was reported in 1996 [9.108]. It consisted of a blend of CdSe or CdS nanocrystals mixed with MEH-PPV. This material system exhibits a type-II heterostructure wherein electrons are energetically favored to stay in the nanocrystals, whereas holes are transferred to the polymer matrix. The mixture was spin-coated on an ITO substrate, followed by metal evaporation to form the cathode. The efficiency of exciton dissociation (charge separation) was observed via the quenching of photoluminescence emitted by the nanocrystals. These devices were investigated as photovoltaic photodetectors. The reported quantum efficiency was $\approx 12\%$ at zero bias conditions, while it reached $\approx 60\%$ at 3 V reverse bias. The spectral sensitivity of the reported device was limited by the absorption of MEH-PPV and Cd(S,Se) nanocrystals to the visible spectral range up to 650 nm.

Orders of magnitude increase in photoconductivity in this system may be obtained after post deposition treatments of ligand exchange on the nanocrystal surface. It was found that shorter ligands were necessary to improve carrier transport among nanocrystals by decreasing inter-nanoparticle spacing [9.109].

An alternative device structure with the sensitivity extended beyond 1 μm may consist of a nanocomposite film of Pb(S,Se) nanocrystals in MEH-PPV polymer, sandwiched between a thin PPV buffer layer and the metal contacts. Upon photoexcitation, therefore, electron hole pairs created in the nanocrystals separate and electrons hop amongst nanocrystals to the anode, whereas holes are transported via the polymer towards the cathode. However, the responsivity of such photodiodes in the short wavelength infrared (SWIR) spectral range diode was estimated to be below 10 mA/W, which is prohibitively low for practical sensing applications.

Solution-Processed Quantum-Dot Photoconductors

Solution-processed quantum dot *photoconductive* detectors may provide a viable alternative for SWIR detection. For sensitive photodetection there are two prerequisite features: high photoconductive gain and low noise. Photoconductive gain expresses the number of electrical carriers circulated in the circuit per absorbed photon. This figure of merit determines the detector's ability to respond to light and is a crucial parameter for high sensitivity at a given noise level. The major physical parameters that affect gain in a photoconductor are the minority carrier lifetime and the majority carrier transit time. For a sensitizing center characterized by a given carrier lifetime, therefore, increase in majority carrier mobility leads to higher photoconductive gains. Carrier transport in nanocrsytal blends takes place via a thermally activated hopping mechanism, and the inter-nanoparticle distance is a determining parameter for the carrier transport in these materials. High mobility thus mandates for close-packing of nanocrystals.

Increase in carrier lifetime in a photoconductor, also called photosensitization, is the other mandatory requirement for highly efficient photoconductors. This is usually achieved by the introduction of sensitizing centers that trap one type of carrier but not the other. As an example, in PbS photoconductors, the photosensitization of PbS is followed by oxidation, and in particular formation of lead sulfates ($PbSO_4$) (see [9.103] for review). These oxide species act as sensitizing centers that prolong the minority (electron) carrier lifetime, allowing holes to transverse the device within this carrier lifetime.

Noise in photoconductors is determined by generation–recombination (G–R) and shot noise. The excess noise introduced by carrier transport along barriers formed at the interfaces of polycrystalline materials is also observed in polycrystalline photoconductors. These barriers that are randomly modulated by generation–recombination of thermal or photoexcited carriers cause excess noise to be superimposed to the shot and G–R noise components. Therefore, in highly efficient devices, the high carrier mobility and long carrier lifetime required for high photoconductive gain must be achieved without compromising the noise performance of the device.

The close-packed, highly conductive structures of nanoparticles may be created via a necking mechanism [9.103]. For example, the responsivity in such structures was reported to be as high as 2700 A/W; however, a dramatic noise increase enhanced by excess noise ($\approx 40\,\mathrm{mA/cm^2}$) may limit practical applications. In order to present the best performing photoconductive device, responsivity and noise current should be jointly taken into account to yield optimum specific detectivity D^*. Currently, the best performing devices based on PbS nanoparticles demonstrate a D^* on the order of 10^{13} Jones, which is roughly an order of magnitude higher than the epitaxially grown InGaAs photodiodes [9.2].

9.14.3 Nanocrystalline Detectors with Carrier Multiplication

Optical detectors utilizing semiconductor nanocrystals may exhibit internal quantum efficiencies in excess of 100%. Recently, a process in which absorption of a single photon produces not just one, but multiple electron–hole pairs (multiexcitons) was reported for photovoltaic detectors [9.110–112]. This effect arises from strong carrier–carrier interactions in quantum-confined nanocrystals and is usually referred to as carrier multiplication (CM). As demonstrated recently, the absorption of a single high-energy photon by a PbSe nanocrystal can produce up to seven excitons, which corresponds to a quantum efficiency of 700% [9.113].

Basic Principles of Optical Detectors with Carrier Multiplication

In a traditional photoexcitation scenario, absorption of a photon with energy $\hbar\omega > E_g$ results in a single

electron–hole pair, whereas the photon energy in excess of the energy gap E_g is dissipated as heat by exciting lattice vibrations (phonons). Strong carrier–carrier interactions may lead to a competing carrier generation/relaxation channel, in which the excess energy of the conduction-band electron does not dissipate via electron–phonon scattering but is instead transferred to the valence-band electron exciting it across the energy gap in a collision-like process mediated by strong carrier–carrier Coulomb coupling. This transition into a final multiexciton state occurs either in a coherent or incoherent way. For example, an inverse Auger scattering (which is actually an impact ionization) or direct generation of multiexcitons via virtual single-exciton states initiate the CM process (see [9.112, 114–116] for descriptions of various possible mechanisms).

The ultimate limit on the photon-to-exciton conversion efficiency is imposed by energy conservation, which leads to the ideal spectral dependence of quantum efficiency calculated as $\eta = \hbar\omega/E_g$. The process of CM has its low-energy threshold defined by the energy and momentum conservation considerations. The experimental evidence for high efficiency CM in quantum-confined nanocrystals was obtained in a number of compounds, including an important photovoltaic material Si [9.117, 118].

Among the main challenges for practical applications of CM is the extraction of charges from nanocrystals on time scales faster than Auger recombination. Recent work has demonstrated that charge separation at the interface between nanocrystals and, for example, surface-adsorbed electron acceptors or porous TiO_2 is highly efficient and occurs on a subpicosecond time scale, which is significantly faster than Auger decay. Other challenges are associated with the poor electrical conductivity of nanocrystal blends and photocorrosion of nanocrystals.

9.14.4 Plasmonic-Enhanced Detectors

Directing light at the interface between metal and dielectric can induce a resonant interaction between the light waves and free electrons at the surface of the metal. As a result, the generation of surface plasmons occurs. Experimental and theoretical studies over the past decades have confirmed that by creatively designing the metal–dielectric (or metal–semiconductor) interface surface plasmons (and surface plasmon polaritons – SPP) can be generated with the shorter wavelength than that of the impinging light, which under certain circumstances may dramatically improve absorption of the impinging light. The emerging field obtained the name plasmonics and a number of new applications were explored, including plasmonic-enhanced light absorption in photodetectors.

Basic Principles of Plasmonic-Enhanced Optical Detectors

Currently, at least three ways of plasmonic effect application in photovoltaic devices are exploited [9.119].

1. *Light scattering using particle plasmons.* Using the method of light scattering with particle plasmons, the light scatters non-uniformly when the particle is placed at the interface between two dielectrics. In particular, the impinging light bends inside the dielectric (semiconductor) that effectively increases the optical path length. Moreover, light scattered at an angle beyond the critical angle for reflection (16° for the Si/air interface) will remain trapped in the active region. If the backside of an active area is coated with a reflective metal, the incident light will pass several times through the semiconductor active region, increasing the effective path length. The enhanced coupling of impinging light into semiconductor region by scattering from plasmonic nanoparticles was first recognized by *Stuart* and *Hall*, who used dense nanoparticle arrays to resonantly scatter and couple light into Si-on-insulator photo detector structures [9.120, 121]. A ≈ 20fold increase in the infrared photocurrent in such a structure was observed. More recently, applications with enhanced light coupling into single-crystalline Si, amorphous Si, Si-on-insulator, quantum well and GaAs solar cells covered with metal nanoparticles were reported [9.119–124].
   The light-trapping effects are most pronounced at the peak of the plasmon resonance, which can be tuned by engineering the dielectric constant of the medium. For example, small Ag or Au particles in air have plasmon resonances at 350 and 480 nm, respectively. The resonances can be redshifted in a controlled way over the spectral range 500–1500 nm by (partially) embedding them in SiO_2, Si_3N_4 or Si, which are all standard materials in semiconductor manufacturing. In addition, the dielectric spacer layer between the nanoparticles and the semiconductor reduces surface recombination owing to the presence of the metal. To provide efficient light scattering or trapping, both the shape and the size of metal nanoparticles should be engineered appropriately [9.119, 122].

2. *Light concentration using particle plasmons.* Using the method of light concentration with particle plasmons, metallic nanoparticles can be used as subwavelength antennas in which the plasmonic near-field is coupled to the semiconductor, increasing its effective absorption cross-section. This method takes advantage of the strong local field enhancement around the metal nanoparticles to increase absorption in a surrounding semiconductor material (localized surface plasmons – LSP). For nanoparticle spacing much smaller than the wavelength of light, near-field dipolar interactions between adjacent nanoparticles dominate, leading to the formation of collective plasmon modes, in which the individual particles interact strongly and oscillate in phase with one another. This works particularly well for small (5–20 nm diameter) particles, and antennas are particularly useful in materials where the carrier diffusion length is small, and non-equilibrium carriers must thus be photogenerated close to the collection junction area. For efficient photoconversion, the absorption rate in the semiconductor must be larger than the reciprocal of the typical plasmon decay time (lifetime $\approx 10-50$ fs). Such high absorption rates are achievable in many organic and direct-band gap inorganic semiconductors. Enhanced photoconversion efficiencies were demonstrated for thin organic photovoltaic films doped with very small (≈ 5 nm diameter) Ag nanoparticles, organic bulk heterojunction solar cells, dye-sensitized solar cells with embedded small metal nanoparticles, etc. [9.119–122].
3. *Light trapping using surface plasmon polaritons.* In another alternative method of light trapping using surface plasmon polaritons, impinging light is converted into SPPs, which are electromagnetic waves that travel along the interface between a metal back contact and the semiconductor absorber layer. Near the plasmon resonance frequency, the evanescent electromagnetic SPP field is confined close to the interface at dimensions much smaller than the wavelength. SPPs excited at the metal/semiconductor interface can efficiently trap and guide light in the semiconductor layer. In this geometry the impinging light flux is effectively bent and directed along the lateral direction of the photodetector active volume. At frequencies near the plasmon resonance (typically in the 350–700 nm spectral range, depending on metal and dielectric) SPPs suffer from relatively high losses. However, further into the infrared, typical propagation length is substantial. For example, for a semi-infinite Ag/SiO_2 geometry, SPP propagation lengths range from 10 to 100 μm in the 800–1500 nm spectral range [9.119].
The SPP coupling mechanism is beneficial for efficient light absorption if absorption of the SPP in the semiconductor is stronger than in the metal. For SPPs at a GaAs/Ag interface the semiconductor absorption fraction is high in the spectral range from the GaAs/Ag SPP resonance (600 nm) to the band gap of GaAs (870 nm). For a Si/Ag interface, with smaller optical absorption in Si owing to the indirect band gap, plasmon losses dominate over the entire spectral range, although absorption in the 700–1150 nm spectral range is still higher than single-pass absorption through a 1 μm thick Si film [9.119]. In this case, it is more beneficial to use a geometry in which a thin metal film is embedded in the semiconductor, as in this case plasmon absorption is much smaller owing to the smaller mode overlap with the metal.

Examples of Plasmonic-Enhanced Optical Detectors

Integrated photodetectors applying the method of light trapping using surface plasmon polaritons, were recently demonstrated using an organic (bilayer polymer) p/n diode [9.125]. This plasmonic diode is formed from a heterostructure sandwiched between two metal electrodes, one of them being the plasmonic waveguide in which the SPP propagate. Excitons are generated when the SPP wave is absorbed by the organic heterostructure and subsequently dissociate into electrons and holes, creating photocurrent (see the schematic structure of the device in Fig. 9.66a). The external quantum efficiency of this SPP detector is quite poor (only 10^{-3}%), but efforts are being made to optimize it.

A schematic example of engineered photodetector is shown in Fig. 9.66b, where nanoparticles are placed

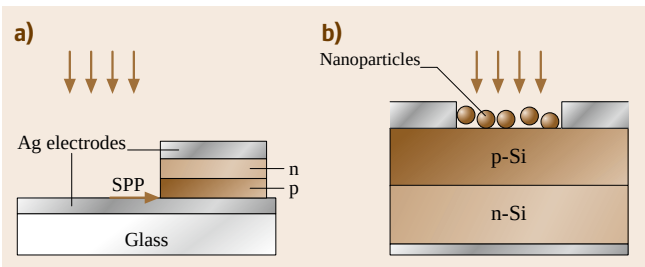

Fig. 9.66a,b Schematics of plasmonic-enhanced optical detectors: **(a)** with surface plasmon polaritons excitation; **(b)** with light scattering or concentrating using particle plasmons

over the surface of a semiconductor device, such as a p/n junction photodetector based on silicon technology. The enhanced optical absorption via one of the mechanisms – either light scattering with particle plasmons or localized surface plasmons (LSP) excitation in nanoparticles increases external quantum efficiency of the photodiode.

Another application with plasmonic devices targets imaging detectors that mimic the human eye [9.126]. Modern image sensing techniques, which subdivide the light spectrally or record information about the polarization of the incoming light, can extract much information for applications ranging from biological studies to remote sensing. Spectral imaging techniques typically rely on filter or interferometers combined with scanning or sampling to record a spectral image cube (which has wavelength as a third dimension). This leads to inefficient use of the incoming light and/or long recording times. With plasmonic devices, the surface plasmons enable direct recording of spectral image cubes in a single exposure. By texturing metal surfaces at the nanometer scale, incoming light is converted to surface plasmons and can then be separated according to wavelength and polarization, before being recoupled to light through subwavelength apertures that illuminate individual photodetector elements. This photon-sorting capability provides a new approach for spectral and polarimetric imaging with extremely compact device architecure.

9.14.5 Superconducting Nanowire Single Photon Detectors

The superconducting photon-counting detectors currently used in various applications are either transition edge sensors [9.127–129] or superconducting-tunnel-junction detectors [9.130, 131].

Transition Edge Sensors

The transition edge sensors are superconducting bolometer type detectors, in which the resistive thermometer is a superconducting film which is voltage biased at a point of the superconducting-normal transition (Sect. 9.11.4). The thermal resistance between the superconducting film and substrate is due to electron–phonon decoupling for thin films at low temperatures or the so-called Kapitza resistance [9.132] for thick films at higher temperatures. This detector operates with a negative electro-thermal feedback. Absorption of a high energy photon results in a drop in current, which is measured with a SQUID (superconducting quantum interference device) amplifier. This type of detector is mainly used for high energy photon counting.

Superconducting Tunnel Junction Detectors

The superconducting tunnel junctions (or Josephson junction) detectors are used for the detection of single UV/visible photons and well as long wavelength and terahertz detection. These detectors typically consist of two thin films of a superconducting metal such as niobium, tantalum or hafnium separated by a thin insulating layer. When operated at temperatures well below the superconductor's critical temperature (typically below 1 K), the equilibrium state of the junction is easily perturbed by any photon striking it, breaking the Cooper pairs and creating excess quasiparticles. By applying a small bias voltage across the junction and a suitable parallel magnetic field to suppress the Josephson current, an electrical charge proportional to the energy of the perturbing photon can be extracted from the device.

The two types of superconducting photon counting detectors described briefly above are capable of counting near-infrared and visible light photons with an energy resolution of 0.15 eV at a rate of tens of kilohertz. They operate at temperatures less than 1 K and require a SQUID-based readout. For a variety of imaging applications as well as for telecommunication and other needs, counting rates up to 10^7 events per second or higher are needed, whereas the requirement for the energy resolution is relaxed. A good compromise between counting rate and energy resolution might be achieved by making use of superconducting nanowire single-photon counters.

Superconducting Nanowire Single Photon Detectors

In the past several years, a new type of optical detector based on nanostructured materials – superconducting nanowire single photon detectors (SNSPD) – has attracted much interest. First reports on this type of photodetector showed promise as high-speed photon counters at UV, visible and near IR wavelengths [9.133–135].

The detection principle is as follows [9.133]. The superconducting nanowire is biased with a DC current just below the critical current (above which the wire no longer superconducts). A photon absorbed by the wire excites electrons, locally disrupting the superconductivity in a small hotspot region, and forcing the superconducting current to divert around this hotspot region. If the wire is narrow enough, the local current

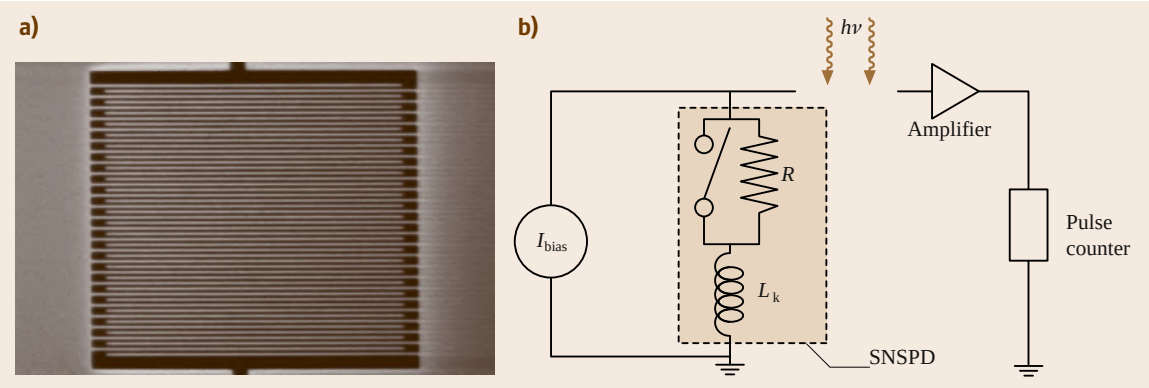

Fig. 9.67 **(a)** Scanning Electron Microgram of a typical SNSPD with $5 \times 5\,\mu m^2$ nanowire meander. **(b)** An example of block schematics of electrical connection of SNSPD: R is a normal resistance of SNSPD, L_k is a kinetic inductance, I_{bias} is a source of a below critical bias current. The switch together with the resistor R and inductance L_k represent the model circuit of SNSPD

density around the hotspot is forced to increase, and can exceed the critical value, switching adjacent regions to non-superconducting regimes. This results in the formation of resistive bridge across the whole wire, and an output voltage drop. Since such nanowires are only 100 nm wide, a meander or a parallel nanowire structure must be used to provide efficient optical coupling and reasonable quantum efficiency.

The basic structure of the SNSPD comprises a meander – the parallel connection of a large number of superconducting nanowires (Fig. 9.67a). The devices are usually made from thin NbN films (typically below ≈ 5 nm thickness) deposited on either quartz, or sapphire, or Si substrates by magnetron sputtering of pure Nb in an Ar + N_2 gas mixture. The films are then patterned to form meander structures of several square microns in size with a filling factor of $\approx 50\%$ and a line width of 100 nm or less. Structured NbN films have a sheet resistance just above the superconducting transition. The NbN meanders typically have a superconducting transition temperature of $T_c \approx 9.5$ K and a critical current density of $I_c \approx 2 \times 10^6$ A/cm^2 at 4.2 K [9.136]. The critical current at the operational temperature of 6.5 K is typically within the range 8–10 μA. The devices are cooled in a vacuum chamber with a helium bath cryostat having an optical access through a quartz window.

The other material for SNSPD is NbTiN, a material with critical temperature $T_c = 15$ K and critical current density $I_c = 5.8 \times 10^6$ A/cm^2 [9.137]. The detectors may be fabricated on a silicon substrate, enabling easy integration in advanced electronic circuits.

The SNSPD is usually modeled as a switch that opens when a photon is absorbed: a part of the detector becomes resistive with $R > 1$ kΩ (Fig. 9.67b, [9.136, 137]). The current then flows through the amplifier giving a voltage pulse of $V = I_{bias} R_A G$ (with R_A the amplifier input impedance ($R \gg R_A$) and G the amplifier gain). The model also contains a kinetic inductance L_k that depends on the nanowire and meander parameters and which limits the counting rate of these detectors [9.135]. According to this model, the kinetic inductance relates to the reset time τ as $\tau = L_k / R_A$ and a reset time below 10 ns was achieved [9.137].

Quantum Efficiency

The absorption process in NbN converts light energy to heat. Thinner detectors are more sensitive because the same amount of heat in a small volume leads to a larger change in temperature, thus affecting the superconductor operation mode more efficiently. The absorbance A_b of a thin metal film sandwiched between vacuum and dielectric depends on the refraction index n' of dielectric and square (sheet) resistance $R_\diamond$ as [9.136, 138]

$$A_b = \frac{4 Z_0 R_\diamond}{\left[Z_0 + (n'+1)\, R_\diamond\right]^2}\,, \tag{9.209}$$

where Z_0 is an impedance of free space. For a combination from sapphire and a metal film of 4.5 nm thickness and with a square resistance equal to the square resistance of NbN films, the absorbance should be $\approx 12\%$. However, there is an optimum metal film thickness that provides maximum absorption [9.138]. Moreover, the light entering side can be covered with another dielec-

tric with a higher value of the refraction index, which together with some other technical features may significantly increase absorbance of a thin NbN film. Values of absorbance up to 70% or higher were reported recently [9.138]. In principle, the thin, 4.5 nm thickness layer of NbN allows building optical detectors that are sufficiently sensitive to detect absorption of a single photon.

For SNSPD detectors, the quantum efficiency can be defined as the ratio of the measured photon-count rate to the number of photons crossing the meander per second. Typical detectors currently have limited quantum efficiencies (10–20% [9.136, 137]), largely because of their limited optical absorption. In a typical SNSPD detector, the quantum efficiency remains almost constant at short wavelength and continuously drops down at longer wavelength. Increasing the current bias stabilizes quantum efficiency at a longer wavelength range. Improving quantum efficiency requires a deeper understanding of the optical properties of thin NbN and NbTiN films.

Detection Efficiency

The photon detection efficiency (PDE) is the probability that a photon incident on the device area results in a voltage pulse in SNSPD. As discussed in the Sect. 9.7.4, PDE depends on the geometrical factor $\varepsilon_{\text{Geom}}$, the absorbance A_{b}, and the probability P_{r} of resistive state formation due to an absorption event as [9.139]

$$\text{PDE} = \varepsilon_{\text{Geom}} \times P_{\text{r}} \times A_{\text{b}} \,. \tag{9.210}$$

While P_{r} depends on the microscopic physics of the nanowires, $\varepsilon_{\text{Geom}}$ accounts for the actual active area of the detector and A_{b} depends only on the optical properties of fabricated structures and the incident electromagnetic field (e.g., its polarization). A_{b} needs to be maximized to make efficient detectors; however, there are many ways an incident photon can remain unabsorbed. For example, the photon can pass through open gaps between the nanowires (the effect of a fill factor – a main portion of the geometrical factor $\varepsilon_{\text{Geom}}$) or be transmitted through the subwavelength thickness of NbN (absorptance A_{b}). In addition, a low value for P_{r} may further suppress PDE. Currently, for the devices with 50% fill-factor and absorbance A_{b} of 20%, a PDE cannot be achieved greater than $\approx 10\%$. For higher absorbance level, the PDE of SNSPD could reach 40% or even higher values as was reported in [9.140].

Dark Current Count

The dark count rate of SNSPD depends on the ratio of the bias current to critical current ($I_{\text{bias}}/I_{\text{c}}$) and on the pulse counter trigger level. For an operating bias current above $\approx 0.95 I_{\text{c}}$, the dark count rate is typically several thousands to a few tens of thousands pulses per second [9.136, 137]. In the dark, below a certain counter trigger level the detector mainly counts environmental noise not related to actual dark counts (detection events without an incident photon) of the superconducting detector. The lowest dark count rate measured for NbTiN-based detectors was $4 \times 10^{-3}\,\text{s}^{-1}$ for $I_{\text{bias}}/I_{\text{c}} < 0.95$ [9.137].

NEP

The NEP is defined to reveal the interplay between dark count rate and quantum efficiency and is given by [9.137]

$$\text{NEP} = \frac{h\nu}{\eta}\sqrt{2R_{\text{dark-count}}}\,, \tag{9.211}$$

where $h\nu$ is the photon energy, η the quantum efficiency, and $R_{\text{dark-count}}$ the dark count rate. NEP for NbTiN-based detectors was obtained as low as $1 \times 10^{-19}\,\text{W}\,\text{Hz}^{-1/2}$, which is two orders of magnitude lower than for the best NbN-based detectors and three orders of magnitude lower than for typical Si avalanche photodiodes [9.137].

10. Incoherent Light Sources

Since the invention and industrialization of incandescent lamps at the end of the 19th century electrical lighting has become a commodity in our daily life. Today, incoherent light sources are used for numerous application areas. Major improvements have been achieved over the past decades with respect to lamp efficiency (Fig. 10.1), lifetime and color properties.

In the following chapters an overview of various lamp types and their properties is given. They are subdivided by light generation mechanism: thermal emission of radiation close to thermal equilibrium (incandescent lamps), atomic and molecular emission in gas discharge lamps, and emission from solid-state light sources (LEDs).

10.1 Incandescent Lamps

The incandescent lamp is the oldest electrical light source still in widespread use. It can be found in almost any application, especially where comparatively small lumen packages are required and where simplicity and compactness are favored.

10.1.1 Normal Incandescent Lamps

Incandescent lamps produce light by the electrical heating of a metal wire to such a high temperature that radiation in the visible part of the spectrum is emitted [10.1]. The metal wire is mounted in a glass bulb filled with an inert gas (Fig. 10.2).

According to Planck's law the filament must be heated up to at least 2400 K for a white emission color. In view of the efficiency for converting electrical energy into visible light, even higher filament temperatures would be favorable. Unfortunately, increasing the temperature reduces lamp life due to enhanced evaporation rates of the metal. Since tungsten has a high melting point and a low vapor pressure it permits high operating temperature and consequently higher efficiencies can be attained than by any other metal. A possible measure to improve lifetime is the reduction of the tungsten evaporation rate by the addition of rare gases (Kr, Xe). Alternatively, halogens are used in a so-called regener-

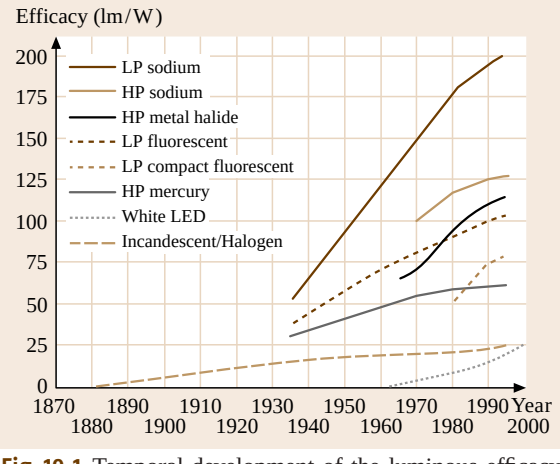

Fig. 10.1 Temporal development of the luminous efficacy of electrical light sources (LP = low pressure, HP = high pressure)

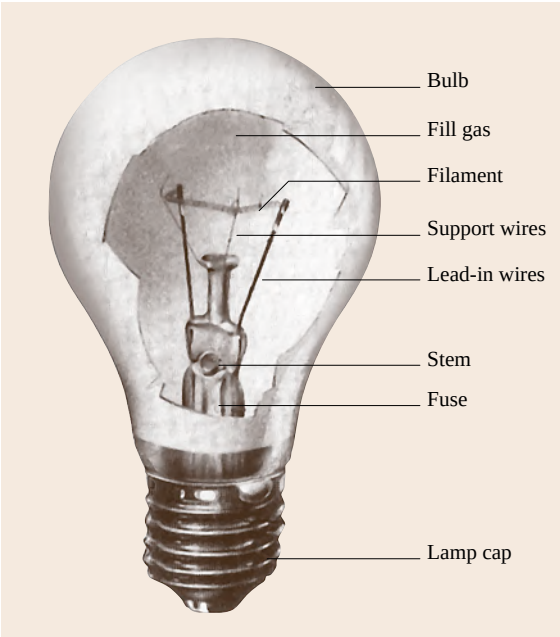

Fig. 10.2 Schematic drawing of an incandescent lamp

ative cycle effectively to transport tungsten back to the filament. An increase in luminous efficiency is achieved by coiling the tungsten wire. A coiled filament allows higher operation temperatures for a specified lifetime (typically 1000 h). Most common operation parameters yield luminous efficiencies between 8 and 17 lm/W at filament temperatures of 2400 and 3100 K, respectively. These values correspond to an energy efficiency of a few percent. Incandescent lamp wattages range up to 2000 W.

10.1.2 Tungsten Halogen Lamps

In a normal incandescent lamp, tungsten evaporates off the filament and condenses on the bulb wall, resulting in so-called blackening. Halogen lamps comprise a halogen, i. e. iodine, bromine, chlorine, added to the normal gas filling. These form volatile tungsten compounds at the glass wall, which are transported back to the hot filament. Here, the tungsten halides are decomposed enabling a so-called chemical transport cycle (Fig. 10.3).

By reduction of the net tungsten evaporation rate, the filament of halogen lamps can be operated at higher temperature compared to standard incandescent lamps. Thus, luminous efficiencies can be increased for reduced lamp size. This allows their application in compact reflectors. Halogen incandescent lamps are available up to 2000 W with luminous efficacies up to 25 lm/W. This value has recently been improved to 35 lm/W by coating the glass bulb with infrared reflective multilayers, and lifetimes up to 2000 h were obtained.

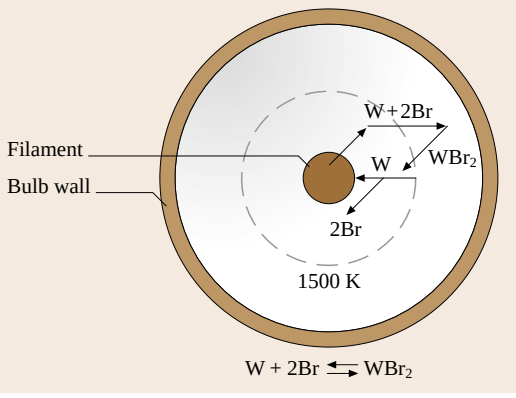

Fig. 10.3 Principle of the chemical transport cycle in tungsten halogen lamps ▶

10.2 Gas Discharge Lamps

10.2.1 General Aspects

A gaseous discharge is obtained by driving an electric current through a gas, typically present between two electrodes. Alternatively, electrodeless microwave-excited discharges and pulsed dielectric-barrier discharges (e.g. used for plasma displays) are known as incoherent light sources.

The actual carriers of the electric current in the gas are electrically charged particles, positive ions and negative electrons. In a neutral nonconductive gas the number of charge carrying particles is extremely small. These particles can be released from the fill gas or the cathode surface by energetic collisions. Many physical factors influence the properties of a gas discharge, the most important ones being the type and pressure of the gas, the electrode material, the operating temperature of the electrodes, the shape and surface structure of the electrodes, the distance between the electrodes, the geometry of the discharge vessel, and the cur-

rent density. For the purpose of light generation, two main types are distinguished: low-pressure and high-pressure discharge lamps. For lighting applications, both are operated in the arc discharge mode, which is characterized by high current densities ($> 1\,A/cm^2$). To limit the discharge currents, electronic ballasts are used [10.2].

In a low-pressure discharge lamp (gas pressure typically less than 100 Pa) the electrons have a mean free path length larger or of the order of the vessel diameter (e.g. a few cm). Due to low collision rates with the neutral gas atoms they gain high energies (> 1 eV) from the applied electrical field and effectively excite the cold atoms by inelastic collisions. The electrons and atoms are not in thermal equilibrium (Fig. 10.4).

In high-pressure discharge lamps the operating pressure is typically in the range between 10 kPa and 10 MPa. Here, collisions between electrons and atoms or ions are much more frequent, resulting in a thermal equilibrium that is characterized by equal particle temperatures.

In low-pressure discharges atomic line radiation is emitted preferably from resonance transitions of the element with the lowest excitation potential (e.g. Hg: 185 and 254 nm, Na: 589 nm). In high-pressure lamps various contributions to the spectrum are obtained: broadened atomic lines (resonance-, van der Waals- and Stark-broadening), molecular radiation bands and quasi-continuous emission due to free–free (Bremsstrahlung) and free–bound (recombination of electrons with ions and atoms) transitions. As a result of these quasi-continuous spectra, the color rendering properties of high-pressure discharge lamps are fair to excellent, depending on the type of filling [10.3].

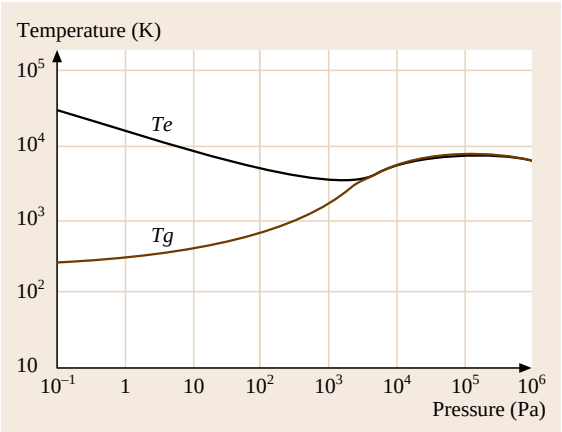

Fig. 10.4 Relationship between electron temperature, gas temperature and gas pressure

10.2.2 Overview of Discharge Lamps

In Fig. 10.5 the most relevant types of discharge lamps are displayed. The light sources are distinguished with respect to their emission spectra and application fields. In the case of low-pressure mercury and xenon excimer lamps luminescent materials are applied for conversion of ultraviolet (UV) radiation into visible light. The temporal improvement in efficiencies is depicted in Fig. 10.1.

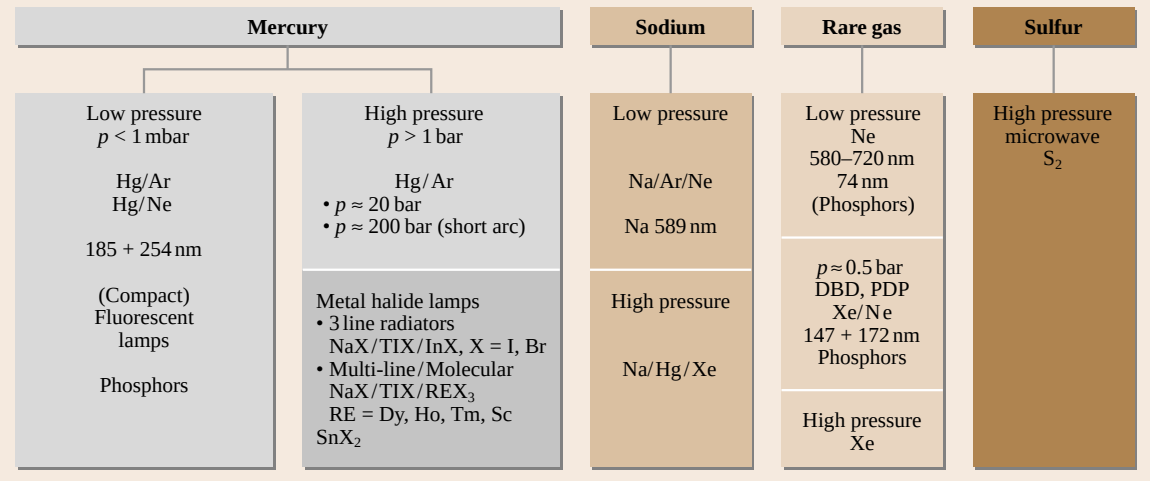

Fig. 10.5 Overview of gas discharge lamps

10.2.3 Low-Pressure Discharge Lamps

The most widely applied radiators in low-pressure discharge lamps are Hg and Na. These elements are the best choice with respect to efficiency for the conversion of electrical input power into radiation.

Low-Pressure Mercury Lamps

The working principle of a low-pressure Hg (also known as a fluorescent lamp) is given in Fig. 10.6. Fluorescent lamps are generally designed in the form of a linear or bent tubular bulb with an electrode sealed in at each end (electrodeless versions are available where the electrical energy is coupled inductively into the discharge vessel via metal coils). The discharge vessel is filled with an inert gas (typically Ar) and a few mg Hg. Since the major part of the emission of Hg atoms (97%) at low pressures (e.g. 5 Pa) is in the ultraviolet, the inner surface of the bulb is coated with a fluorescent powder or phosphor, which converts the UV radiation into visible light. The composition of the phosphor determines the spectral power distribution and the color of the emitted light.

The generation of UV photons is due to transitions of Hg atoms between the excited state levels $^1P_1$, $^3P_1$ and the ground state level $^1S_0$. About 64% of the electrical input power is converted into photons at a wavelength of 185 and 254 nm. According to the transitions indicated in Fig. 10.7 only 3% are emitted in the visible part of the spectrum. As a result of the Stokes shift, the overall efficiency is only 28%. This value corresponds to a luminous efficiency of 100 lm/W.

Typical lamp parameters for fluorescent lamps are: electrical input power up to 140 W, luminous efficiency up to 100 lm/W, color temperature between 2700 and 8000 K. Lamps are available in a large variety of geometries, e.g. cylindrical or circular or U-shaped tubes. The latter are also known as energy-saving or compact fluorescent lamps. Depending on the construction of fluorescent lamps, the lifetime ranges from 5000 to 25 000 h.

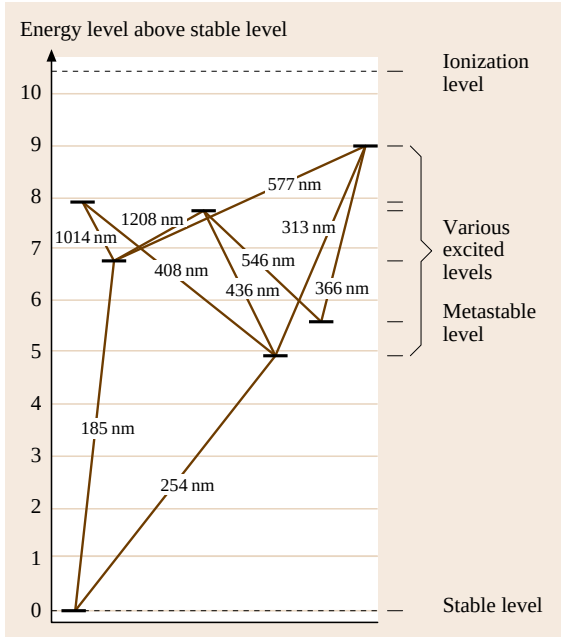

Fig. 10.7 Simplified energy-level scheme and radiative transitions of the Hg atom

Fluorescent Coatings

The most important component of a fluorescent lamp is the fluorescent powder. It is coated onto the inner side of the glass tube. The powder consists of one or several luminescent materials (phosphors), which are in general inorganic compounds doped by transition metals (e.g. Mn^{2+}, Mn^{4+}) or rare-earth ions (e.g. Tb^{3+},

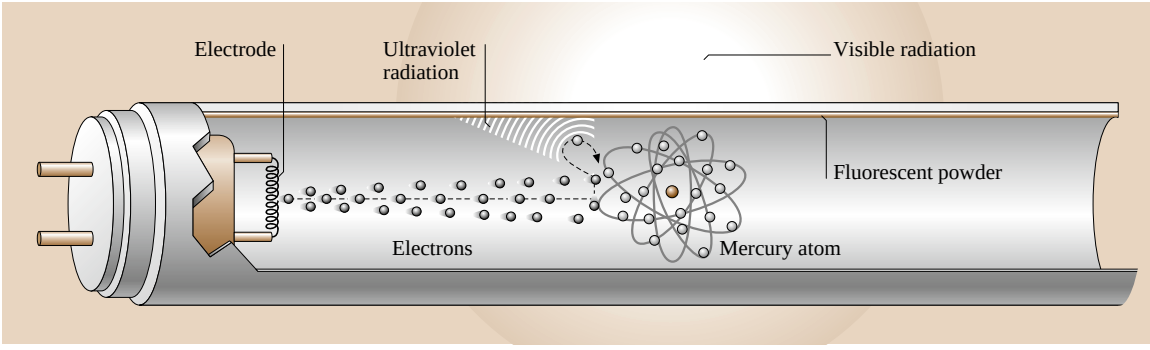

Fig. 10.6 Sketch of a low-pressure mercury discharge (fluorescent) lamp

Eu^{3+}). The composition of the fluorescent powder is optimized to convert the absorbing atomic resonance lines of mercury low-pressure discharges (185 and 254 nm) into the desired lamp spectrum. In some cases the fluorescent composition also includes so-called sensitizers (e.g. Ce^{3+}) if the first dopant, i. e. the activator, does not sufficiently absorb the mercury lines. Figure 10.8 displays the principle of photon down-conversion in a luminescent material.

The first step of light conversion is the absorption of incident photons either by the activator or the sensitizer. In the case of absorption by the sensitizer the energy is subsequently transferred to the activator. The excited activator ion, for instance Eu^{3+}, decays to the ground state by emitting a photon with a wavelength according to the energy gap between the excited and ground state. The energy difference between the emitted and the absorbed photon (Stokes shift), which is about 50%, is dissipated as heat in the fluorescent powder.

Nowadays, fluorescent compositions with quantum efficiency close to unity are commercially available for many lamp application areas. Table 10.1 gives an overview of most commonly applied luminescent materials. For illumination purposes, halophosphate phosphors, invented in the 1940s, are still widespread since they yield a white emission spectrum with a reasonable efficiency and color rendering. However, a trichromatic phosphor blend results in higher lamp efficacy and improved color rendition. A typically applied phosphor blend comprises $BaMgAl_{10}O_{17}:Eu$, $LaPO_4:CeTb$, and $Y_2O_3:Eu$. These so-called color 80 lamps (indicated with an [a] in Table 10.1) exhibit a spectral power distribution as depicted in Fig. 10.9.

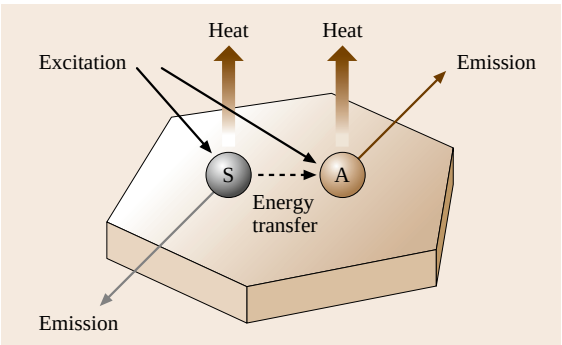

Fig. 10.8 Simplified mechanism of light generation in a fluorescent powder. The abbreviations S and A indicate sensitizer and activator, respectively

Lamps with an even higher color rendition are obtained by a tetra- or pentachromatic phosphor blend. Color 90 lamps additionally contain phosphors with an emission-band position where the trichromatic phosphor blend does not radiate, viz. in the yellow ($Y_3Al_5O_{12}:Ce$) and deep red ($GdMgB_5O_{10}:Ce, Tb, Mn$) spectral range.

Due to the tunability of the spectra, fluorescent lamps have entered many other application areas be-

Table 10.1 Overview of the most commonly used luminescent materials in fluorescent lamps

Composition of luminescent materials	Emitted peak wavelength (nm)	Color point x, y [a] (after CIE 1931)	Application area

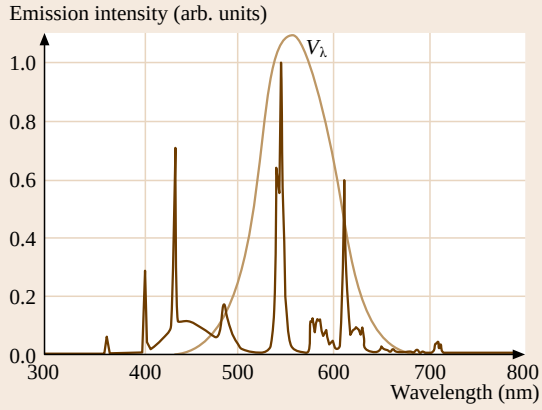

Fig. 10.9 Spectrum of a color 80 fluorescent lamp with a blend of $BaMgAl_{10}O_{17}$:Eu, $LaPO_4$:Ce,Tb, and Y_2O_3:Eu and the eye sensitivity curve V_λ

yond illumination, such as medical and cosmetic skin treatment, decoration, reprography, horticultural lighting. The latter, for instance, comprises a dichromatic phosphor blend consisting of $BaMgAl_{10}O_{17}:Eu$ and $Y_2O_3:Eu$. The spectrum of this mixture is adjusted according to the action spectrum for photosynthesis of green plants.

Other Low-Pressure Discharge Lamps

In low-pressure sodium lamps the discharge has the same origin as in mercury lamps. Sodium emits almost monochromatic yellow light, viz. a doublet consisting of 589.0 and 589.6 nm lines (Na D-lines). However, the melting point of Na is higher than Hg. Thus the optimal operating temperature is at about 530 K. At these temperatures the highly reactive Na metal requires a chemically stable wall material such as quartz (SiO_2) or alumina (Al_2O_3). To reduce thermal losses the discharge vessel is mounted inside an outer evacuated bulb (Fig. 10.10).

Low-pressure sodium lamps exhibit the highest ever achieved luminous efficiency due to the favorable position of the Na lines with respect to the spectral sensitivity of the human eye, which peaks at a wavelength of 555 nm. At a discharge power of 200 W luminous efficiencies of 200 lm/W (172 lm/W system efficiency) are obtained. A disadvantage is the low rendition of colors due to missing emission at other wavelengths, e.g. in the blue, green and red parts of the spectrum. For this reason their application is limited to street and outdoor lighting where high efficiencies are of importance. In addition, an advantage is their long lifetime, which are of the order of 20 000 h.

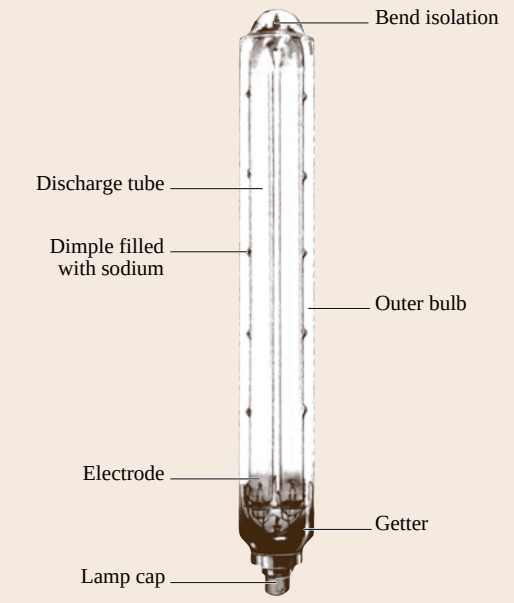

Fig. 10.10 Sketch of a low-pressure sodium lamp

When increasing the Na vapor pressure, as realized in high-pressure Na lamps, the broadened spectral lines improve color rendition significantly (see below).

Besides low-pressure Hg and Na lamps other types of radiators are used for special applications: low-pressure neon discharges and xenon excimer discharges. The former are applied in automotive brake lights and advertisement lighting. Excimer radiation from xenon is used in plasma displays and flat backlights, photocopier lamps and UV purification. The major advantage of these discharges is their fast switching behavior: in contrast to Hg and Na, Xe does not need to be evaporated. Fast switching is achieved with pulsed barrier discharge resulting in the formation of Xe excimers. Atomic and molecular radiation at 147 and 172 nm is observed, respectively.

10.2.4 High-Pressure Discharge Lamps

As the pressure is raised in a low-pressure discharge, the rate of elastic collisions increases. Although each collision transfers little energy to heavy particles the plasma is heated effectively due to the high particle densities. To sustain central plasma temperatures in the range 4000–10 000 K a temperature gradient is estab-

lished. The heat flux along this gradient to the discharge wall is a loss, which limits the radiation efficiency of such arcs to around 60%. Fortunately, selective emission of the plasma allows for efficient radiation in the visible part of the spectrum. High-pressure discharge lamps containing metals like Hg or Na are known.

Besides, other efficient radiators are added to the lamp filling in so-called metal halide lamps. Each combination of metals used generates radiation with a specific color and radiant efficiency. In theory at least, no fewer than 50 different metals can be used to dose metal halide lamps. As a result, lamp manufacturers have introduced various combinations on the market with a wide range of applications.

A technical breakthrough in high-pressure sodium and metal halide lamps has been achieved by the introduction of polycrystalline alumina (sintered Al_2O_3 ceramics) as a wall material. Compared to quartz, a major advantage is its chemical resistance against the hot sodium vapor that is present in high-pressure sodium lamps. In addition ceramic materials offer the possibility to achieve the high wall temperatures needed for effective evaporation of the salt fillings. In quartz envelopes, the maximum temperature is limited by recrystallization of the wall at about 1370 K. This value can be greatly exceeded by using Al_2O_3 instead of SiO_2. On the other hand, vacuum tight sealing of electrodes and the design of the lamps' end construction is more complicated with ceramic materials. This fact is due to their inconvenient thermal expansion behavior and brittleness. In the lighting industry, this is still a current field of research and development of modern light sources.

High-Pressure Mercury Lamps

The construction of a high-pressure mercury lamp is shown in Fig. 10.11. The discharge vessel is filled with mercury, and argon is used as a starting gas [10.1]. Thermal isolation of the discharge vessel is achieved by use of an evacuated outer bulb. The lamp is switched on using a high-voltage ignition pulse, typically of the order of several kV. After ignition, the voltage across the discharge drops down to about 20 V, which is mainly the sum of the cathode and anode fall voltage. At this stage, the lamp is operating as a low-pressure discharge emitting UV radiation mainly at 254 nm. Thermal losses in the arc result in an increase of the wall temperature and thus increasing evaporation of the liquid mercury with time. With a further increase in mercury vapor pressure the radiated energy is concentrated progressively towards the spectral lines of longer wavelengths. When fully run up the lamp establishes a typical mercury pressure 200–1000 kPa and a bluish-white light is produced (Fig. 10.12). At these pressures a part of the emission is still in the UV. By coating the inner surface of the

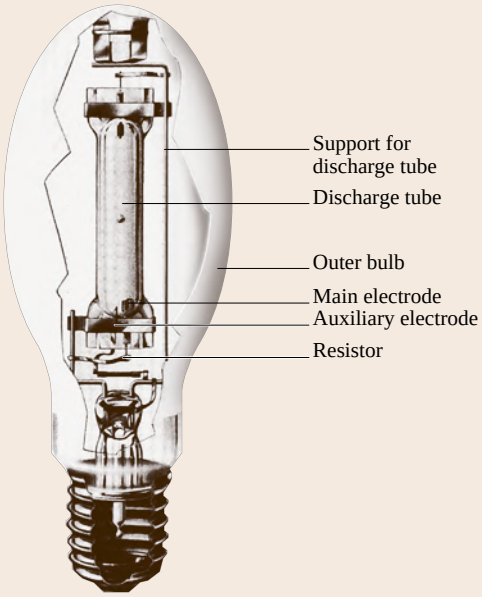

Fig. 10.11 Sketch of a high-pressure mercury lamp. The inner surface of the outer bulb may be coated with phosphor, which additionally converts UV light into visible light

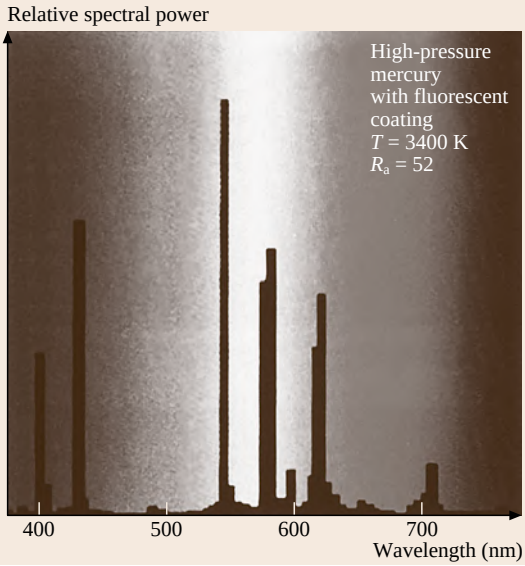

Fig. 10.12 Spectrum of a high-pressure mercury lamp

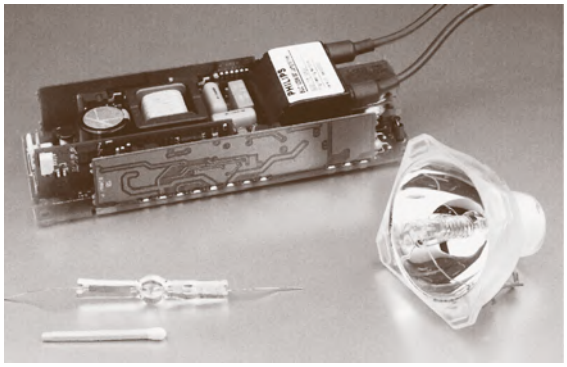

Fig. 10.13 UHP lamp system (lamp, reflector and electronic driver) for application in projection systems and beamers

outer bulb with a fluorescent powder, e.g. $YVO_4 : Eu$, that converts this UV radiation into visible light, the luminous efficiency can be further increased. In addition, the spectral composition of this light considerably improves the color-rendering properties.

Besides its radiative properties Hg also serves as a buffer gas in today's high-pressure discharge lamps; the electrons are elastically scattered by mercury atoms, which results in a low arc electrical conductivity According to Ohm's law, electrical field strengths of the order of several 10 V/mm are present in the discharge column, which enables an input electrical power at moderate discharge currents. The lamp current must not be too large with respect to electrode stability: electrode temperatures are in the range 2400–3500 K when the electrons are generated thermionically. It should be emphasized that both properties – the volatile character enabling high atom densities and the large cross section for elastic electron scattering – are unique to mercury.

High-pressure mercury lamps are used in various indoor and outdoor applications.

The power range is 50–1000 W with luminous efficiencies around 50–60 lm/W. Color rendition is only moderate to poor. Color temperatures are 3400–6000 K.

A recent development of a high-pressure mercury discharge is the so-called UHP lamp (ultra high performance lamp), which was invented by Philips in the 1990s (Fig. 10.13 [10.4]). This lamp has a very high operating mercury pressure (about 2×10^7 Pa) and a very short arc length of about 1 mm. This point-like light source with its broadened white spectrum is used in projection systems and beamers. In contrast to conventional high-pressure mercury lamps at these high pressures a significant part of the visible radiation is generated not only by pressure-broadened atomic mercury lines but also by Hg_2 molecules. UHP lamps are available on the market in the power range 100–250 W. A key issue for UHP lamps is the maintenance of stable properties of the discharge and electrodes for more than 5000 h. This is achieved with a chemical cycle in which evaporated tungsten is transported back onto the electrodes via compounds including oxygen and bromine. In addition, UHP lamps have to be operated with special electronic gear to control electrode erosion and arc jumping.

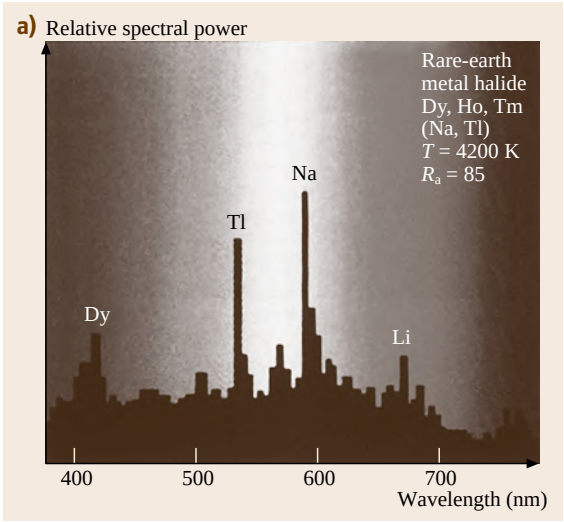
Metal Halide Discharge Lamps

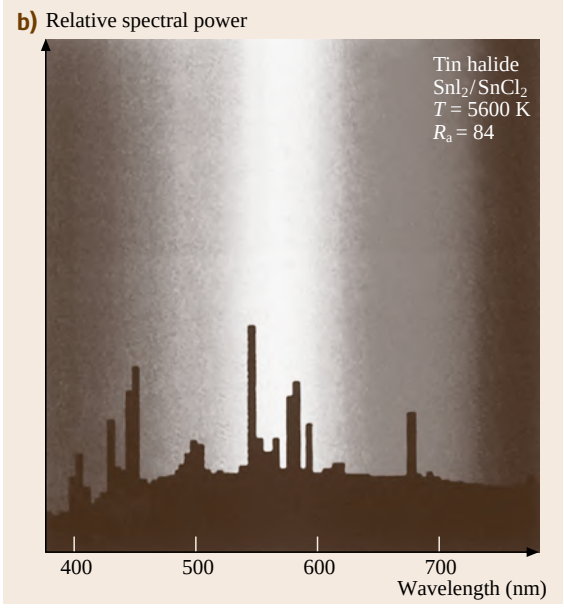
Metal halide lamps are similar in construction to high-pressure mercury lamp. The major difference between the two types is that the discharge tube of the former contains metal halides in addition to the mercury, and argon as the starting gas. The metal halides determine the spectral properties of the lamps. As mentioned above mercury serves as a buffer gas that determines the electrical properties, e.g. lamp voltage. The metals are dosed in the form of halides because of their volatile character. High particle densities are needed for efficient radiation. Furthermore, the metal halides are less aggressive with respect to wall corrosion compared to pure metals.

There are three main groups of metal halide lamps: multi-line radiators, molecular radiators and three-band color radiators. In the first type rare-earths and associated elements such as Dy, Ho, Tm or Sc are added to the lamp filling. These species have a large number of transitions at low mean excitation energy. Consequently, such plasmas efficiently emit multi-line radiation in the visible spectrum. Furthermore, NaI and TlI are often added to such lamp fillings to improve luminous efficiency and color properties. The second type is based on molecular radiators such as SnI_2 or $SnCl_2$, which produce a quasi-continuous spectrum. Finally, the third class is based on NaI, TlI and InI_3. Such spectra consist of three color bands in the yellow, green and blue, respectively.

Typical spectra of these three metal halide lamp types are shown in Fig. 10.14a–c. Metal halide lamps are used for a variety of indoor and outdoor lighting applications. The electrical input power ranges from 35 W to more than 1000 W. In general, metal halide lamps have high luminous efficiencies of up to 100 lm/W at good to excellent color rendering. Lifetime is up to 20 000 h, depending on the type of filling used.

A speciality of metal halide lamps is its halide cycle (Fig. 10.15), which is quite similar to the aforementioned tungsten–halogen cycle. When a metal halide lamp first starts, the spectrum is initially that of mercury vapor, since the halides remain unevaporated at the relatively cool wall of the discharge tube (typical





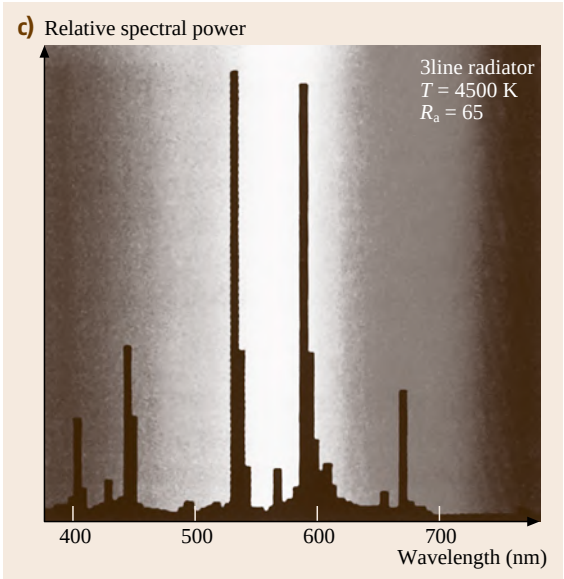


Fig. 10.14 **(a)** Spectrum of a NaI/TlI/DyI_3/HoI_3/TmI_3 lamp for sports and flood lighting. **(b)** Spectrum of a SnI_2/$SnCl_2$ lamp for studio and theater lighting. **(c)** Spectrum of a three-band color (NaI, Tl, InI_3) metal halide lamp. The lithium line is due to the presence of impurities in the wall material (quartz) ◀▲

wall temperature of 1000 K). As the wall temperature increases, the halides melt and partly vaporize. The vapor is carried into the hot region of the arc by diffusion and convection, where the halide compounds are dissociated into the halogen and metal atoms. As indicated in Fig. 10.14, different halides dissociate at different temperatures. The metal atoms are excited at the hot plasma center, which typically has a temperature of 5000 K. Here the main contribution of atomic radiation takes place. The metals then move nearer the cooler discharge wall where they recombine with the halogen atoms to form once again the halide compound. The whole cycle then repeats itself.

As mentioned above a recent improvement of metal halide lamps was achieved by the introduction of a ce-

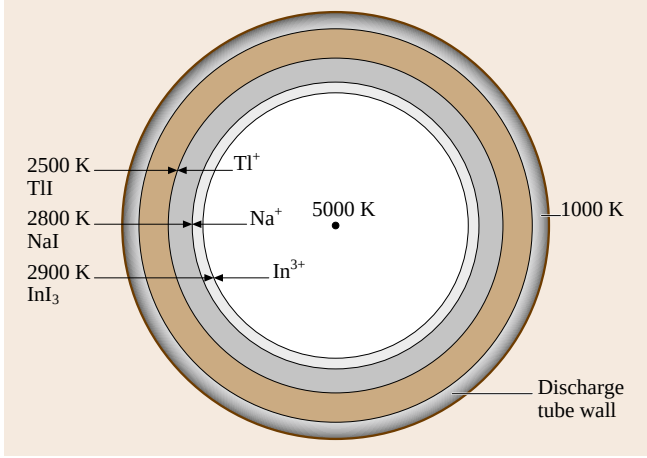

Fig. 10.15 Schematic diagram of the halide cycle of a three-band color metal halide lamp (NaI, TlI, InI_3)

ramic wall material (polycrystalline alumina) instead of quartz. Such lamps show improved color stability and long lamp life. However, these lamps are not suitable for optical applications, e.g. in projection systems. The reason is the translucent behavior of polycrystalline Al_2O_3 (PCA) due to multiple scattering of light at grains and pores. Nevertheless, the total transmission for visible light is nearly 95%. The application of PCA to high-power metal halide lamps is also limited due to cracking of the material induced by thermal shock and thermal expansion. In the lighting industry, the applicability of ceramic wall materials is still a current field of research and development of modern light sources. Furthermore, upcoming legislation has initiated several activities on the replacement of mercury in this type of discharge by nontoxic materials [10.3].

Other High-Pressure Discharge Lamps

Besides high-pressure mercury and metal halide lamps, other high-pressure light sources are also known. The so-called blended-light lamp is derived from the conventional high-pressure mercury lamp. The principal difference between the two is that, whereas the latter is dependent on an external ballast to stabilize the lamp current, the blended-light lamp has a built-in ballast in the form of a tungsten filament connected in series with the discharge tube. Consequently, the light from the discharge and the filament combine (or blend). The improved spectral quality is traded off against reduced total efficiency of the system.

In high-pressure sodium lamps, the broadening of the D-lines is used to improve color properties compared to a low-pressure Na discharge. Luminous efficiencies of up to 130 lm/W are obtained. A technical breakthrough has been achieved with the introduction of a ceramic wall material (polycrystalline Al_2O_3). This withstands the hot and highly aggressive Na vapor, resulting in a much longer lamp life compared to quartz (SiO_2).

Another class of high-pressure discharge lamps is represented by the sulphur lamp, invented by Turner et al. at Fusion Systems in 1994. The advantage of such a lamp is their long life due to electrodeless operation. It is operated with a microwave at a wavelength of 2.45 GHz, the electrical input power being of the order of 3 kW. A spherical bulb having a diameter of about 30 mm is filled with sulphur powder. Under continuous operation, sun-like white light is emitted by S_2 molecules, having a partial pressure of about 600 kPa. The high burner efficiency of about 170 lm/W is possible since at these high pressures UV radiation from the sulphur molecules is reabsorbed by the plasma. Thus, emission mainly occurs in the visible part of the spectrum. A technical drawback of microwave lamps is the low energy efficiency of the generator, typically about 65%. Therefore, the overall efficiency of the system is reduced to about 100 lm/W, being of the order of conventional discharge lamps.

Nevertheless, electrodeless discharge lamps are still a hot topic in research and development. A general advantage of these systems is their potentially long life and large luminous flux. The latter, for instance, might be distributed by light pipes for use in industrial and general lighting applications.

10.3 Solid-State Light Sources

10.3.1 Principle of Electroluminescence

In solid-state lamps the electric current is converted into light by recombination of excited states of atoms into the ground state via emission of a photon, i. e. radiative recombination. The nature of the excited state may differ for different types of electroluminescence (EL) principles. Typically the applied voltage has to be at least as large as the emission of the material to fulfill the energy-conservation law.

Besides radiative recombination, many other decay mechanisms are possible in electroluminescence that reduce the overall efficiency, which is typically measured in $w_{\mathrm{opt,\,out}}/w_{\mathrm{el,\,in}}$, given as a percentage. Weighted by the eye response curve, the use of lumens per watt (lm/W) gives the optically relevant light output in relation to the invested electrical power. The most important loss factors are non-radiative recombination through phonons or second-order processes converting the electrical power primarily into heat. An important additional loss factor is the outcoupling of the light. Since most EL materials have a higher refractive index than air, part of the light is trapped inside the device by total internal reflection. Due to absorption losses, this light is partly lost, which reduces the overall efficiency. In addition, more specific loss channels will be discussed for the different mechanisms.

General illumination was not feasible using EL devices for a long time, since the total emitted power or lumen package was fairly low and/or the efficiencies

were low. This has changed in recent years with the advent of InGaN technology, which turned out to be very stable against high power densities and the resulting heat development. Thus electroluminescence has started to become the third class of illumination devices, creating a new market for lamps, gears and luminaries.

10.3.2 Direct Versus Indirect Electroluminescence

Electroluminescence (EL) in general appears in two distinctly different mechanisms: direct EL and indirect EL. Direct EL describes the direct recombination of electrons and holes in a suitable semiconductor structure. This material can be inorganic, like in most conventional light-emitting diodes (LEDs), which were initially built from GaP and GaAs or more recently and very successful from InGaN, or organic such as, e.g., Alq_3 (q = 8-hydroxychinolinate). In this version, charge carriers are injected from contacts via direct transport with ultimately very little kinetic energy. The carriers meet in the recombination zone, wherein excitons are formed, which successively decay radiatively or non-radiatively; the first process releasing a photon, the latter creating heat. Ideally, the injection barrier from the contacts to the conduction levels of the materials is low and thus the energy necessary to generate recombination and thus light is simply the energy of the emitted light, resulting from the effective band-gap of the material. Thus the theoretically achievable efficiency of direct EL generation is unity.

In contrast, the indirect EL process results from creating excited states through impact ionization. This type of EL is found in classical thin-film (TF) or powder EL devices, also called TFEL or alternating-current thin-film EL (ACTFEL) devices. Here carriers are accelerated by means of an external electrical field. These accelerated electrons collide with ions in the matrix. By impact ionization, these ions or luminescent centers are excited and the radiative recombination of the generated electron–hole pairs releases a photon. Therefore the theoretical efficiency of this process is limited to about 40%. These devices are typically operated using high-voltage high-frequency AC bias and the brightness as well as the spectrum is a function of voltage and frequency. Typically, a few hundred cd/m^2 maximum brightness are achieved in state-of-the-art indirect EL devices. Because efficiency and brightness are limited, we will not consider indirect EL in much detail, since the respective devices have achieved little importance as light sources. They are mainly used in displays, indication or signaling and decorative lighting. It is not expected that dramatic improvements will occur in the near future. The interested reader is referred to detailed descriptions in [10.5].

10.3.3 Inorganic Light-Emitting Diodes (LEDs)

The first practical inorganic semiconductor LEDs were conceived at Texas Instruments in 1961 by Biard and Pitman. These devices emitted in the near infrared because the material used was InGaP with a band-gap of 1.37 eV. One year later the first LED in the visible was built by Holonyiak and co-workers at General Electric. They used a different composition to fabricate a device that emitted red light. From that time on, the use of more refined processing and other materials (such as e.g. AlGaAs) has led to the development of the common LED, mainly used for indicator lights as, for example, shown in Fig. 10.16.

Fig. 10.16 Schematic of a classical indicator and high-power illumination LED

Fig. 10.17 AlInGaP LED shaped as a truncated inverted pyramid (TIP) for efficient light extraction

For several decades, LEDs were not attractive for illumination purposes, mainly for the two following reasons. First, the optical output power (i. e. the lumen package, defining the amount of light emitted from a single LED) was fairly limited, since the packaging and the materials in use did not allow high current densities in the small chips. Since the efficiency was far less than 100%, a lot of heat would have been generated, destroying the semiconductor chip. Secondly, and more important, no real blue LED material was available. For several years II–VI compound semiconductors such as ZnSSe/ZnTe were researched as possible candidates for blue with limited success. However, in 1993 *Nakamura* et al. achieved the breakthrough for solid-state lighting by proving the successful use of InGaN as a material in LEDs [10.6]. Since the material is chemically very stable, it is on one hand difficult to achieve high-quality epilayers for high-efficiency LED operation, on the other hand, the high stability allows very high current densities without disintegration of the LED material. Therefore the lumen package can be increased to values relevant for lighting applications. More important, however, is the insensitivity of InGaN to defects. Although the defect density in common InGaN LEDs is much higher than what would be acceptable in other material combinations, such as e.g. AlGaAs ($10^9/\mathrm{cm}^3$ vs. $10^6/\mathrm{cm}^3$), the low surface recombination velocity of InGaN and other properties allows efficient LEDs to be built from defect-rich layers. Additionally, with the advent of bright and stable blue LEDs it became possible to generate white light from solid-state devices, either by color conversion of blue LEDs using phosphors or by externally mixing the light from blue, green and red LEDs.

The principal of LEDs is explained in great detail in the semiconductor device literature [10.6–8]. We will limit ourselves here to the use of LEDs for light generation and the respective relevant aspects. Due to the importance of color conversion in generating white light from LEDs, we will discuss in more detail the nature of the phosphors being used.

Pure-Color LEDs

White light is, generally speaking, always a mixture of several pure colors. At least a combination of blue and orange light is needed, which yields a white appearance, however a very low color rendering (CRI, color rendering index), i. e. many colors are poorly reproduced under illumination of such a light source. Increasing the number of colors by combining red, green and blue (RGB) LEDs already enables much higher CRI values and thus a high-quality white light. In the limit of many different visible LEDs, the black-body radiation spectrum of 5500 K (essentially the spectrum of sunlight) is generated, which has, by definition, a CRI of 100. However, due to the finite size of the LED dies and their package, it is rather difficult to achieve homogeneous mixing of the discrete LEDs, at least in a small package. The following paragraph will briefly describe the technology of pure-color LEDs, which are already widely used in all applications, where colored light is necessary, like e.g. signaling. The advantage here is clearly the much higher efficiency, since they replace filtered white light, which has very low efficiency and lifetime.

Two major materials are used in colored LEDs: AlInGaP for red, orange and yellow and InGaN for green and blue (Fig. 10.18).

The quaternary mixture of AlInGaP is the prime candidate for red to yellow emission colors. It is typically grown on GaAs wafers, since the lattice matching of substrate and epilayer guarantees a low number of defects, which is essential for high efficiency and long lifetime. After deposition of the various layers, the wafer is bonded to a GaP substrate and the original GaAs substrate, which absorbs in the spectral region of the LED emission is removed. This increases the efficiency, since half of the light is emitted towards the substrate and would be lost if the substrate was absorbing. A lot of light is still trapped inside the die due to total internal reflection. Since the refractive index of the material is larger than one, all light emitted under an angle larger than the Brewster angle is reflected back into the crystal. Due to some residual absorption,

e.g. at the metal contacts, multiple internal reflections further diminish the efficiency. By shaping the semiconductor chip in the form of a truncated inverted pyramid, the highest efficiency of a red light source has been obtained by an LED from Lumileds [10.9] (Fig. 10.17).

This LED is estimated to have close to 100% internal efficiency and an outcoupling efficiency of about 55%, resulting in 102 lm/W wall plug efficiency. This value demonstrates the potential of LED technology as a future lighting source, since this is the most efficient red-light source available. The lumen package of AlInGaP LEDs is, however, limited due to thermal quenching of the emission. For power densities beyond 0.1 W/cm^2, the efficiency and also the lifetime of AlInGaP LEDs drops significantly, since the chip temperature increases.

For the higher energy emission from green to blue and beyond, InGaN has become the material of choice. After several years of intense research, it became possible to create working LEDs in the InGaN material system. The major difficulty to overcome was the problem of p-doping of GaN. This is achieved by doping Mg into the InGaN lattice, which happens at temperatures above 1100 °C in the deposition process. By varying the amount of In in the composition of the LED, the emission can be tuned from UV to green. However, due to segregation effects and subsequent development of lattice defects, the efficiency drops with increasing wavelength, i. e. for high In contents. Comparing the different materials classes, it turns out, that the defect density of InGaN LEDs is much higher than what would be tolerable in more conventional III–V compound semiconductors. This is mainly due to the lack of a lattice-matched substrate material. So far mostly Al_2O_3 (sapphire) with a lattice mismatch of ≈ 15% is used. Nevertheless, the devices, with unsurpassed stability and high efficiency, prove that the InGaN system is obviously much less sensitive to defects than other material combinations. The reason for that is not yet entirely clear. However, it has been measured that InGaN has the lowest surface recombination velocity of all III–V composite semiconductors, thus giving excited carriers more chances of radiative recombination. Current efficiencies range from 20% (20 lm/W) for blue to 12% (60 lm/W) at green wavelengths, with continuously increasing tendency in new values literally being published week by week.

As a summary, the efficiencies as a function of wavelength are plotted in Fig. 10.19 together with the eye's sensitivity curve for the two material systems.

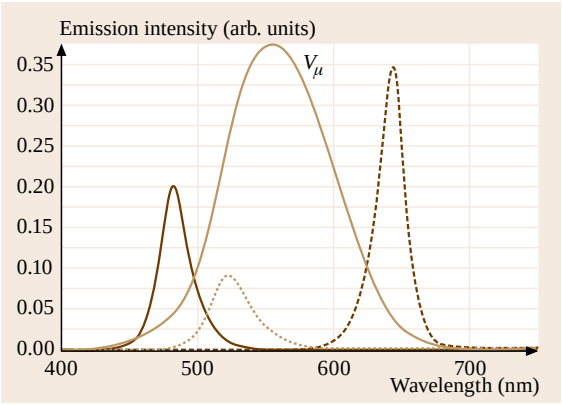

Fig. 10.18 Spectra of blue and green InGaN and red AlInGaP LEDs and the eye sensitivity curve V_λ

White LEDs

As mentioned above, combining the light of several colored LEDs can create white light. Several different concepts have been used, which will be briefly reviewed here (Fig. 10.20). All of them have in common that a volume of light mixing has to be provided, since the different colors have to be directionally randomized before emission to avoid inhomogeneous illumination colors. This is typically achieved through multiple reflections of the different LEDs in an appropriate housing. A common method is the use of a poly(methyl methacrylate) (PMMA) plate, where the light from different LEDs is coupled. Through total in-

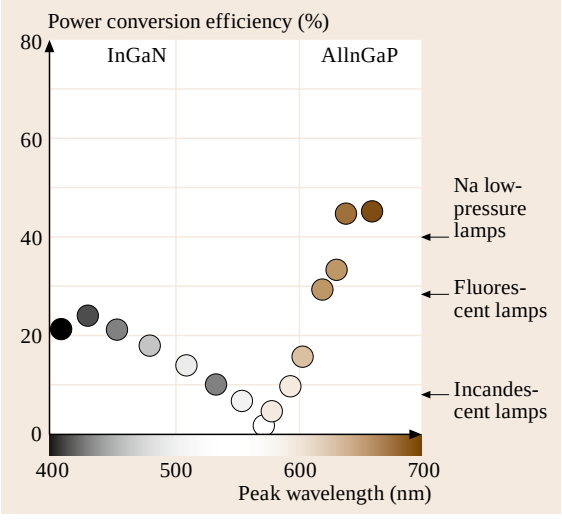

Fig. 10.19 Efficiency of InGaN and AlInGaP LEDs as a function of emission wavelength

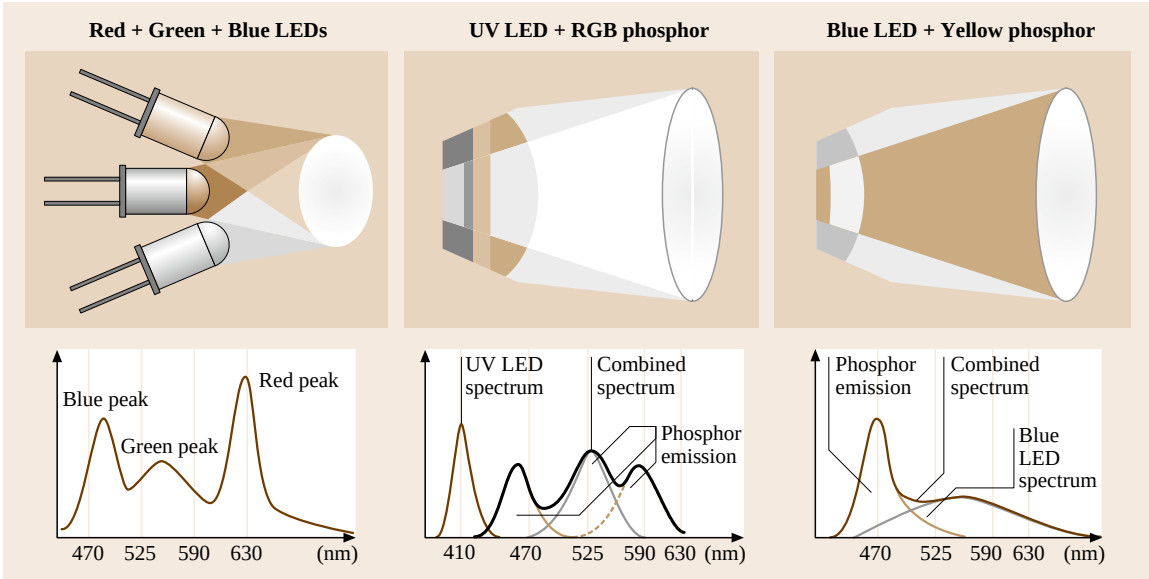

Fig. 10.20 Summary of different methods of generating white light with LEDs

ternal reflection, the colors are randomized and thus homogeneously mixed to the desired white. A second way to achieve a white color from polychromatic LED modules is to use a diffuser plate in front of the LEDs, again to randomize the spatial distribution of the different colors emitted by the LEDs. Finally tube-like hollow reflectors are being used for the same purpose, however in these systems the de-mixing and thus non-white appearance is often obvious at large angles.

To date, the most common method of achieving white emission from LEDs is by partially converting blue light from the semiconductor to lower-energy emission by means of phosphors, which are deposited onto the LED chip. This implies that the phosphor must show strong absorption of the blue light and a high photochemical stability due to the high excitation density of up to several 100 W/cm^2. The widely used combination of blue InGaN LEDs (430–480 nm) with $(Y, Gd)_3(Al, Ga)_5O_{12} : Ce$ (YAG : Ce) thereby dominates the white-LED market today [10.7]. However, more advanced concepts are being realized, including blue LEDs in combination with yellow and red phosphors or red and green phosphors. The former concept aims at the enhancement of red radiation in the entire spectrum to realize illumination-grade warm-white LEDs. The red luminescent materials used in combination with yellow YAG : Ce in so-called red-enhanced LEDs are (Ca, Sr)S : Eu [10.10,11] and $(Ca, Sr)_2Si_5N_8 : Eu$ and $(Ca,Sr)AlSiN_3$:Eu [10.12]. Red-enhanced LEDs show high CRIs above 90 for low color temperatures between 2500 and 4000 K.

White LEDs with high color rendering at arbitrary color temperatures between 2500 and 10 000 K are obtained by applying blue LEDs with a combination of green and red phosphors. *Mueller–Mach* and *Mueller* e.g. found that $SrGa_2S_4 : Eu$ (535 nm) and SrS : Eu (615 nm) are an appropriate combination for trichromatic LEDs [10.13].

Compared to dichromatic YAG : Ce LEDs, LEDs with a trichromatic spectrum yield higher color rendering while the luminous efficacy is still almost as high.

10.3.4 Organic LEDs

Organic LEDs became an important area of research and development after the publication of direct EL observed from a device incorporating only organic charge-transfer materials and emitters by *Tang* and *van Slyke* from Kodak in 1987 [10.14]. The authors were working with organic photoconductors, which have been used for several decades in copiers and printers. Applying a forward bias to an appropriate device built with these materials, light was generated from directly injected carriers. A second important date was the publication of direct organic EL observed in a single-layer polymer-based device by *Friend* et al. in 1990, making a new class of materials available: semiconducting poly-

mers [10.15]. These marked the beginning of intense R&D in organic EL.

The general build-up of an organic LED (OLED) is represented in Fig. 10.21. The stack typically consists of a substrate (mostly glass, however plastic is considered) with a thin layer (typically 100 nm) of indium–tin oxide (ITO). This is the most prominent representative of transparent conducting materials, which is needed to be able to couple the light out. On top of the ITO layer the organic material is deposited, either as a multilayer stack in small-molecule OLEDs or as a polymer coat in polymeric OLEDs. The top contact, usually the cathode, is built by evaporating reactive materials such as e.g. Ca, Mg or Ba to facilitate injection of electrons into the molecular materials. This is often followed by a less reactive metal, such as Al, to prevent fast oxidation of the top contact. Since many of the organic materials and especially the reactive cathode metal are water- and oxygen-sensitive, a nearly hermetic sealing is required to achieve a practical lifetime of the devices. This is achieved by encapsulating the glass with a second glass or metal can, which often also contains additional getter materials to absorb residual water and oxygen.

In general two types of organic direct EL are distinguished: polymeric and small-molecule organic LEDs. Both systems rely in principle on the same basic mechanisms and, although there are distinctive differences, especially in the case of conjugated polymers, the device set-up is identical for the two versions. Whereas small-molecule OLEDs are deposited using high-vacuum sublimation or gas-phase transport, polymeric OLEDs are typically spin-coated or in the case of displays, ink-jetted.

The conduction mechanism in organic materials is different to inorganic semiconductors. In the molecular solid, after charge injection, the molecule becomes oxidized and reduced, respectively, depending on the nature of the charge injected. If an electron is injected from the molecule to the electrode, a hole is injected into the molecule, which oxidizes the molecule. The charge then moves under the influence of the applied electric field across the molecule and by hopping from the originally excited molecule to the neighboring one. Thus the conductivity of organic layers is rather low, on the order of $10^{-3}\,\mathrm{cm}^2/(\mathrm{V\,s})$ in good materials, down to $10^{-8}\,\mathrm{cm}^2/(\mathrm{V\,s})$ for nearly insulating ones. The hole mobility is typically larger ($10^{-3}\,\mathrm{cm}^2/(\mathrm{V\,s})$) than the electron mobility ($10^{-5}\,\mathrm{cm}^2/(\mathrm{V\,s})$). The mobility can be higher in certain materials classes (up to $10^{-1}\,\mathrm{cm}^2/(\mathrm{V\,s})$), but those are not typically used in EL devices.

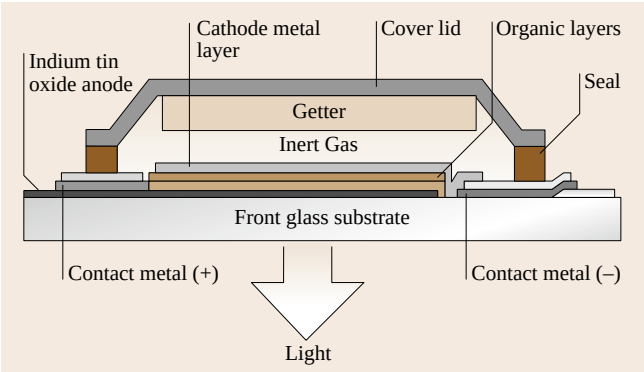

Fig. 10.21 Schematic build-up of an organic LED

The materials fabricated in OLEDs depend on which type of system is being used.

In small-molecule devices the organic layers are usually brought onto the substrate in a layer of multiple materials having defined functions for each material. A typical device layout is shown in Fig. 10.21. On top of the ITO a hole conductor is deposited. This is in most cases a material with high electron affinity to facilitate injection of holes from the anode and high hole mobility to achieve good hole transport. The next layer is than a matrix material with a large band-gap and high triplet energy, doped with an emitter material. These two functions can also be combined into the same material. On top of this layer a hole-blocker is deposited, to prevent the fast-moving holes from flowing directly to the anode. The hole-blocker has to have a very large band-gap and a large electron affinity to efficiently prevent holes from flowing through the structure. Finally an electron conductor/injector is deposited on top to facilitate electron injection into the device.

In polymeric OLEDs all these functions are combined in the material, a conjugated or non-conjugated polymer. Thus the layer sequence is typically reduced to two layers. First, a hole-injection layer, which also serves as a smoothing layer for the roughness of the substrate. This layer is made insoluble and is finally coated with the light-emitting polymer. The total thickness is typically 100–200 nm. Charge transport of electrons and holes as well as emission is provided from the different functional groups of the polymer. A schematic comparison of the different electronic structures of small molecules and polymer OLEDs is shown in Fig. 10.22.

In the recombination zone, electrons and holes meet and create excitons on the excited molecules. These excitons can have either a total spin of 1 or 1/2, thus creating a singlet or a triplet state. The singlet state is

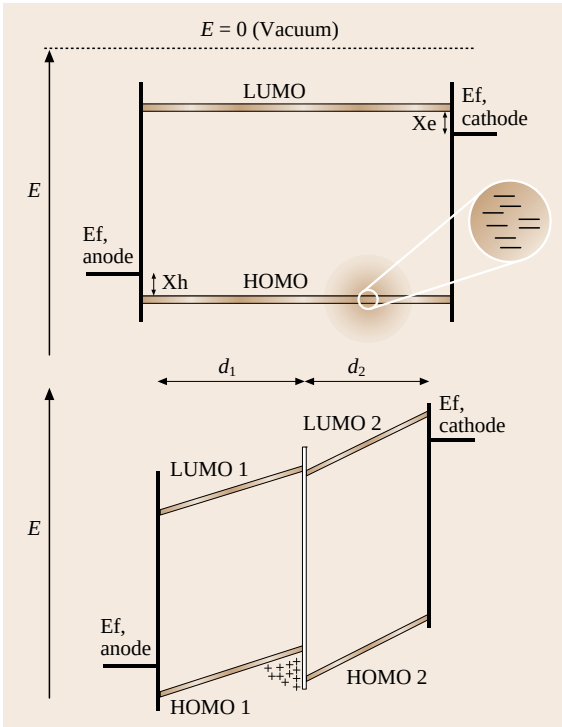

Fig. 10.22 Schematic band diagram of polymeric (single-layer) and small-molecule (double-layer) OLEDs, respectively

optically allowed and therefore able to generate a photon, whereas the triplet state is a forbidden transition, thus no emission of light is possible from these excitons. By statistics, the probability of creating a singlet is only 1/4 for all injected pairs, limiting the principle efficiency of organic EL devices to 25%. However, using other emitters, which have strong spin–orbit coupling it is possible to overcome the selection rules and the probability of forming a radiatively decaying exciton theoretically increases to unity, thus opening the road to very efficient organic LEDs.

Since the delocalization of the electron density across the molecule depends on the steric configuration of the molecule, and the electrical properties depend on the relative position between the molecules in the layer, the film formation is highly important in organic LEDs. Additionally, the coupling of two neighboring molecules can lead to the formation of cooperative electronic states, which exhibit a new excited state, only present in the coupled molecules. This phenomenon is called excimer in the case of identical molecules and exciplex, if two different molecules are involved. The energy of this excited state without ground state is typically lower than the excited states of the single molecules. Therefore, this effect can be used to generate other wavelengths than those available from the constituent molecules only. However, the efficiency of singlet excimers and exciplexes is typically very low.

A crucial problem in organic LEDs (as well as in inorganic ones) is the outcoupling efficiency of the generated light. Due to the fact that many of the materials used have a high refractive index, light generated within the film and emitted at an angle larger than the critical angle of the material suffers from total internal reflection and the light is guided through the structure. Multiple reflections at partially absorbing interfaces reduce the amount of light coupled out. An estimate of the outcoupling ratio, using classical ray optics, gives a value of $1/n^2$, where n is the refractive index of the material. For most materials, this value amounts to 20%, i. e. 4/5 of the light generated does not leave the structure, rendering OLEDs often much less efficient than what could be achieved with improved outcoupling. Intense work is being conducted to identify the most promising methods to improve light outcoupling from thin-film organic LEDs. Recent measurements, using an optically coupled hemispherical lens on top of an OLED substrate indicate that the outcoupling can at least be doubled by appropriate means, improving the efficiency by the same factor of two. This topic is certainly one of the most important areas of OLED research.

Many of the materials used in today's OLEDs are sensitive to moisture and oxygen. Irreversible oxidation occurs at the surface, rendering the material insulating and thus creating a nonemissive (black) spot. These black spots are progressive, i. e. once formed they have a tendency to grow until the OLED is rendered useless. These black spots often start at pinholes in the electrode materials, which in the case of many cathode materials are themselves often the most critical materials with respect to oxidation within the whole OLED stack. To save the OLED from these failure mechanisms, near-perfect encapsulation is necessary, which often includes a getter material put in a sealed package, in close proximity to the OLED cathode to capture any remaining oxygen and water molecules before damage to the OLED occurs. In the near future, it is hoped that thin-film packaging, i. e. the deposition of a nearly impermeable material on top of the OLED will solve this problem.

Although this is one of the most often encountered failure mechanisms of OLEDs, it is not the only one by far. Also, many OLED materials are intrinsically unstable, limiting the useful life of OLEDs and creating

the need for more research and development in the field of organic LED materials.

For application as light sources OLEDs have some way to go to achieve high efficiency at high brightness and a long lifetime. However, since all of these properties have been shown in single devices, it is thought possible that OLEDs will be able to deliver. Due to the way in which they generate light, OLEDs will provide a very different light source to existing sources. A diffuse, large area, flat lamp that can eventually become flexible, color-tuneable and transparent is envisioned with OLEDs, creating new potential applications for light sources in the future. To generate white light from OLEDs several possibilities can be used. External mixing of colors (e.g. from pixelated sources), intrinsic broadband (white) emitters, mixed emitters, stacked emitters or phosphor-converted blue or UV-emitting OLEDs (using e.g. the phosphors described above) can be fabricated; the different options having different advantages and disadvantages depending on the applications for the light source. Most estimates establish a time frame of five to ten years before OLEDs will become an important incoherent light source.

10.4 General Light-Source Survey

Table 10.2 gives a summary of the main types of light sources and selected electrical and light technical properties as discussed in this chapter.

Table 10.2 Electrical and technical data of the basic types of light sources (state of affairs 2003)

Light source	Electrical input power (W)	Luminous flux (lm)	Luminous efficacy (lm/W)	Color rendering quality
Incandescent	10–1000	80–15000	8–15	Excellent
Halogen	20–2000	300–60000	15–30	Excellent
Low-pressure Hg discharge	7–150	350–15000	50–100	Good
High-pressure Hg discharge	50–1000	2000–60000	40–60	Good
Metal halide discharge	20–2000	1600–24000	80–120	Good to excellent
Low-pressure Na discharge	20–200	2000–40000	100–200	Poor
High-pressure Na discharge	40–1000	1600–14000	40–140	Moderate to good
Sulfur microwave discharge	Up to 5000	Up to 450000	80–90 (system)	Good
White dichromatic inorganic LED	1–5	20–150	20–30	Good
White trichromatic inorganic LED	1	20–25	20–25	Excellent
Organic LED (at 1000 cd/m^2)	15 mW (per cm^2)	0.3 lm (per cm^2)	30	Excellent

11. Lasers and Coherent Light Sources

This chapter describes lasers and other sources of coherent light that operate in a wide wavelength range. First, the general principles for the generation of coherent continuous-wave and pulsed radiation are treated including the interaction of radiation with matter, the properties of optical resonators and their modes as well as such processes as Q-switching and mode-locking. The general introduction is followed by sections on numerous types of lasers, the emphasis being on today's most important sources of coherent light, in particular on solid-state lasers and several types of gas lasers. An important part of the chapter is devoted to the generation of coherent radiation by nonlinear processes with optical parametric oscillators, difference- and sum-frequency generation, and high-order harmonics. Radiation in the extended ultraviolet (EUV) and x-ray ranges can be generated by free electron lasers (FEL) and advanced x-ray sources. Ultrahigh light intensities up to 10^{21} W/cm^2 open the door to studies of relativistic laser–matter interaction and laser particle acceleration. The chapter closes with a section on laser stabilization.

11.1 Principles of Lasers

11.1.1 General Principles

A laser (an acronym for *light amplification by stimulated emission of radiation*) is a device that produces and amplifies an intense beam of highly coherent, highly directional light. The original proposal of extending the maser (*microwave amplification by stimulated emission of radiation*) idea to the infrared or visible region of the electromagnetic (EM) spectrum, thus giving a laser, was however first made in 1960 by *Maiman* [11.1] using a flash-pumped rod of ruby with polished ends (ruby laser) after a proposal in 1958 by *Townes* and *Schawlow* [11.2]. Nowadays laser devices range in size from semiconductor lasers as small as a grain of salt to solid-state lasers as large as a storage building. Lasers are widely used in industry for, e.g., cutting and welding metals and other materials, in medicine for surgery, in optical communications, in optical metrology, and in scientific research. They are an integral part of such familiar devices as bar-code scanners used in supermarkets, laser printers, compact disc and digital versatile disc (DVD) players. The output wavelength of a laser is determined by the properties of its active medium. Altogether, several thousand lasing lines have been reported ranging from the soft-x-ray down to the far-infrared spectral region and new lines appear frequently in optics and laser journals. Depending upon the type of laser and its operational regime, the corresponding output power may vary from a fraction of a milliwatt to several hundred kilowatts in continuous-wave operation, and from tens of kilowatts to petawatt peak power in pulsed-mode operation.

A laser consists of at least three components (Fig. 11.1):

1. A gain medium that can amplify light by means of the basic process of *stimulated emission*
2. A pump source, which creates a *population inversion* in the gain medium

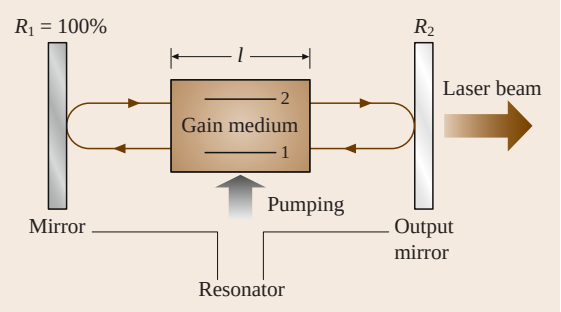

Fig. 11.1 Schematic of a laser oscillator

3. Two mirrors that form a *resonator* or optical cavity in which light is trapped, traveling back and forth between the mirrors.

The laser beam is usually the fractional part of light trapped in the cavity that escapes from one of the two mirrors (the *output coupler*), which has a nonvanishing transmission at the laser oscillation wavelength. The gain medium can be solid (including semiconductors), liquid, or gas, and the pump source can be an electrical discharge, a lamp, or another laser. Other specific components of a laser vary depending on the gain medium and whether the laser is operated continuously or pulsed. Lasers may be in fact divided into two broad groups:

1. Continuous wave (CW) or quasi-CW
2. Pulsed.

A CW laser exhibits a steady flow of coherent energy and its output power undergoes little or no change with time. Many gas lasers, such as HeNe and Ar-ion lasers, operate CW; several solid-state lasers, such as Nd^{3+} and Ti^{3+}:Al_2O_3 lasers, are also often operated in CW mode. In pulsed lasers, the output beam power changes with time so as to produce a short optical pulse, usually in a repetitive way and with pulse duration usually ranging from nanoseconds ($1\,\text{ns} = 10^{-9}\,\text{s}$) to femtoseconds ($1\,\text{fs} = 10^{-15}\,\text{s}$). Typical examples of pulsed lasers are many solid-state and liquid lasers, such as Nd:YAG, Ti:Al_2O_3, and dye lasers.

Spontaneous and Stimulated Emission, Absorption

A laser exploits three fundamental phenomena that occur when an electromagnetic wave interacts with a material, namely the processes of spontaneous and stimulated emission, and the process of absorption (Fig. 11.2).

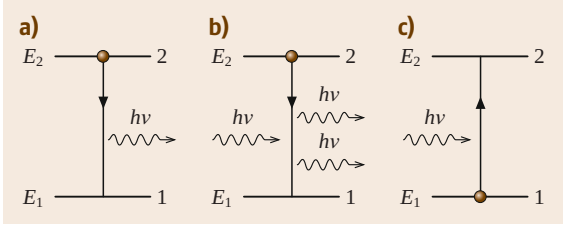

Fig. 11.2a–c Fundamental interaction processes of a quantized atom with an EM wave. **(a)** Spontaneous emission. **(b)** Stimulated emission. **(c)** Absorption

Spontaneous Emission and Nonradiative Decay. Let us consider the energy levels of some given material and indicate by E_1 and E_2 the energies of the ground level 1 and of an excited level 2 of the medium. If the atom is initially raised in the excited state 2, it spontaneously tends to decay into the stable ground state 1. If the available energy for the transition, $E_2 - E_1$ is released in the form of an EM wave, the process is referred to as spontaneous, or radiative, emission (Fig. 11.2a). Owing to energy conservation, the frequency ν_0 of the emitted radiation is given by

$$\nu_0 = \frac{(E_2 - E_1)}{h}\,, \tag{11.1}$$

where h is the Planck's constant. Since the previous relation can also be written as $E_2 - E_1 = h\nu_0$, we can say that a single photon of energy $h\nu_0$ is emitted during each spontaneous emission process. Note also that this process occurs even if the atom is isolated and no external perturbation is applied. The probability of spontaneous emission can be characterized in the following way. Let us consider an ensemble of atoms and assume that, at time t, there are N_2 atoms per unit volume (*population*) in level 2. Quantum mechanical calculations show that the rate of decay of these atoms due to spontaneous emission, i. e., $(\mathrm{d}N_2/\mathrm{d}t)_{\text{sp}}$, is proportional to N_2 according to

$$\left(\frac{\mathrm{d}N_2}{\mathrm{d}t}\right)_{\text{sp}} = -\frac{N_2}{\tau_{\text{s}}}\,, \tag{11.2}$$

where τ_{s} is referred to as the spontaneous emission lifetime and depends on the particular transition involved. The direction, the polarization, and the phase of the emission event are random, so that the overall emitted light by the different atoms of the given population is said to be incoherent.

If the atom is not isolated but interacts, e.g., by collisions with other atoms, the decay from the excited state 2 to the ground state 1 may occur by a release

of the internal energy $(E_2 - E_1)$ into some form other than EM radiation (e.g., into kinetic or internal energy of surrounding atoms in a gas or lattice vibrations in a crystal). The phenomenon is referred to as *nonradiative decay*. The corresponding rate of decay from the excited state 2 can usually be expressed in a similar manner as (11.2), namely $(\mathrm{d}N_2/\mathrm{d}t)_{\mathrm{nr}} = -N_2/\tau_{\mathrm{nr}}$, where τ_{nr} is the nonradiative lifetime. When both radiative and nonradiative decay are taken into account, the rate of decay of population N_2 can be written as

$$\left(\frac{\mathrm{d}N_2}{\mathrm{d}t}\right)_{\mathrm{decay}} = -\frac{N_2}{\tau_{\mathrm{s}}} - \frac{N_2}{\tau_{\mathrm{nr}}} \equiv -\frac{N_2}{\tau} \,, \tag{11.3}$$

where the time constant τ, defined by $1/\tau = 1/\tau_{\mathrm{s}} + 1/\tau_{\mathrm{nr}}$, is referred to as the *lifetime* of the excited state 2.

Stimulated Emission. If an EM wave of frequency ν close to ν_0 is incident onto the atom while in its excited state 2, the interaction of the wave with the atom may stimulate the atom to decay to level 1 with the simultaneous emission of EM radiation. The process is referred to as *stimulated emission*. In this case, one photon, with the same frequency ν of the incoming radiation and with the same propagation direction, polarization state and phase is emitted (Fig. 11.2b). This is a major distinction to spontaneous emission. It is the fundamental reason why a laser emits coherent light as compared to the incoherent light emitted by other light sources (such as lamps or light-emitting diodes (LEDs)), which exploit spontaneous emission. Quantum mechanical calculations show that the process of stimulated emission can be described by

$$\left(\frac{\mathrm{d}N_2}{\mathrm{d}t}\right)_{\mathrm{st}} = -W_{21}N_2 \,, \tag{11.4}$$

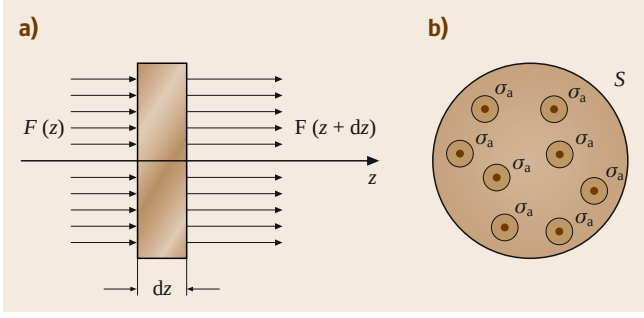

Fig. 11.3a,b Coherent amplification of an EM wave. **(a)** Photon flux-balance diagram in an infinitesimal section dz of the amplifier. **(b)** Physical meaning of the transition cross section

where W_{21} is the rate of stimulated emission. This rate is proportional to the photon flux $F = I/(h\nu)$ of the incoming wave, where I is the wave intensity. We can in fact write $W_{21} = \sigma_{21}F$, where σ_{21} is a quantity having the dimension of an area (the stimulated emission *cross section*), which depends on the characteristics of the given transition and on the frequency difference $\Delta\nu = \nu - \nu_0$, i. e., $\sigma_{21} = \sigma_{21}(\Delta\nu)$. Owing to energy conservation in the process of stimulated emission, the function $\sigma_{21}(\Delta\nu)$ is very narrow at around $\Delta\nu = 0$.

Absorption. Lastly, let us consider the case of an atom initially lying in its ground state 1. In the absence of perturbations, such as collisions with other atoms or with photons, the atom stably remains in this state. However, if an EM radiation of frequency $\nu \simeq \nu_0$ is incident onto the atom, there is a finite probability that the atom will be raised to level 2. The energy difference $E_2 - E_1$ required by the atom to undergo the transition is obtained from the energy of the EM wave, namely one photon of the incoming wave is destroyed. This process is referred to as *absorption* (Fig. 11.2c). As for stimulated emission, the absorption process can be described by

$$\left(\frac{\mathrm{d}N_2}{\mathrm{d}t}\right)_{\mathrm{a}} = -W_{12}N_2 \,, \tag{11.5}$$

where W_{12} is the rate of absorption. Again one can show that $W_{12} = \sigma_{12}F$, where σ_{12} is the absorption cross section. Einstein showed at the beginning of the 20th century that, for nondegenerate levels, $W_{12} = W_{21}$, and thus $\sigma_{12} = \sigma_{21}$. If levels 1 and 2 are g_1-fold and g_2-fold degenerate, respectively, one then has $g_2\sigma_{21} = g_1\sigma_{12}$.

Coherent Amplification of Light

Consider a monochromatic EM plane wave at frequency ν which propagates along the z-direction inside a medium made of a collection of atoms. Let E_1 and E_2 be the energies of two nondegenerate levels 1 and 2 of the atom (this time 1 is not necessarily the ground state). We assume that the resonance frequency of the transition, $\nu_0 = (E_2 - E_1)/h$, is coincident (or very close) to ν. If $F(z)$ is the photon flux of the EM wave at plane z and N_1, N_2 are the populations in levels 1 and 2 (which are assumed to be z-independent), the change $\mathrm{d}F$ of the photon flux due to the processes of absorption and stimulated emission along the elemental length $\mathrm{d}z$ of the material is given by (Fig. 11.3a)

$$\mathrm{d}F = \sigma(N_2 - N_1)F(z)\,\mathrm{d}z \,, \tag{11.6}$$

where $\sigma \equiv \sigma_{21} = \sigma_{12}$ is the transition cross section. Note that in writing (11.6) we did not consider radia-

tive and nonradiative decays since nonradiative decay does not add new photons whereas spontaneous emission creates photons which are emitted in any direction and thus gives negligible contribution to the incoming photon flux. Most importantly, note that for $N_2 > N_1$, one has $\mathrm{d}F/\mathrm{d}z > 0$ and the EM wave is amplified during propagation, i. e., the medium acts as a coherent *optical amplifier*. Conversely, for $N_2 < N_1$, one has $\mathrm{d}F/\mathrm{d}z < 0$ and the medium behaves as an *absorber*. If we let l be the length of the medium, the photon flux $F(l)$ at the output plane is related to the one $F(0)$ at the input plane by the relation $F(l) = F(0)\exp(g)$, where $g = (N_2 - N_1)\sigma l$ is the gain coefficient. The condition for light amplification ($g > 0$) is therefore $N_2 > N_1$, which is often referred to as *population inversion*. We note that in the previous calculation N_1 and N_2 have been assumed independent of the intensity I of propagating wave. This is fine however provided that I is weak enough so as that changes of N_1 and N_2 due to absorption and stimulated emissions can be neglected; however, for strong intensities one needs to account for the phenomenon of *saturation*.

As a final comment, we note that an examination of (11.6) leads to a simple physical interpretation of the transition cross section σ. First, let us suppose that all the atoms of the medium are in the ground state and let us associate with each atom an effective absorption cross section σ_a in the sense that, if a photon enters this cross section, it is absorbed by the atom (Fig. 11.3b). If S is the cross-sectional area of the EM wave, the number of atoms in the element $\mathrm{d}z$ of the material is $N_t S\,\mathrm{d}z$ (N_t is the total atomic population, i. e., $N_1 = N_t$ and $N_2 = 0$), thus giving a total absorption cross section of $\sigma_a N_t S\,\mathrm{d}z$. The fractional decrease of photon flux in the element $\mathrm{d}z$ of the material is therefore $(\mathrm{d}F/F) = -(\sigma_a N_t S\,\mathrm{d}z/S) = -\sigma_a N_t\,\mathrm{d}z$. If we compare this expression with (11.6), we conclude that $\sigma_a = \sigma$, so that the meaning we can attribute to σ is that of an effective absorption cross section as just defined.

Population Inversion: The Pumping Process

At thermal equilibrium any material behaves as an absorber. In fact, the distribution of populations N_2^e and N_1^e of levels 1 and 2 at thermal equilibrium is described by the Boltzmann statistics

$$\frac{N_2^e}{N_1^e} = \exp\left(-\frac{E_2 - E_1}{k_B T}\right), \qquad (11.7)$$

where k_B is the Boltzmann constant and T is the absolute temperature. Note that $N_2^e < N_1^e$; in particular N_2^e is negligible as compared to N_1^e if $k_B T \ll E_2 - E_1$; at room temperature ($T = 300\,\mathrm{K}$) one has $k_B T \simeq 208\,\mathrm{cm}^{-1}$. (A reciprocal centimeter is a simple convenient unit for measuring energies in spectroscopy and refers to the inverse of the wavelength of a photon possessing the given energy E. The actual energy E in the SI unit (Joule) can be obtained by multiplying cm^{-1} by hc, with $c = 3\times10^{10}\,\mathrm{cm/s}$ and $h = 6.63\times10^{-34}\,\mathrm{J\,s}$). Therefore the condition $N_2^e \ll N_1^e$ is well satisfied for transitions in the near-infrared and visible. To obtain optical amplification instead of optical absorption, we need to create population inversion in the medium by means of a *pumping process* [11.3, 4], which drives the population distribution far from thermal equilibrium. At first sight one might think to achieve population inversion between levels 2 and 1 through the interaction of the material with some strong EM radiation at frequency ν_0, such as that emitted by a flash or arc lamp. Since at thermal equilibrium $N_1^e > N_2^e$, absorption will dominate over stimulated emission, and this will produce an increase of N_2 and a decrease of N_1 from their thermal equilibrium values. However, when N_1 tends to reach the same value of N_2, absorption and stimulated emission processes compensate each other, i. e., the medium tends to become transparent. Such a situation is referred to as *saturation* of the two-level transition. Therefore, owing to saturation, it is impossible to produce population inversion in a two-level system (at least in the steady state). This goal can be achieved, however, when more than two energy levels are considered. Typically three or four energy levels are involved (Fig. 11.4), and correspondingly one speaks of *three-level* or *four-level* lasers. In a three-level laser (Fig. 11.4a), atoms are raised from the ground level 1 to the level 3 through a pumping mechanism. If the material is such that, once an atom excited into level 3 rapidly decays into a lower level 2

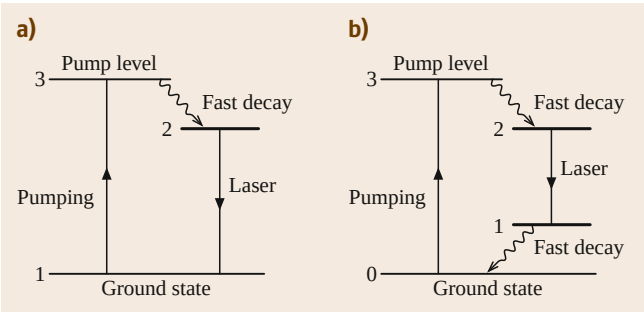

Fig. 11.4a,b Schematic of the energy-level diagram for **(a)** a three-level laser, and **(b)** a four-level laser

(by, e.g., a fast nonradiative decay), then population inversion can be obtained between level 2 and 1. Note that, in a three-level laser scheme, to achieve population inversion it is necessary to raise at least half of the atoms from the ground state 1 to state 3. In a four-level laser (Fig. 11.4b), atoms are again raised from the ground level 0 to an excited state 3, with a rapid decay to the upper laser level 2; however this time laser action takes place from level 2 to an excited lower-lying level 1. Once laser oscillation starts, level 1 is populated by stimulated emission; therefore to maintain population inversion in stationary conditions (continuous-wave operation), the lower laser level 1 should rapidly depopulate through, e.g., a very fast nonradiative decay into the ground state 0. Compared to a three-level laser, the four-level laser offers the great advantage that population inversion is ideally achieved when just one atom is raised to the pumping level 3. Four-level lasers are thus more used, whenever possible, than three-level lasers. More recently, the so-called *quasi-three-level lasers* have also become a rather important laser category. In these lasers the energy level scheme is similar to that of a four-level laser, however levels 0 and 1 are now nondegenerate sublevels of the ground energy level. The population of the ground state is distributed in all the sublevels according to Boltzmann statistics, and therefore, at room temperature, some population is left in level 1.

The mechanism that allows atom excitation from the ground energy level into the excited pump level 3 is referred to as the *pumping process*. The rate of population of the upper state 2 due to the pumping, $(\mathrm{d}N_2/\mathrm{d}t)_\mathrm{p}$, can be written as

$$\left(\frac{\mathrm{d}N_2}{\mathrm{d}t}\right)_\mathrm{p} = W_\mathrm{p} N_\mathrm{g} \,, \tag{11.8}$$

where W_p is the pumping rate and N_g is the population of the ground state. For a four-level laser, one can assume N_g to be constant (and much larger than N_2). In this case one can write from (11.8) $(\mathrm{d}N_2/\mathrm{d}t)_\mathrm{p} = R_\mathrm{p}$, where $R_\mathrm{p} = W_\mathrm{p} N_\mathrm{g}$ is the pump rate per unit volume. The energy required for pumping is generally supplied either optically or electrically. The minimum pump power P_m needed to produce a given pump rate R_p is given by $P_\mathrm{m} = (\mathrm{d}N_2/\mathrm{d}t)_\mathrm{p} V h\nu_\mathrm{mp}$, where $(\mathrm{d}N_2/\mathrm{d}t)_\mathrm{p}$ is the number of atoms per unit volume and time raised to the upper laser level by the pumping process, V is the volume of the active medium, and ν_mp is the minimum pump frequency, given by the difference between the ground level and the upper laser level. For either electrical or optical pumping, the actual pump power P_p turns out to be larger than the minimum value P_m, so that one can define a pump efficiency $\eta_\mathrm{p} = P_\mathrm{m}/P_\mathrm{p}$. Therefore, the relation between the pump rate R_p and the actual pump power P_p is given by

$$R_\mathrm{p} = \eta_\mathrm{p} \left(\frac{P_\mathrm{p}}{V h \nu_\mathrm{mp}}\right) . \tag{11.9}$$

Optical Pumping. In optical pumping by an incoherent source, light from a powerful lamp (usually medium- to high-pressure Xe and Kr flashlamps for pulsed lasers, or high-pressure Kr lamps for CW lasers) is absorbed by the active medium. Solid-state gain media, such as Nd:YAG, and liquid lasers are particularly well suited to optical pumping: absorption lines are in fact very broad and this makes the absorption of the (broadband) light of the lamps efficient. The flashlamps generate significant heat into the material that must be dissipated by water cooling. The pumping source may, however, itself be a laser; in this case one speaks of *laser pumping*. Among the most used laser pump sources, we just mention semiconductor lasers (*diode laser pumping*), argon-ion laser and second-harmonic or third-harmonic generation of Nd lasers. With the advent of powerful and reliable semiconductor lasers, diode-laser pumping is nowadays commonplace for many solid-state and fiber lasers.

Electrical Pumping. In gas lasers and semiconductor lasers, the excitation mechanism usually consists of an electrical current flow through the active medium. Gas lasers generally need to be electrically pumped because, due to the small width of their absorption lines, optical pumping would be very inefficient. In gas lasers, electrical pumping is achieved by passing an electric current either CW, at radio frequency or pulsed, directly through the gas itself. During the discharge, ions and free electrons are produced which acquire kinetic energy from the applied field and are able to excite neutral atoms via collisions: $\mathrm{A} + e \rightarrow \mathrm{A}^* + e$, where A^* denotes the atomic species in an excited state. Since electron impact excitation is a nonresonant process, it is a rather efficient pumping method for a gas. In some cases, the gas may contain two species, one of which is first excited by the discharge and then undergoes resonant energy transfer with the other via collision (an example is the HeNe laser). Electrical pumping in semiconductor lasers is achieved by flowing a large current density in a p-n or p-i-n diode. Though optical pumping can be used for semiconductor lasers, electrical pumping proves to be much more convenient.

Pumping processes different from optical or electrical pumping may also be employed in some special lasers; we just mention chemical pumping in chemical lasers, where population inversion is produced directly from an exothermic reaction.

Laser Oscillation

To obtain laser oscillation, the amplifying medium is placed between two mirrors, forming a laser cavity (Fig. 11.1). Light propagating along the cavity axis and passing through the pumped laser medium is reflected back through it, stimulating further emission in the same direction. This means that laser photons undergo multiple reflections within the cavity, being amplified at each pass through the laser medium. One mirror (total reflector) reflects almost all the incident light back through the laser medium while the other (partial reflector or output coupler) transmits a fraction $T_2 = 1 - R_2$, which constitutes the output laser beam. The combination of laser gain medium, pumping source and optical cavity forms a simple laser oscillator: if the amplification is large enough to overcame losses, i. e., when a *threshold condition* is reached, a single photon (which is always present due to quantum noise) can be amplified by several orders of magnitude to produce a huge number of coherently generated photons trapped inside the resonator. In addition, for an open resonator, only the photons which propagate in the paraxial direction of the resonator axis can reach the threshold for oscillation, so that an important property of the output laser beam is that it is *directional*. We can obtain the threshold condition for laser action by a simple argument based on gain/loss balance of light photons in one cavity round-trip. In fact, in one round-trip the photons pass twice through the gain medium and hence the round-trip gain of photons is $\exp(2\sigma Nl)$, where $N = N_2 - N_1$ is the population inversion, and l is the length of the active medium. On the other hand, the round-trip loss for photons can be written as $(1 - T_1)(1 - T_2)(1 - L_i)^2$, where $T_1 = 1 - R_1$ and $T_2 = 1 - R_2$ are the power transmission of the two mirrors whereas L_i accounts for the one-way internal loss in the cavity (due to, e.g., scattering or diffraction loss for open resonators). The population inversion N_c needed to reach threshold (also called *critical inversion*) is simply obtained by equating the round-trip gain and loss. After setting $\gamma_1 = -\ln(1 - T_1)$, $\gamma_2 = -\ln(1 - T_2)$ and $\gamma_i = -\ln(1 - L_i)$, the critical inversion turns out to be given by

$$N_c = \frac{\gamma}{\sigma l} , \tag{11.10}$$

where

$$\gamma = \gamma_i + \frac{\gamma_1 + \gamma_2}{2} \tag{11.11}$$

is referred to as the single-pass *logarithmic loss* of the cavity. Once the critical inversion is reached, oscillation builds up from spontaneous emission.

To calculate the pump rate R_{cp} needed to reach the threshold condition (the *critical pump rate*), let us consider the four-level laser (Fig. 11.4b). In steady-state conditions and in the absence of lasing, the population accumulated on the upper laser level can simply be calculated from a balance between the number of atoms pumped per unit volume and time in the upper laser level and the number of atoms that decay via radiative and nonradiative ways. Assuming $N_1 \simeq 0$, one obtains $\Delta N \simeq N_2 = R_p \tau$. When $N_2 = N_c$, from the previous equation and with the help of (11.10) the critical pump rate is obtained as $R_{cp} = \gamma/(\sigma\tau l)$. Note that the critical pump rate increases as $\sigma\tau$ decreases. Therefore the product $\sigma\tau$, which depends on the properties of the given transition, can be regarded as a figure of merit for a given laser.

Properties of Laser Beams

Laser radiation shows an extremely high degree of monochromaticity, coherence, directionality and brightness as compared to other noncoherent light sources [11.3].

The *monochromaticity* of laser radiation results from the circumstance that light oscillation sets in at one resonance frequency of the optical cavity, and owing to the balance between gain and loss in CW operation the line width $\Delta\nu_L$ of the oscillating mode is ultimately limited by quantum noise. Conversely, light from incoherent sources which exploit spontaneous emission (including LEDs) has a much lower degree of monochromaticity (as much as 11 orders of magnitude) since the spectral distribution of spontaneously emitted photons is broadened at around the atomic resonance frequency ν_0 owing to various broadening mechanisms. For laser radiation in the visible or near-infrared, line widths $\Delta\nu_L$ as low as a few Hz may, in fact, be achieved in frequency-stabilized laser sources.

The *coherence* of laser radiation refers to either *temporal* or *spatial* coherence. To define *spatial coherence*, let us consider two points P_1 and P_2 that, at a time $t = 0$, belong to the same wavefront, i. e., the phase difference between their electric fields at time $t = 0$ is zero. If the difference $\varphi_2(t) - \varphi_1(t)$ of their phases also remains zero at times $t > 0$, we say that there is perfect spatial

coherence between the two points P_1 and P_2. In practice, for any point P_1, in order to have some degree of phase correlation, point P_2 must lie within some finite area around P_1, which is called the *coherence area*. The high degree of spatial coherence of laser radiation stems again from the fact that the spatial field distribution of the beam generated by stimulated emission is a mode of the optical resonator.

To define *temporal coherence* at a given point P, let us consider the phase difference $\varphi(t+\tau)-\varphi(t)$ for the electric field at P at times $t+\tau$ and t. For a given delay τ, if the phase difference is independent of time t, we say that there is temporal coherence over a time τ. If this occurs for any value of τ, the EM wave is said to have perfect temporal coherence. If, conversely, this occurs only for delays τ smaller than a given delay τ_0, the wave is said to have partial temporal coherence, and τ_0 is called the *coherence time* of the EM wave at point P. The concept of temporal coherence is closely related to that of monochromaticity; in fact, for a CW laser one can show that the coherence time τ_0 is related to the laser line width $\Delta\nu_L$ by the simple relation $\tau_0 \approx 1/\Delta\nu_L$. The high degree of temporal coherence of laser radiation is therefore due to its extreme degree of monochromaticity.

The *directionality* of the laser beam is due to the fact that the gain medium is placed inside an *open* optical resonator and, as a consequence, stimulated emission preferentially occurs in the direction orthogonal to the two cavity mirrors (Fig. 11.1), where feedback from the mirrors is most effective and diffraction losses are the smallest. The laser beam emitted from the output coupler shows a divergence angle which, in the ideal case, is limited by diffraction. From diffraction theory, the divergence angle for a monochromatic beam of wavelength λ turns out to be given by

$$\theta_d = \beta\left(\frac{\lambda}{2w}\right) , \tag{11.12}$$

where β is a numerical coefficient (of order 1) whose specific value depends on the particular transverse field distribution and $2w$ is the diameter of the beam. For example, considering laser radiation in the visible ($\lambda = 500\,\text{nm}$), the divergence of a laser beam of transverse diameter $2w \approx 1\,\text{cm}$ is solely $\theta_d \approx \lambda/2w \simeq 5\times10^{-5}\,\text{rad}$. This means that, after propagation for a length $L = 1\,\text{km}$, the beam size is increased to solely $w+\theta_d L \approx 6\,\text{cm}$!

The *brightness* of laser radiation is closely related to the directionality and stems from the capability of a laser oscillator to emit a high optical power in a small solid angle of space. For a given emitting source, of area ΔS, if P denotes the optical power delivered in a fractional solid angle $\Delta\Omega$ of space, the brightness of the emitter is defined as $B = P/(\Delta S\Delta\Omega)$. The brightness of a laser source, in which the solid angle of emission $\Delta\Omega$ is determined by its divergence angle θ_d, is given by

$$B = \left(\frac{2}{\beta\pi\lambda}\right)^2 P . \tag{11.13}$$

A laser of moderate power (e.g., a few milliwatts) has a brightness several orders of magnitude greater than that of the brightest conventional sources.

11.1.2 Interaction of Radiation with Atoms

Absorption and Stimulated Emission Rates

Consider a monochromatic EM wave of frequency ν incident on a two-level atom with a transition frequency $\nu_0 = (E_2 - E_1)/h$ close to ν. The calculation of the absorption and stimulated emission rates W_{12} and W_{21} can be done following a semiclassical approach, in which the atom is treated quantum mechanically whereas the EM wave classically [11.3, 5–9]. If the atom is initially in its ground state (level 1), the incident wave may induce a transition to level 2 owing to the coupling of the electromagnetic field with the electric and magnetic dipole (and multipole) moments of the atom. The strongest interaction is usually that arising between the electric field $\boldsymbol{E}(t) = \boldsymbol{E}_0\cos(2\pi\nu t)$ of the EM and the electric dipole moment of the transition, which is defined by the matrix dipole element $\mu_{12} = \int u_2^*(\boldsymbol{r})e\boldsymbol{r}u_1(\boldsymbol{r})\,\mathrm{d}\boldsymbol{r}$, where $\boldsymbol{r}$ is the distance of the electron of the atom, with charge e, from its nucleus, and where $u_1(\boldsymbol{r})$ and $u_2(\boldsymbol{r})$ are the electronic eigenfunctions for the atomic energy levels 1 and 2 respectively. In this electric-dipole approximation, a perturbation theory, which assumes that the interaction between the EM wave and the atom is not disturbed by, e.g., collisions or other phenomena (including spontaneous emission), leads to the following expression for the absorption and stimulated emission rate

$$W_{12} = W_{21} = \frac{2\pi^2}{3n^2\epsilon_0 h^2}|\mu_{12}|^2\rho\delta(\nu-\nu_0) , \tag{11.14}$$

where $\rho = n^2\epsilon_0 E_0^2/2$ is the energy density of the EM wave, n is the refractive index of the medium, and δ is the impulse Dirac function. In particular, for a plane wave of intensity $I = c\rho/n$, from (11.14) the following expression for the cross section

$\sigma_{12} = W_{12}/F = h\nu W_{12}/I$ can be derived

$$\sigma_{12} = \frac{2\pi^2}{3n\epsilon_0 ch}|\mu_{12}|^2 \nu\delta(\nu-\nu_0)\,. \tag{11.15}$$

Analogously, if initially the electron is on level 2, owing to the interaction with the EM wave there is a probability that the electron decays into state 1 emitting a photon by stimulated emission. The semiclassical perturbation calculation leads for the stimulated emission cross section $\sigma_{21} = h\nu W_{21}/I$ the same expression as that of σ_{12}, i. e., $\sigma_{21} = \sigma_{12}$, provided that the two levels are not degenerate.

The expression for $\sigma_{12} = \sigma_{21}$ as given by (11.15) is unphysical since it implies that the transition probability is zero for $\nu \neq \nu_0$ and ∞ for $\nu = \nu_0$. The inconsistency is removed by observing that the interaction of the monochromatic EM wave with the atom is not perfectly coherent, but it is disturbed by, e.g., collisions with other atoms or with lattice phonons, spontaneous emission and nonradiative decay of the atom. The effect of such disturbing interactions is to broaden the transition line of each atom in the ensemble, in the sense that in (11.15) the Dirac δ function $\delta(\nu-\nu_0)$ should be replaced by a new function $g(\nu-\nu_0)$, symmetric about $\nu = \nu_0$ with $\int g(\nu-\nu_0)\,\mathrm{d}\nu = 1$, which is generally given by the Lorentzian function (Fig. 11.5a)

$$g(\nu-\nu_0) = \frac{2}{\pi\Delta\nu_0}\frac{1}{1+\left[2(\nu-\nu_0)/\Delta\nu_0\right]^2}\,, \tag{11.16}$$

where $\Delta\nu_0$ depends on the particular broadening mechanism involved. Note that the full-width at half-maximum (FWHM) of the Lorentzian function is simply $\Delta\nu_0$. The resonant character of the stimulated emission and absorption processes is maintained since the line broadening $\Delta\nu_0$ is typically several orders of magnitude smaller than ν_0 (e.g., in a low-pressure gas, for a transition in the visible one has $\nu_0 \approx 5\times10^{14}$ Hz whereas $\Delta\nu_0 \approx 10^6$–10^8 Hz). Since the aforementioned broadening mechanism acts in the same way on each atom of the ensemble, it is referred to as a *homogeneous broadening* mechanism.

A somewhat different case occurs when the resonance frequencies ν_0' of the atoms in the ensemble are distributed around a central frequency ν_0 (*inhomogeneous broadening*). This distribution is described by the function $g^*(\nu_0'-\nu_0)$ such that $\int g^*(\nu_0'-\nu_0)\,\mathrm{d}\nu_0' = 1$ and $g^*(\nu_0'-\nu_0)\,\mathrm{d}\nu_0'$ is the fractional part of the atoms in the ensemble whose resonance frequency lies in the interval $(\nu_0', \nu_0'+\mathrm{d}\nu_0')$. For the most common mechanisms of inhomogeneous line broadening (such as Doppler broadening in a gas or local-field effects in ionic crystals or glasses) the distribution $g^*(\nu_0'-\nu_0)$ is given by a Gaussian function (Fig. 11.5b)

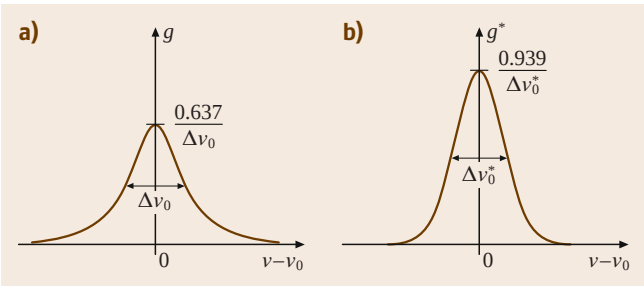

Fig. 11.5a,b Lorentzian **(a)** and Gaussian **(b)** line shapes corresponding to homogeneous and inhomogeneous transition broadening, respectively

$$g^*(\nu_0'-\nu_0) = \frac{2}{\Delta\nu_0^*}\left(\frac{\ln 2}{\pi}\right)^{1/2} \times \exp\left(-\frac{4\ln 2(\nu_0'-\nu_0)^2}{\Delta\nu_0^{*2}}\right), \tag{11.17}$$

where $\Delta\nu_0^*$ is the transition line width (FWHM), which depends on the particular broadening mechanism.

Taking into account the simultaneous presence of both homogeneous and inhomogeneous broadening mechanisms, one can show that the cross section $\sigma = \sigma_{12} = \sigma_{21}$ for stimulated emission and absorption assumes the most general form

$$\sigma = \frac{2\pi^2}{3n\epsilon_0 ch}|\mu_{12}|^2 \nu g_\mathrm{t}(\nu-\nu_0)\,, \tag{11.18}$$

where the total line shape g_t is given by the convolution

$$g_\mathrm{t}(\nu-\nu_0) = \int g^*(\nu_0'-\nu_0)g(\nu-\nu_0')\,\mathrm{d}\nu_0'\,. \tag{11.19}$$

If we consider an ensemble of atoms and indicate by N_1 and N_2 the populations of atoms in the energy levels 1 and 2, as discussed in the previous section a small-signal EM wave of frequency ν which propagates inside the medium experiences amplification for $N_2 > N_1$ or absorption for $N_2 < N_1$. In the former case, one can introduce the absorption coefficient per unit length $\alpha(\nu) = \sigma(\nu-\nu_0)(N_1-N_2)$, whereas in the latter case one can introduce the gain coefficient per unit length $g(\nu) = \sigma(\nu-\nu_0)(N_2-N_1)$. For a weak-signal wave, so that saturation can be neglected, the intensity of the propagating wave is thus exponentially attenuated or amplified along the propagation direction according to $I(z) = I(0)\exp(-\alpha z)$ or $I(z) = I(0)\exp(gz)$, respectively.

These considerations apply to atomic or molecular transitions which are *electric-dipole* allowed, i. e., for which the dipole matrix element μ_{12} of the transition does not vanish. Transitions between atomic or molecular energy levels with the same parity (e.g., between *s* states in an atom) are electric-dipole forbidden. This does not mean however that the atom or molecule cannot pass from level 1 to level 2 when interacting with an EM wave; in this case the transition can occur owing to the interaction of the EM wave with, e.g., the magnetic dipole moment (or the electric quadrupole moment) of the transition, though the strength of the cross section describing this process is much smaller than that of an allowed electric dipole transition. For an electric dipole transition the absorption transition rate W_e is proportional to $\approx |\mu_e E_0|^2$, where μ_e is the electric dipole moment of the transition, E_0 the amplitude of the electric field of the EM wave and $-E_0\mu_e$ is the classical energy of an electric dipole in an external field E_0. Likewise, for a magnetic dipole interaction, the transition rate W_m is proportional to $\approx |\mu_m B_0|^2$, where μ_m is the magnetic dipole of the transition, B_0 is the amplitude of the magnetic field of the EM wave, and $-B_0\mu_m$ is the classical energy of a magnetic dipole in an external magnetic field B_0. By approximating $\mu_e \approx ea$ and $\mu_m \approx \beta$, where $a = 0.529\times10^{-10}$ m is the Bohr radius and $\beta = 9.27\times10^{-24}$ A m^2 is the Bohr magneton, one then obtains:

$$\left(\frac{W_e}{W_m}\right) = \left(\frac{eaE_0}{\beta B_0}\right)^2 = \left(\frac{eac}{\beta}\right)^2 \simeq 10^5 \,. \qquad (11.20)$$

Spontaneous Emission

Spontaneous emission is the phenomenon by which an atom in an excited energy level tends to decay toward the ground state (even in absence of any external perturbation) by emitting an EM wave, i. e., one photon. A correct explanation of spontaneous emission requires a quantum electrodynamic approach in which both the atom and the EM field are quantized. In practice, due to quantization of the EM field, the mean values of both E^2 and H^2 fields are nonvanishing even in the absence of a (classical) EM wave (zero-point field fluctuations). Such intrinsic fluctuations always perturb the atom in an excited state and trigger its decay toward a lower energy level with the emission of one photon with frequency ν close to the atomic transition frequency ν_0. Atomic decay due to spontaneous emission follows an exponential law with a time constant τ_s, which is referred to as the spontaneous emission lifetime (11.2). The quantum electrodynamic calculation of τ_s in the electric dipole approximation and for an atom placed in an optical cavity was done by *Weisskopf* and *Wigner* [11.10]. A simple and rigorous calculation of τ_s may be derived using an elegant thermodynamic argument, which was proposed by Einstein well before any development of the quantum electrodynamics [11.11]. Assume that the material is placed inside a black-body cavity whose walls are kept at a constant temperature T. Once the thermodynamic equilibrium is reached, the spectral EM energy density distribution $\rho(\nu)$ inside the cavity is given by the Planck distribution

$$\rho(\nu) = \left(\frac{8\pi\nu^2}{c^3}\right)\frac{h\nu}{\exp(h\nu/k_B T)-1} \qquad (11.21)$$

where $\rho(\nu)$ is such that $\rho(\nu)\,d\nu$ is the EM energy per unit volume of the cavity associated to modes with frequencies in the interval $(\nu, \nu + d\nu)$. We note that in (11.21) the factor $(8\pi\nu^2/c^3)$ represents the density of EM modes per unit volume of the cavity, whereas the term $h\nu/[\exp(h\nu/k_B T)-1]$ is the energy per mode. The populations N_1^e and N_2^e in the atomic levels 1 and 2 at thermal equilibrium are described by a Boltzmann statistics (11.7); on the other hand, at steady state the number of excitation per unit time from level 1 to level 2 due to the absorption of black-body radiation should balance the number of decays per unit time from level 2 to level 1 due to both stimulated emission and spontaneous emission, i. e., $W_{12}N_1^e = W_{21}N_2^e + N_2^e/\tau_s$. One then obtains $1/\tau_s = W_{12}\exp(h\nu_0/k_B T) - W_{21}$. For a spectrally broad radiation (such as black-body radiation) one can write $W_{12} = W_{21} = \int d\nu c\sigma(\nu-\nu_0)\rho(\nu)/(nh\nu) = 2\pi^2|\mu_{12}|^2\rho(\nu_0)/(3n^2\epsilon_0 h^2)$, where we used (11.15). Using this expression for $W_{12} = W_{21}$ and (11.21) for $\rho(\nu_0)$, one finally obtains

$$\tau_s = \frac{3h\epsilon_0 c^3}{16\pi^3\nu_0^3 n|\mu_{12}|^2} \,. \qquad (11.22)$$

Using a similar thermodynamic argument, one can also show that the spectrum of the photon emitted by spontaneous emission is given by the line shape $g_t(\nu-\nu_0)$ of the transition (11.19), i. e., the probability that the photon emitted by spontaneous emission has a frequency in the range $(\nu, \nu + d\nu)$ is given by $g_t(\nu-\nu_0)\,d\nu$. This property is very interesting since it enables one to measure the transition line shape $g_t(\nu-\nu_0)$ simply in an emission experiment by passing the spontaneously emitted light through a spectrometer of sufficiently high resolution.

To estimate the radiative lifetime τ_s, let us consider for instance an electric-dipole-allowed transition

at a frequency corresponding to the middle of the visible range ($\lambda_0 = c/\nu_0 = 500\,\text{nm}$). Assuming $|\mu_{12}| \simeq ea$ (where $a \simeq 0.1\,\text{nm}$ is the atomic radius), from (11.22) one obtains $\tau_s \simeq 10\,\text{ns}$. For a magnetic dipole transition $1/\tau_s$ turns out to be 10^5 times smaller, i. e., $\tau_s \simeq 1\,\text{ms}$. Note that, according to (11.22), τ_s decreases as the cube of the transition frequency, so that the importance of spontaneous emission increases rapidly with frequency. This implies that, as spontaneous emission is often negligible in the middle- to far-infrared, where nonradiative decay dominates, in the x-ray region (e.g., $\lambda_0 < 5\,\text{nm}$) spontaneous emission is the dominant decay process and τ_s becomes exceedingly short (10–100 fs). Such a short lifetime represents a major challenge for achieving a population inversion in x-ray lasers. It should finally be noted that the rate of spontaneous emission as given by (11.22) can be either enhanced or reduced when the atom radiates in a dielectric cavity whose density of EM modes (i. e., the number of resonant cavity modes per unit frequency and per unit volume) is changed from the value $(8\pi\nu^2/c^3)$ due to, e.g., tight spatial confinement, such as in *microlasers*. For instance, spontaneous decay is fully inhibited for an atom placed inside a photonic crystal whenever the atomic transition frequency ν_0 falls inside a bandgap of the photonic crystal.

Line Broadening Mechanisms

Homogeneous Broadening. A line broadening mechanism is said to be homogeneous when it broadens the line of each atom in the same way. In this case the line shape of the single-atom cross section and that of the overall absorption cross section are identical. There are two main homogeneous broadening mechanisms: *collisional broadening* and *natural broadening*.

Collisional broadening occurs in a gas, where the atom may collide with other atoms, ions, free electrons, or with the walls of the container, as well as in a solid, where collisions are due to the interaction of the atom with the lattice phonons. During a process of absorption or stimulated emission of a two-level atom with a monochromatic EM wave, the collisions interrupt the coherent interaction of the EM with the atom; if we write the electronic wave function ψ of the atom during the transition as $\psi = c_1(t)u_1(\boldsymbol{r})\exp[-\mathrm{i}E_1 t/\hbar] + c_2(t)u_2(\boldsymbol{r})\exp[-\mathrm{i}E_2 t/\hbar]$, assuming that the collision does not induce a decay, it simply introduces a random and rather instantaneous relative phase jump of the coefficients c_1 and c_2, and thus of the oscillating part of the atomic dipole $\mu = \int -e\boldsymbol{r}|\psi(\boldsymbol{r}, t)|^2\,\mathrm{d}\boldsymbol{r}$, which is proportional to $c_1 c_2^*$. Since in the electric-dipole interaction

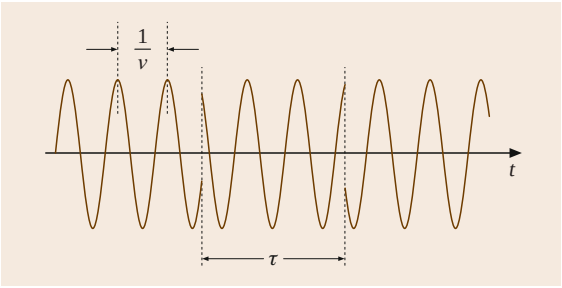

Fig. 11.6 Schematic of the sinusoidal electric field of frequency ν showing random phase jumps at time intervals τ

the radiation–atom coupling is expressed by the energy term $-\mu_e \boldsymbol{E}$, a different but equivalent picture is to assume that it is the phase of the electric field that shows random phase jumps rather than the atomic dipole moment (Fig. 11.6). Therefore we can consider the case of coherent (i. e., not disturbed) interaction of the two-level atom with an EM wave which is not monochromatic but whose spectral content is broadened at around ν owing to the phase jumps. Let $I(\nu') = Ig(\nu' - \nu)$ be the spectral intensity distribution of the EM wave with random phase jumps (Fig. 11.6), where I is the total field intensity and g its spectral shape (with $\int g(\nu' - \nu)\,\mathrm{d}\nu' = 1$). For each fractional spectral component $Ig(\nu' - \nu)\,\mathrm{d}\nu'$ of the EM wave, we may introduce an elemental absorption transition rate $\mathrm{d}W_{12}$ given, according to (11.14), by $\mathrm{d}W_{12} = [2\pi^2|\mu_{12}|^2/(3n\epsilon_0 ch^2)]\delta(\nu' - \nu_0)Ig(\nu' - \nu)\,\mathrm{d}\nu'$. The total transition rate, $W_{12} = \int \mathrm{d}W_{12}$, is then given by $W_{12} = \sigma_{12}(\nu - \nu_0)I/(h\nu)$, where the cross section σ_{12} is given by (11.15) after replacing the delta function $\delta(\nu - \nu_0)$ with $g(\nu - \nu_0)$. To calculate the line shape g, let us assume that the distribution of the time interval τ between two successive collisions be described by an exponential probability density, $p(\tau) = [\exp(-\tau/\tau_c)]/\tau_c$, where τ_c is the mean value of τ. According to the Wiener–Kintchine theorem, the spectrum g can be calculated as the Fourier transform of the autocorrelation function of the sinusoidal field with phase jumps at time intervals τ (Fig. 11.6). This yields a Lorentzian line shape (11.16) with a FWHM of $\Delta\nu_0$, related to the mean value of collision time τ_c by

$$\Delta\nu_0 = \frac{1}{\pi\tau_c}\,. \tag{11.23}$$

For instance, for an atomic or molecular gas at pressure p and absolute temperature T, from kinetic theory and employing the hard-sphere model of a gas, one has $\tau_c = (2Mk_BT/3)^{1/2}[1/(8\pi pa^2)]$, where M is the atomic mass and a its radius. Note that τ_c is inversely propor-

tional, and hence $\Delta\nu_0$ is directly proportional, to the gas pressure p. As a rough rule of thumb, we can say that, for any atom in a gas, collisions contribute to the line broadening by an amount $(\Delta\nu_{coll}/p) \approx 1\,\text{MHz/Torr}$.

For an atom or an ion in a crystal, collisions occur with lattice phonons. Since the number of phonons in a given lattice vibration is strongly dependent on the lattice temperature T, the corresponding line broadening $\Delta\nu_0$ increases with increasing values of T. For instance, in the Nd:YAG laser Nd^{3+} ions are hosted in the YAG crystal, and collision broadening increases from $\Delta\nu_0 \approx 126\,\text{GHz}$ at room temperature ($T = 300\,\text{K}$) to about 250 GHz at $T = 400\,\text{K}$.

A second homogeneous line broadening mechanism originates from spontaneous emission and is referred to as natural (or intrinsic) line broadening. It can be shown that the natural broadening is again described by a Lorentzian function with a FWHM of $\Delta\nu_0$ given by

$$\Delta\nu_0 = \frac{1}{2\pi\tau_s}\,, \tag{11.24}$$

where τ_s is the spontaneous lifetime. For, e.g., an electric dipole transition at the center of the visible ($\lambda \approx 500\,\text{nm}$), one has $\Delta\nu_{nat} \simeq 16\,\text{MHz}$. Since $\tau_s \approx 1/\nu^3$, the natural line width rapidly increases for transitions at shorter wavelengths (to the UV or x-ray spectral regions).

We finally note that, when the two aforementioned homogeneous line broadening mechanisms act simultaneously, the overall line shape is obtained from the convolution of the two corresponding Lorentzian functions. One then obtains a Lorentzian function with a FWHM given by $\Delta\nu_0 = \Delta\nu_{coll} + \Delta\nu_{nat}$.

Inhomogeneous Broadening. A line broadening mechanism is said to be inhomogeneous when it distributes the atomic resonance frequencies over some spectral range. A first case of inhomogeneous broadening is that of ions in ionic crystals or glasses, where the local crystal field induces, via the Stark effect, a local variation of the energy-level separation of the ion. For random local field variations, the corresponding distribution of the transition frequencies $g^*(\nu - \nu_0)$ turns out to be given by a Gaussian function (11.17) with a line width $\Delta\nu_0^*$ that depends on the amount of field inhomogeneity within the crystal or glass.

A second inhomogeneous mechanism, typical of gases, arises from atomic motion and is referred to as *Doppler broadening*. In fact, due to the motion of the atom, the frequency ν' of the EM wave as seen in the rest frame of the atom is shifted as compared to the frequency ν of the wave in the laboratory reference frame according to the relation $\nu' = \nu[1 - (v_z/c)]$, where v_z is the component of the atomic velocity in the propagation z-direction of the EM wave. From the point of view of atom–radiation interaction, this shift is equivalent to a change of the resonance frequency of the atom rather than to a change of the EM frequency. Taking into account the Maxwellian distribution of molecular velocities in a gas, one can show that the distribution of the transition frequencies $g^*(\nu' - \nu_0)$ is given again by a Gaussian function (11.17) with a line width $\Delta\nu_0^*$ given by

$$\Delta\nu_0^* = 2\nu_0\left(\frac{2k_B T \ln 2}{Mc^2}\right)^{1/2}\,, \tag{11.25}$$

where M is the atomic (or molecular) mass and T the gas temperature. As an example, for the $\lambda = 632.8\,\text{nm}$ line of the HeNe laser, at $T = 300\,\text{K}$ and using the appropriate mass for Ne, one obtains $\Delta\nu_0^* \simeq 1.7\,\text{GHz}$. As a general rule, Doppler broadening in a gas is usually larger than collisional broadening for a gas pressure lower than the atmospheric pressure; collisional broadening, in turn, is usually larger than the natural broadening.

Nonradiative Decay

Besides decaying via radiative emission, an atom in an excited state may decay toward a lower-lying level in a nonradiative way. A first mechanism of nonradiative decay arises from collisions and is called *collisional deactivation*. In this case, for a liquid or a gas, the transition energy is released as excitation and/or kinetic energy of the colliding species, or it is transferred to the container walls; for an ion in a crystal or in a glass the deactivation occurs through the interaction with lattice phonons or glass vibrational modes. When, e.g., the excitation energy of an atomic excited species B^* in a gas is released as a kinetic energy of the species A, the collisional deactivation process occurs via the superelastic collision $B^* + A \rightarrow B + A + \Delta E$, where ΔE, the excitation energy to be released, is left as kinetic energy of the colliding partners. When the electronic energy of species B^* is released in the form of the internal energy of species A, we have instead $B^* + A \rightarrow B + A^* + \Delta E$, where now ΔE is the difference between the internal energies of the two colliding species. In this latter case, deactivation process is efficient provided that ΔE is appreciably smaller than the thermal energy $k_B T$ of colliding species. A simple description of the nonradiative decay of a given species in an excited state is expressed by a nonradiative lifetime τ_{nr} such that N_2/τ_{nr} is the

Table 11.1 Main parameters for transitions in most common gas, liquid and solid-state lasers

Transition	λ (nm)	σ_p (cm^2)	τ (μs)	$\Delta\nu_0$
HeNe	632.8	5.8×10^{-13}	30×10^{-3}	1.7 GHz
Ar^+	514.5	2.5×10^{-13}	6×10^{-3}	3.5 GHz
Nd:YAG	1064	2.8×10^{-19}	230	120 GHz
Nd:glass	1054	4×10^{-20}	300	5.4 THz
Rhodamine 6 G	570	3.2×10^{-16}	5.5×10^{-3}	46 THz
Ti^{3+}:Al_2O_3	790	4×10^{-19}	3.9	100 THz

number of atoms, per unit volume and time, that decay owing to the deactivation process.

Nonradiative decay acts in combination with spontaneous emission and, according to (11.3), the overall lifetime τ of an excited state is given by: $\tau = (1/\tau_{nr} + 1/\tau_s)^{-1}$.

Concluding Remarks

From the preceding discussions, we can say that the most important material parameters of interest for a laser are the transition wavelength λ, the transition cross section at the peak σ_p, the lifetime of the upper laser level τ, and the line width $\Delta\nu_0$ of the transition line shape. These parameters, for the most common gas, liquid and solid-state lasers, are summarized in Table 11.1. We note that, as compared to gas and liquid lasers, the cross sections for solid-state lasers (Nd:YAG, Nd:glass, and Ti^{3+}:Al_2O_3) are relatively small and, correspondingly, the lifetimes relatively long because in these lasers the transitions are electric-dipole forbidden (or weakly allowed). We note also that the line widths of gas lasers are much smaller than those of solid-state or dye lasers.

11.1.3 Laser Resonators and Modes

As discussed in the introductory section, in a laser oscillator the inverted amplifying medium is placed inside a *laser resonator* or *laser cavity*, which can be viewed as a *trapping box* for light radiation capable of sustaining stationary (i. e., monochromatic) or weakly damped electromagnetic field configurations at some selected optical frequencies [11.3, 5]. Such EM field configurations and the corresponding optical frequencies are called *cavity modes* and *resonance frequencies*, respectively. The most widely used resonators for lasers are open cavities, composed of at least by two plane or spherical mirrors of circular shape (spherical resonators), placed in front each other at some distance L. Except for microlasers, in ordinary lasers the resonator length L is typically much larger than the oscillating wavelength λ, ranging from a few centimeters to a few tens of centimeters, whereas mirror dimensions range from a fraction of centimeter to a few centimeters. The optical cavity is open to reduce drastically the number of modes that can oscillate with low loss. In fact, if the cavity were closed, the number N of resonant modes that might oscillate, i. e., the number of modes whose resonance frequency falls within the gainline of the active medium, is approximately given by $N \approx (8\pi\nu^2/c^3)V\Delta\nu_0$, where $(8\pi\nu^2/c^3)$ is the density of modes, $\Delta\nu_0$ the line width of the gain medium, and V is the cavity volume. Note that V is usually several orders of magnitude larger than λ^3 at optical wavelengths. To estimate N, let us consider an active medium with a narrow line width, such as the $\lambda = 633$ nm transition of the HeNe laser ($\Delta\nu_0^* = 1.7$ GHz). Assume a resonator length $L = 50$ cm closed by a lateral cylinder with diameter $2a = 3$ mm. The cavity volume is then $V = \pi a^2 L$, and the number of cavity modes that fall under the gainline of the HeNe laser is $N \approx 1.2\times10^9$. In the open optical resonant cavities only those modes traveling nearly parallel to the resonator axis experience low losses to allow for laser oscillation. Therefore, the oscillating modes are expected to show a field distribution mostly confined around the optical axis of the resonator and propagating paraxially along it, making the output laser beam highly directional. These cavity modes and corresponding resonance frequencies depend upon three integer numbers n, m and l, which are referred to as *mode indices*. The latter two indices m and l (transverse mode indices) determine the transverse field distribution (i. e., in a plane orthogonal to the paraxial resonator axis) of the mode, whereas the former index n (the longitudinal mode index) determines the longitudinal field distribution (i. e., along the resonator axis) of the mode and gives, in particular, the number of longitudinal nodes of the standing wave. For spherical mirrors with sufficiently wide apertures, transverse modes are expressed by Gauss–Hermite or Gauss–Laguerre functions, depending on rectangular or circular boundary conditions. In particular, the leading-

order mode, corresponding to transverse mode indices $m = l = 0$, is a *Gaussian beam* and represents the most common transverse field distribution of any output laser beam. For this reason the study of laser modes is closely related to the propagation properties of Gaussian (or Gauss–Hermite) beams.

Gaussian Beams

The electric field of a monochromatic (and uniformly polarized) light wave propagating at a small angle (i. e., paraxially) along the z-direction of an xyz cartesian system of coordinates can be described as follows

$$E(x, y, z, t) = E_0 u(x, y, z) e^{i(\omega t - kz)} + \text{c.c.}\,, \quad (11.26)$$

where $\omega = 2\pi\nu$, ν is the *optical frequency*, $k = 2\pi/\lambda$ is the wavenumber, λ is the optical wavelength, $u(x, y, z)$ is the complex field envelope obeying the so-called *paraxial wave equation*, which in case of free-space propagation reads

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} - 2ik\frac{\partial u}{\partial z} = 0\,. \quad (11.27)$$

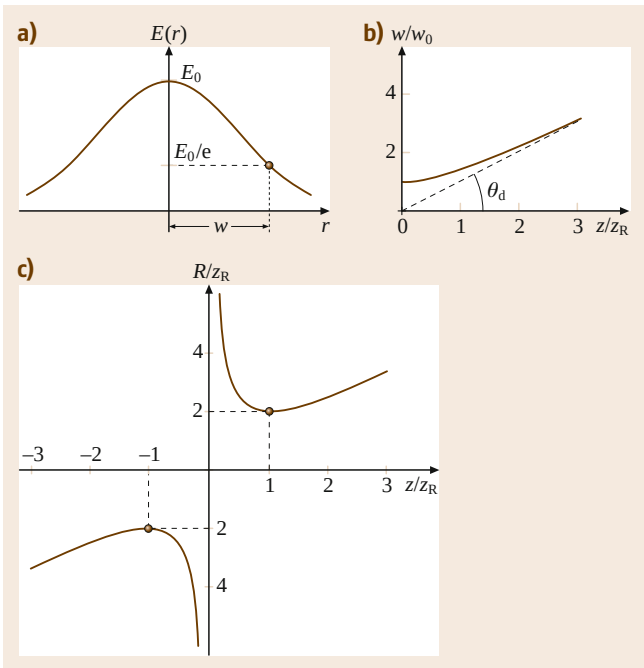

Fig. 11.7a–c The fundamental Gaussian beam in free-space propagation: **(a)** the Gaussian transverse amplitude profile, being $r = (x^2 + y^2)^{1/2}$; **(b)** the beam spot size $w(z)$; **(c)** the wavefront radius of curvature $R(z)$

Among the solutions of (11.27) that retain their functional form during propagation, the *fundamental Gaussian beam* solution turns out to be particularly suited to describe laser beams both inside and outside the resonator [11.12]. A Gaussian beam is a solution of the paraxial equation (11.27) of the form

$$u(x, y, z) = \frac{w_0}{w(z)} \exp\left(-\frac{x^2 + y^2}{w^2(z)}\right) \times \exp\left(-ik\frac{x^2 + y^2}{2R(z)}\right) \times \exp[i\varphi(z)]\,. \quad (11.28)$$

In the preceeding equation, $w(z)$, $R(z)$ and $\varphi(z)$ are given by

$$w(z) = w_0\sqrt{1 + \left(\frac{z}{z_R}\right)^2}\,, \quad (11.29)$$

$$R(z) = z\left[1 + \left(\frac{z_R}{z}\right)^2\right]\,, \quad (11.30)$$

$$\varphi(z) = \tan^{-1}\left(\frac{z}{z_R}\right)\,, \quad (11.31)$$

where $z_R = \pi w_0^2/\lambda$ is a parameter referred to as the *Rayleigh range*. Note that $u(x, y, z)$ is given by the product of three terms: an amplitude factor with a transverse Gaussian distribution, $(w_0/w)\exp[-(x^2 + y^2)/w^2]$ (Fig. 11.7a); a transverse phase factor, $\exp[-ik(x^2 + y^2)/(2R)]$; and a longitudinal phase factor $\exp(i\varphi)$. The amplitude factor in (11.28) shows that, while propagating, the beam intensity distribution retains its shape, but its transverse size w, which is called the *beam spot size*, changes along the propagation direction z according to (11.29). Note that $w(z)$ is a symmetric function of z with a minimum spot size $w = w_0$ at the plane $z = 0$, which is hence referred to as the *beam waist* (Fig. 11.7b). For $z = z_R$, one has $w = \sqrt{2}w_0$ so that the Rayleigh range z_R represents the distance from the beam waist at which the beam spot size increases by a factor $\sqrt{2}$. At large distances (i. e., for $z \gg z_R$), w increases linearly with z, according to $w \approx (w_0/z_R)z$. Hence we can define a beam divergence due to diffraction as $\theta_d = \lim_{z\to\infty} w(z)/z$, obtaining

$$\theta_d = \frac{\lambda}{\pi w_0}\,. \quad (11.32)$$

The transverse phase factor in (11.28) has the same form as that for a spherical wave in the paraxial approximation, R playing the role of the radius of curvature of the spherical wavefront. Thus, we can say that a Gaussian

beam has an approximately spherical wavefront with a radius of curvature varying along propagation according to (11.30). Note that $R(z)$ is an odd function of z (Fig. 11.7c), showing a minimum $R_{\min} = 2z_R$ at $z = z_R$; for $z \gg z_R$, R increases linearly with z, whereas one has $R \to \infty$ as $z = 0$. Thus the wavefront is flat at $z = 0$ and, at large distances, its radius increases linearly with z just as for a spherical wave. The longitudinal phase factor φ provides, in addition to the usual phase shift $-kz$ of plane waves, a longitudinal phase shift (sometimes referred to as the *Gouy phase shift*), slowly varying with z from $-(\pi/2)$ to $(\pi/2)$ on going from $z \ll z_R$ to $z \gg z_R$.

An important parameter of a Gaussian beam at a given propagation plane z is the so-called *complex-q* parameter, defined by the relation:

$$\frac{1}{q} = \frac{1}{R} - \mathrm{i}\frac{\lambda}{\pi w^2} \,. \tag{11.33}$$

It can be shown that, for a Gaussian beam propagating in free space, the q parameter changes along propagation according to

$$q(z) = z + \mathrm{i}z_R \,. \tag{11.34}$$

Equations (11.29) and (11.30) can indeed be obtained upon inserting the parameter q from (11.33) into (11.34) and then separating the real and imaginary part of the resulting equation.

The fundamental Gaussian beam described above belongs to a more general set of eigensolutions of (11.27) which can be written as the product of an Hermite polynomial with a Gaussian function. These are known as *Hermite–Gaussian beams*, and assume the following form [11.3, 5]

$$\begin{aligned} u_{l,m}(x,y,z) = {} & \frac{w_0}{w(z)} H_l\left(\frac{\sqrt{2}x}{w(z)}\right) H_m\left(\frac{\sqrt{2}y}{w(z)}\right) \\ & \times \exp\left(-\frac{x^2+y^2}{w^2(z)}\right) \\ & \times \exp\left[-\mathrm{i}k\frac{x^2+y^2}{2R(z)}\right] \\ & \times \exp[\mathrm{i}(1+l+m)\varphi(z)] \,, \end{aligned} \tag{11.35}$$

where $w(z)$, $R(z)$ and $\varphi(z)$ are given by (11.29–11.31), respectively, and H_l, H_m are Hermite polynomials of order l and m. The lowest-order Hermite–Gaussian beam is obtained by setting $l = m = 0$ in (11.35). These solutions are often referred to as TEM_{lm} beams, where TEM stands for transverse electric magnetic: within the paraxial approximation, both electric and magnetic fields of the EM wave are, in fact, approximately transverse to the z-direction. Note that, for a TEM_{lm} beam, the number of zeros of the field along the x- and y-directions is given by the subscripts l and m, respectively, and therefore the intensity distribution of the TEM_{lm} beam consists of $l+1$ lobes in the horizontal direction and $m+1$ lobes in the vertical direction (Fig. 11.8).

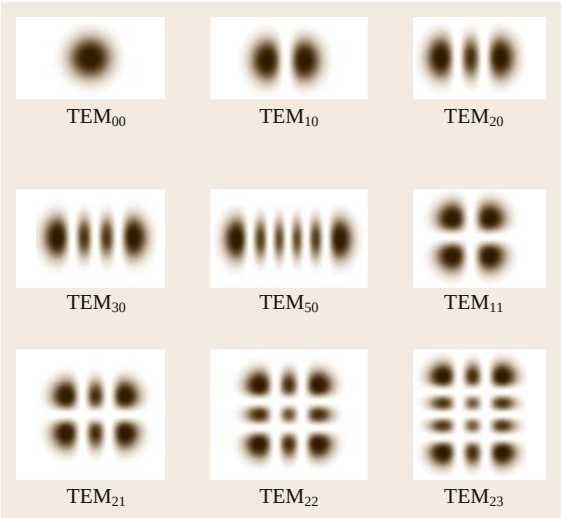

Fig. 11.8 Grey scale intensity patterns of a few low-order Hermite–Gaussian modes

As a final remark, it should be noted that Gauss–Hermite beams maintain their functional shape as they propagate along *an arbitrary* paraxial optical system, described by a paraxial ray matrix $ABCD$. Beam propagation, in this case, is simply ruled by an algebraic relation for the complex q parameter of the Gaussian beam, which is known as the *ABCD law*. In fact, if $z = z_1$ and $z = z_2$ are the input and output planes of the $ABCD$ paraxial optical system, a Gauss–Hermite field distribution $u(x, y, z_1) = H_l(\sqrt{2}x/w_1)H_m(\sqrt{2}y/w_1)\exp[-\mathrm{i}k(x^2+y^2)/(2q_1)]$ at the input plane $z = z_1$ is transformed, at the output plane $z = z_2$, into the distribution

$$\begin{aligned} u(x,y,z_2) = {} & \left(\frac{1}{A+(B/q_1)}\right)^{1+l+m} \\ & \times H_l\left(\frac{\sqrt{2}x}{w_2}\right) H_m\left(\frac{\sqrt{2}y}{w_2}\right) \\ & \times \exp[-\mathrm{i}k(x^2+y^2)/(2q_2)] \,, \end{aligned} \tag{11.36}$$

where the values q_1 and q_2 of the complex-q parameter at the input ($z = z_1$) and output ($z = z_2$) planes are

related by the so-called *ABCD law*

$$q_2 = \frac{Aq_1 + B}{Cq_1 + D} \,. \tag{11.37}$$

As a particular case, note that for free-space propagation from $z_1 = 0$ to $z_2 = z$ one has $A = 1$, $B = z$, $C = 0$, and $D = 1$, so that the *ABCD* law (11.37) yields (11.34).

Optical Resonators: Introductory Concepts

The simplest optical resonator is the *plane-parallel* or *Fabry–Pérot* resonator, consisting of two plane metallic or dielectric mirrors set parallel to one another [11.13]. At first approximation, the modes of this resonator can be considered as the superposition of two plane EM waves propagating in opposite directions along the cavity axis (Fig. 11.9a). In this approximation, resonance frequencies can be readily obtained by imposing the condition that the cavity length L must be an integer multiple of half-wavelengths, i. e., $L = n(\lambda/2)$, where n is a positive integer. This is a necessary condition for the electric field of the EM standing wave to be zero on the two, e.g. metallic, mirrors. It follows that the resonant frequencies are given by

$$\nu_n = n\left(\frac{c}{2L}\right) \,. \tag{11.38}$$

Note that (11.38) can also be obtained by imposing the condition that the phase shift of a plane wave due to one round-trip through the cavity must equal an integral number times 2π, i. e., $2kL = 2n\pi$. This condition is readily obtained by a self-consistency argument: if the frequency of the plane wave is equal to that of a cavity mode, the phase shift after one round-trip must be zero (apart from an integer multiple of 2π). Only in this case, in fact, do the amplitudes at any arbitrary point, due to successive reflections, add up in phase to give an appreciable total field. According to (11.38) the frequency difference between two consecutive modes, i. e., differing by 1 in the longitudinal mode index n, is given by

$$\Delta\nu = \frac{c}{2L} \,. \tag{11.39}$$

This difference is referred to as the *frequency difference* between two consecutive longitudinal (or *axial*) modes. Note that, since the number n indicates the number of half-wavelengths of the mode along the resonator axis, the two consecutive modes have a different longitudinal pattern.

A more general class of laser resonators is the one made of *spherical resonators*, which are formed by two spherical mirrors of radius of curvatures R_1 and R_2, either concave ($R > 0$) or convex ($R < 0$), placed at some arbitrary distance L (Fig. 11.9b). These resonators can be divided into two categories: *stable* resonators and *unstable* resonators. A resonator is said to be unstable when, in bouncing back and forth between the two mirrors, an arbitrary paraxial ray diverges indefinitely away from the resonator axis, either radially or angularly. Conversely, a resonator whose paraxial rays remain bounded is said to be stable. An example of an unstable resonator is shown in Fig. 11.9c. Among stable spherical resonators, symmetric resonators (i. e., having $R_1 = R_2$) are of particular importance; the *confocal* resonator, in which the two spherical mirrors have the focus in common ($R_1 = R_2 = L$), is a noteworthy example of a spherical symmetric resonator. Another important scheme for laser cavities is that employing a *ring* resonator, where the path of the optical rays is arranged to form a closed loop (Fig. 11.9d). Also in this case the resonant frequencies can be obtained by imposing the condition that the total phase shift along the ring path must equal an integer number of 2π. The expression for the resonance frequencies of longitudinal (or axial) modes is thus given by

$$\nu_n = n\left(\frac{c}{L_\mathrm{p}}\right) \tag{11.40}$$

where L_p is the length of the closed loop path. In general, a standing-wave pattern may be formed in ring resonators, because the beam can propagate either clockwise or counterclockwise along the loop. Anyway,

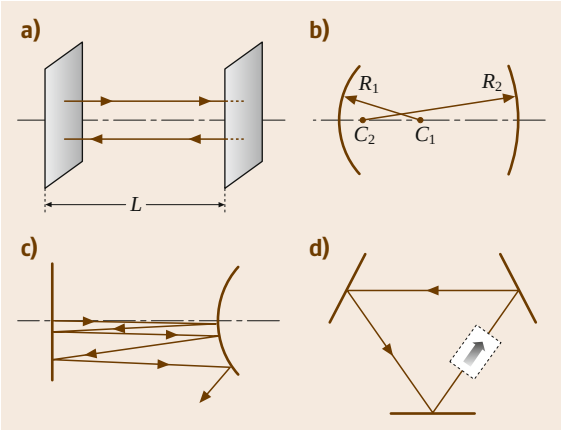

Fig. 11.9 (a) Plane-parallel resonator; (b) Spherical two-mirror resonator; (c) An unstable resonator; (d) A unidirectional ring resonator

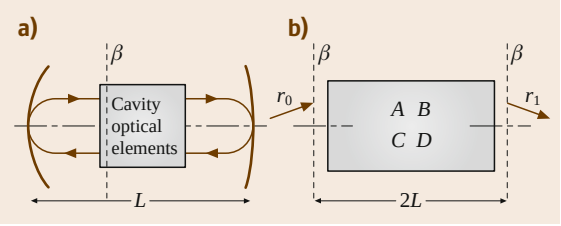

Fig. 11.10 **(a)** A general laser cavity, and **(b)** its equivalent representation given by resonator unfolding with respect to an arbitrary β plane

unidirectional ring resonators can be realized by means of optical diodes inserted along the beam path.

Stability Condition

In general, a laser cavity can be viewed as made of two spherical mirrors comprising a set of intermediate optical elements like lenses, mirrors, prisms, and so on (Fig. 11.10a). If we define an arbitrary plane β orthogonal to the cavity optical axis, it is intuitive (and can be rigorously demonstrated) that the round-trip propagation along the cavity is equivalent to the propagation in a suitable optical system S having β as input and output planes, a transformation known as the *unfolding* of the resonator. Paraxial propagation in such a system can be described by means of the $ABCD$ cavity round-trip matrix (Fig. 11.10b). Accordingly, if we let r_0 and r_0' be, respectively, the transverse coordinate and angle that a ray make with the optical axis when intercepting plane β at time $t = 0$, and r_n and r_n' be the coordinate of the same ray after n cavity round-trip, we have

$$\begin{vmatrix} r_n \\ r_n' \end{vmatrix} = \begin{vmatrix} A & B \\ C & D \end{vmatrix}^n \begin{vmatrix} r_0 \\ r_0' \end{vmatrix} = M^n \begin{vmatrix} r_0 \\ r_0' \end{vmatrix} . \tag{11.41}$$

Therefore, the optical resonator is stable if and only if, for any initial set of coordinates (r_0, r_0'), the corresponding coordinates (r_n, r_n') do not diverge as n increases. This condition is met provided that the eigenvalues $\lambda_{1,2}$ of M are, in modulus, not larger than one. Since $\lambda_{1,2} = \exp(\pm i\theta)$, where $\cos(\theta) = (A + D)/2$, the stability condition requires that θ be real, i. e., that

$$\left| \frac{A+D}{2} \right| \leqslant 1 . \tag{11.42}$$

For the particular case of two-mirror resonators, we can go one step further by explicitly calculating the corresponding $ABCD$ matrix. We recall that a given overall matrix can be obtained by the product of matrices of individual optical elements traversed by the beam, with the matrices written in the reverse order compared to ray propagation through the corresponding elements. In our case, the $ABCD$ matrix is then given by the ordered product of the following matrices: reflection from mirror 1, free-space propagation from mirror 1 to 2, reflection from mirror 2, free-space propagation from mirror 2 to 1

$$\begin{vmatrix} A & B \\ C & D \end{vmatrix} = \begin{vmatrix} 1 & 0 \\ -2/R_1 & 1 \end{vmatrix} \begin{vmatrix} 1 & L \\ 0 & 1 \end{vmatrix} \begin{vmatrix} 1 & 0 \\ -2/R_2 & 1 \end{vmatrix} \begin{vmatrix} 1 & L \\ 0 & 1 \end{vmatrix} .$$

After performing matrix multiplication we obtain

$$\frac{A+D}{2} = \left(1 - \frac{L}{R_1}\right)\left(1 - \frac{L}{R_2}\right) - 1 . \tag{11.43}$$

It is customary to define dimensionless quantities, referred to as the g_1 and g_2 parameters, defined as $g_1 = 1 - L/R_1$ and $g_2 = 1 - L/R_2$. In terms of these parameters, the stability condition transforms into the very simple relation

$$0 < g_1 g_2 < 1 . \tag{11.44}$$

The stability condition given by (11.44) can be conveniently displayed in the (g_1, g_2)-plane as reported in Fig. 11.11. Stable resonators correspond to those points in the gray region of the plane, excluding those which lie on the boundaries, (i. e., satisfying the conditions $g_1 g_2 = 0$ or $g_1 g_2 = 1$), which are referred to as marginally stable resonators. Note that symmetric resonators (i. e., having mirrors of the same radius of curvature $R_1 = R_2 = R$) lie on the bisector line b. As particular examples of these symmetric resonators, one

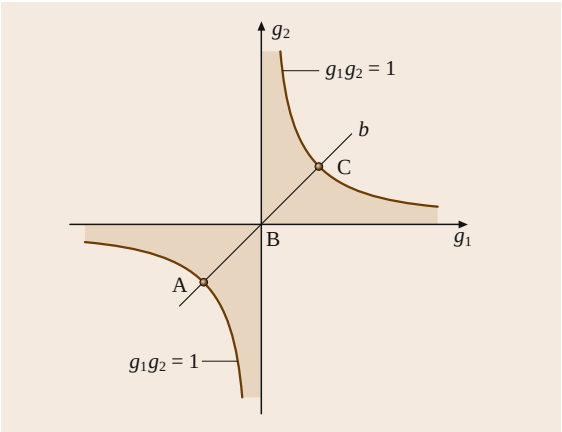

Fig. 11.11 Stability diagram for a general two-mirror spherical resonator. Stable resonators correspond to (g_1, g_2) points lying in the *gray region* of the plane

can see that those corresponding to point A, B and C of the figure are the concentric ($L = 2R$), confocal ($L = R$) and plane ($R = \infty$) resonators, respectively. Since points A, B and C lie on the boundary of the stability region, the corresponding resonators are only marginally stable.

Laser Modes

The modes of an optical resonator are defined as the stationary (i. e., monochromatic) or weakly damped field distributions that can be sustained inside the cavity and that satisfy the boundary conditions imposed by the cavity mirrors. We note that, in open resonators, diffraction losses due to the finite aperture of the mirrors make the modes always leaky. The electric field for a mode in a leaky resonator can then be generally represented as

$$\boldsymbol{E}(x, y, z, t) = \boldsymbol{a}(x, y, z)\cos(\omega t) \times \exp\left[\frac{-t}{2\tau_c}\right] \quad (t > 0)\,, \tag{11.45}$$

where $\boldsymbol{a}(x, y, z)$ is the mode field distribution, ω is the resonance frequency, and τ_c describes field decay due to cavity losses and is referred to as the *cavity photon lifetime*. In order to determine the resonator modes, the corresponding resonance frequencies and diffraction losses let us consider the rather general class of resonators with an optical axis z, as shown in Fig. 11.10a. Propagation of an EM wave back and forth between the two end mirrors of the cavity is equivalent to the unidirectional propagation of an EM wave in a periodic sequence of optical elements (e.g., a lens guide) which is obtained by unfolding the resonator, as shown in Fig. 11.10b. Note that, in the unfolding scheme, the end spherical mirrors should be replaced by thin spherical lenses with focal length equal to the mirror radius of curvature.

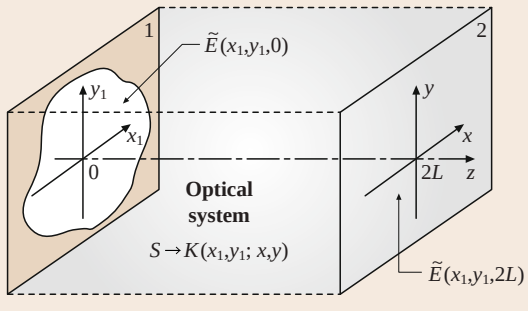

Fig. 11.12 Field calculation at plane 2 ($z = 2L$) when the field $\tilde{E}(x_1, y_1, 0)$ at plane 1 ($z = 0$) is known

Let us first consider the propagation of a monochromatic EM field in a periodic lens guide. By writing the electric field along the lens guide as $E(x, y, z, t) = \tilde{E}(x, y, z)\,e^{i\omega t} + \text{c.c.}$, due to the linearity of the Huygens–Fresnel integral the complex field amplitude $\tilde{E}$ after one period of the lens guide can generally be written by an integral transformation, namely (Fig. 11.12)

$$\tilde{E}(x, y, 2L) = \exp(-i2kL) \times \iint_1 K(x, y; x_1, y_1)\tilde{E}(x_1, y_1, 0)\,dx_1\,dy_1\,, \tag{11.46}$$

where $K(x, y; x_1, y_1)$ is a function of the transverse coordinates of both input and output planes, known as the *propagation kernel*. Note the phase term $(-2kL)$, which represents the phase shift if the wave were a plane wave. The kernel K accounts for all the elements encountered during propagation from input plane 1 ($z = 0$) to output plane 2 ($z = 2L$) and represents, from a physical viewpoint, the field distribution observed at the (x, y)-plane (i. e., at $z = 2L$) when a point-like source at the (x'_1, y'_1) point is placed at the $z = 0$ input plane. Indeed, if $\tilde{E}(x_1, y_1, 0)$ were a bidimensional Dirac δ-function centered at $x_1 = x'_1$ and $y_1 = y'_1$, i. e., if $\tilde{E}(x_1, y_1, 0) = \delta(x_1 - x'_1, y_1 - y'_1)$, then from (11.46) one would readily get $\tilde{E}(x, y, 2L) = K(x, y; x'_1, y'_1)\exp(-i2kL)$. For a general optical system, the calculation of the kernel K is usually rather complicated. However, within the assumption of infinite aperture of all optical elements, the kernel K is simply expressed in terms of the round-trip resonator-matrix elements $ABCD$ by the relation (Huygens–Fresnel–Kirchhoff kernel)

$$K(x, y; x_1, y_1) = \frac{i}{\lambda B}\exp\left\{-\frac{ik}{2B} \times \left[A(x_1^2 + y_1^2) + D(x^2 + y^2) - (2xx_1 + 2yy_1)\right]\right\} \tag{11.47}$$

and the integral in (11.46) can be extended from $-\infty$ to ∞.

Let us now define a mode of a periodic lens guide as a field distribution which reproduces itself after one guide period except for an overall amplitude reduction, due to lens-guide losses, and a phase shift $\Delta\varphi$ accounting for field propagation. Hence $\tilde{E}(x, y, 2L) = |\tilde{\sigma}|\exp(i\Delta\varphi)\tilde{E}(x, y, 0)$, where $|\tilde{\sigma}| < 1$.

It is now convenient to write the phase shift as $\Delta\varphi = -2kL + \varphi$, where $-2kL$ is the shift of a plane wave and φ is an additional phase term due to the fact that the lens-guide mode is not a plane wave. Hence, for a lens-guide mode we require the condition

$$\tilde{E}(x, y, 2L) = \tilde{\sigma} \exp(-2ikL)\tilde{E}(x, y, 0) , \qquad (11.48)$$

where $\tilde{\sigma} = |\tilde{\sigma}| \exp(i\varphi)$. Substitution of (11.48) into (11.46) yields

$$\iint_1 K(x, y; x_1, y_1)\tilde{E}(x_1, y_1, 0)\,dx_1\,dy_1 = \tilde{\sigma}\tilde{E}(x, y, 0) . \qquad (11.49)$$

Note that the mode distribution $\tilde{E}(x, y, 0)$ is an eigenfunction of a Fredholm homogeneous integral equation of the second kind corresponding to the eigenvalue $\tilde{\sigma}$. As a rather general property, it turns out that the Fredholm integral equation admits a doubly infinite discrete set of confined eigensolutions, which can be distinguished by a pair of integer positive numbers l and m. Accordingly, the corresponding eigenvalues will generally be indicated as $\tilde{\sigma}_{lm} = |\tilde{\sigma}_{lm}| \exp(i\varphi_{lm})$, with $|\tilde{\sigma}_{lm}| < 1$ owing to the overall losses (namely, diffraction losses, scattering losses from optical elements, and so on) encountered in one period of propagation along the lens guide.

Now, let us return to the problem of cavity mode calculation. In this case, the mode $\tilde{E}$ of the lens guide corresponds to a mode of the resonator of Fig. 11.10a provided that, after one cavity round-trip, the overall phase shift $\Delta\varphi$ accumulated in one cavity round-trip is zero apart from an integer number of 2π, i. e., $\Delta\varphi = -2kL + \varphi_{lm} = -2\pi n$. From this condition and using the relation $k = 2\pi\nu/c$ between the wavenumber k and frequency ν of the mode, one readily obtains the cavity resonance frequencies as

$$\nu_{nlm} = \frac{c}{2L}\left(n + \frac{\varphi_{lm}}{2\pi}\right) . \qquad (11.50)$$

Note that we have indicated explicitly that these frequencies depend on the three integer numbers l, m, and n. The integers l and m define the transverse field profiles of the mode (Fig. 11.8), i. e., they represent the number of zeros of the field along the x- and y-coordinates, respectively. The integer n defines the longitudinal field configuration, i. e., the number of zeros of the EM standing wave (nodes) as previously discussed for the plane-parallel resonator (11.38).

For stable resonators with infinite apertures the eigenmodes of the Fredholm equation are given by the Gauss–Hermite functions, and their resonance frequencies can be calculated from (11.50) using the propagation law (11.36). For instance, for the important case of two-mirror spherical resonators, it turns out that $\varphi_{lm} = 2(1 + l + m)\cos^{-1}(\pm\sqrt{g_1 g_2})$, where the plus or minus sign depends on whether g_2 (and hence g_1) is positive or negative. The resonance frequencies of the two-mirror spherical resonator are thus given by

$$\nu_{nlm} = \frac{c}{2L}\left[n + \frac{1 + l + m}{\pi}\cos^{-1}(\pm\sqrt{g_1 g_2})\right] . \qquad (11.51)$$

For, e.g., a confocal resonator, one has $g_1 = g_2 = 0$, and hence $\nu_{nlm} = [c/(4L)](2n + 1 + l + m)$. Note that modes with the same value of $(2n + l + m)$ have the same resonance frequency, and they are said to be frequency degenerate. Note also that, for a confocal resonator, the mode spacing is $c/(4L)$.

Photon Lifetime and Cavity *Q*

The modes of an optical resonator are always leaky and therefore show a finite photon cavity lifetime τ_c. In fact, besides diffraction losses due to finite aperture effects of mirrors or intracavity optical elements, some other loss mechanisms are always present in a laser resonator. For instance, the mirror reflectivity of the output coupler is always smaller than 100%, which means that a fractional part of the photons ϕ stored in the cavity escapes from the resonator at each round-trip. Scattering or absorption losses of intracavity optical elements are also another common cause of photon leakage. To calculate the rate of energy decay in a given cavity mode, let I_0 be the initial intensity corresponding to the field amplitude at a fixed point within the cavity, and let R_1 and R_2 be the (power) reflectivities of the two mirrors and L_i the fractional internal loss per pass, which accounts for scattering, absorption and diffraction losses. The intensity at the same point, after a round-trip time $\tau_R = 2L_e/c$, is $I(\tau_R) = R_1 R_2(1 - L_i)^2 I_0 = I_0 \exp(-2\gamma)$, where L_e is the *cavity optical length* and γ is the logarithmic loss per pass, defined by the relation

$$\gamma = \frac{\gamma_1 + \gamma_2}{2} + \gamma_i \qquad (11.52)$$

with $\gamma_1 = -\ln(R_1)$, $\gamma_2 = -\ln(R_2)$, and $\gamma_i = -\ln(1 - L_i)$. In view of the exponential decay law introduced in (11.45), after a round-trip time we must have $I(\tau_R) = I_0 \exp(-\tau_R/\tau_c)$, and thus we conclude that the photon

lifetime is given by

$$\tau_c = \frac{\tau_R}{2\gamma} = \frac{L_e}{c\gamma} \,. \tag{11.53}$$

Having calculated the photon lifetime, the time behavior of the electric field at any point inside the resonator can be written as $E(t) = E_0 \exp(-t/2\tau_c + i\omega t) +$ c.c., where ω is the angular frequency of the mode. The same time behavior then applies for the field of the wave leaving the resonator through the output mirror. Taking the Fourier transform of this field (for $t > 0$) we find that the power spectrum of the emitted light has a Lorentzian line shape with line width (FWHM) given by

$$\Delta\nu_c = \frac{1}{2\pi\tau_c} \,. \tag{11.54}$$

We can now introduce an important quality factor which is strictly related to the photon lifetime. This is the *cavity Q-factor* which is defined, for any resonant system, as 2π times the ratio between the energy stored in the resonator and the energy lost in one oscillation cycle. Thus a high cavity Q-factor implies low losses in the resonant system. Since in our case the energy stored is $\phi h\nu$ and the energy lost per cycle is $(-\mathrm{d}\phi/\mathrm{d}t)h\nu$ we obtain

$$Q = -\frac{2\pi\nu\phi}{\mathrm{d}\phi/\mathrm{d}t} = \frac{\nu}{\Delta\nu_c} \,, \tag{11.55}$$

where the exponential decay law $\phi(t) = \phi_0 \exp(-t/\tau_c)$ for the stored cavity photons ϕ has been used and where the expression for $\Delta\nu_c$ given by (11.54) has also been utilized.

As an example, consider a two-mirror spherical resonator with $R_1 = R_2 = R = 0.98$ and assume $L_i \simeq 0$. From (11.53) we obtain $\tau_c = \tau_T/[-\ln(R)] = 49.5\tau_T$, where $\tau_T = L/c$ is the transit time of the photon for a single pass in the cavity. Note that the photon lifetime is much longer than the transit time, a typical result of low-loss cavities. If we now assume $L = 90\,\mathrm{cm}$, we get $\tau_T = 3\,\mathrm{ns}$ and $\tau_c \simeq 150\,\mathrm{ns}$. From (11.54) we can then calculate $\Delta\nu_c \simeq 1.1\,\mathrm{MHz}$. Finally, assuming a laser wavelength $\lambda \simeq 630\,\mathrm{nm}$ corresponding to an optical frequency $\nu = 5\times10^{14}\,\mathrm{Hz}$, from (11.55) we have $Q = 4.7\times10^8$. Thus laser resonators have a remarkably high Q-value, which means that a very small fraction of the energy is lost during one oscillation cycle.

11.1.4 Laser Rate Equations and Continuous-Wave Operation

A simple and powerful approach for understanding the basic dynamical behavior of a laser is based on a *rate-equation* model, in which simple balance equations for the total number of atoms undergoing a transition and the total number of photons created or annihilated are written [11.3]. For a more-refined treatment of laser dynamics based on either a semiclassical or a full-quantum electrodynamic approach, which may account for certain phenomena such as dynamical laser instabilities, laser coherence and photon statistics, we refer the reader to more-specialized literature [11.6, 8].

Laser Rate Equations

Let us consider a four-level laser scheme (Fig. 11.4b) and make the following assumptions

1. The laser transition is homogeneously broadened
2. The lifetime τ_1 of the lower laser level 1 is short enough that we may neglect the population in level 1
3. A single longitudinal and transverse mode is oscillating in the cavity
4. We neglect the precise transverse and longitudinal spatial variation of the cavity mode
5. We assume uniform pumping of the active medium.

Under these assumptions, we can write the following rate equations for the population inversion $N = N_2 - N_1 \simeq N_2$ in the active medium and the number of photons ϕ of the oscillating mode stored in the cavity

$$\frac{\mathrm{d}N}{\mathrm{d}t} = R_p - B\phi N - \frac{N}{\tau} \tag{11.56}$$

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = -\frac{\phi}{\tau_c} + V_a\, B\phi N \,, \tag{11.57}$$

where R_p is the pump rate per unit volume, τ is the lifetime of the upper laser level 2, and τ_c is the photon lifetime for the oscillating mode. In (11.56), the terms R_p, N/τ and $B\phi N = W_{21}N$ account for the pumping process, radiative and nonradiative decay, and stimulated emission, respectively. The constant B, which represents the stimulated transition rate per photon, per mode is related to the transition cross section σ by the simple equation $B = \sigma c/V$, where V is the mode volume in the laser cavity [11.3]. The first term on the right-hand side in (11.57), ϕ/τ_c, represents the number of cavity photons that are lost per unit time due to internal loss, diffraction loss and output coupling through the mirrors. Finally, the second term in (11.57) represents the number of photons (per unit time) that are created in the oscillating mode owing to stimulated emission: since $B\phi N$ represents the number of atoms per unit volume and per unit time that decay creating a photon in the oscillating cavity mode, the total number of photons created per unit time can be expressed as the product

of $B\phi N$ with the volume V_a occupied by the cavity mode inside the gain medium. Spontaneous emission in not included in the balance equation (11.57) since only a negligible fraction of spontaneously emitted photons belongs to the oscillating mode. However, spontaneous emission photons are important to allow laser action starting.

The laser output power P_{out} is related to the photon number ϕ by the simple relation

$$P_{out} = \frac{\gamma_2}{2\gamma}(h\nu)\frac{\phi}{\tau_c} = \frac{\gamma_2 c}{2L_e}h\nu\phi \,. \tag{11.58}$$

In fact, $(h\nu)(\phi/\tau_c)$ is the total EM energy lost in the cavity per unit time, and solely a fraction $\gamma_2/(2\gamma)$ of this power is available due to transmission through the output mirror. For a typical CW laser operated in the continuous-wave regime, the number of photons ϕ stored in the cavity may vary from about 10^{10} photons for low-power lasers (such as a HeNe laser delivering $P_{out} = 10\,\text{mW}$ power at $\lambda = 632.8\,\text{nm}$) to 10^{17} photons for high-power lasers (such as a CO_2 laser delivering an output power $P_{out} = 10\,\text{kW}$ at $\lambda = 10.6\,\mu\text{m}$).

Threshold Condition

The population inversion needed to reach the threshold for laser oscillation is simply obtained from (11.57) by imposing $d\phi/dt = 0$. An initially small number of photons turns out to be exponentially damped for $N < N_c$ or exponentially amplified for $N > N_c$, where

$$N_c \equiv \frac{1}{\tau_c B V_a} = \frac{\gamma}{\sigma l} \tag{11.59}$$

is referred to as the *critical inversion* (or threshold inversion). In this equation, l is the length of the active medium and the threshold condition $\sigma N_c l = \gamma$ is reached when the gain in the inverted medium, $g = \sigma N l$, equals the logarithmic loss γ of the cavity. The pump rate corresponding to the threshold condition is $R_{cp} = N_c/\tau = \gamma/(\sigma l \tau)$; the corresponding pump power at threshold P_{th} is then obtained using (11.9). The perturbation that starts the laser action when the pump rate R_p reaches the critical value R_{cp} is provided by spontaneous emission.

Output Power and Slope Efficiency

For a pump rate $R_p > R_{cp}$, the rate equations (11.56) and (11.57) admit the solution $N_0 = N_c$ and $\phi_0 = [1/(B\tau)](x-1)$, corresponding to laser being above threshold (Fig. 11.13). Here $x = R_p/R_{cp} = P_p/P_{th} > 1$ is the above-threshold pump parameter, where P_p is the pump power and P_{th} is its threshold value. The corresponding output laser power can be then calculated from (11.58) and can be cast in the form

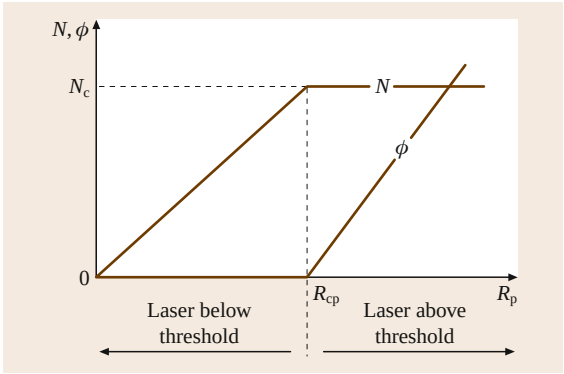

Fig. 11.13 Behavior of population inversion N and photon number ϕ in the oscillating mode versus the pump rate R_p for a four-level laser. R_{cp} is the critical pump rate above which laser action takes place

$$P_{out} = \eta_s(P_p - P_{th}) \,, \tag{11.60}$$

where

$$\eta_s = \eta_p \eta_c \eta_q \eta_t \,. \tag{11.61}$$

Equation (11.60) shows that, within the approximation made, a linear relation is obtained between the output power and the pump power. One can then define the slope efficiency of the laser as $\eta_s = dP_{out}/dP_p$. According to (11.61), η_s is given by the product of four contributions:

1. The *pump efficiency* η_p
2. The *output coupling efficiency* $\eta_c = \gamma_2/(2\gamma)$
3. The laser *quantum efficiency* $\eta_q = (h\nu)/(h\nu_{mp})$
4. The *transverse efficiency* $\eta_t = A_b/A$

where $A_b = V_a/l$ is the transverse mode area in the active medium and A the transverse pumping area. The slope efficiency of a laser may typically vary from less than 1% in low-efficiency lasers (such as in the HeNe laser) to 20–50% or even higher in high-efficiency lasers.

Relaxation Oscillations

One can show that the solution, given above, for lasers above threshold is stable, i. e., that any initial perturbation of the system (e.g., of cavity losses) is damped. When the ratio τ/τ_c between the upper laser level lifetime and cavity photon lifetime is larger than 1 (or much larger, such as in laser transitions which are electric-dipole forbidden), relaxation to the steady state occurs

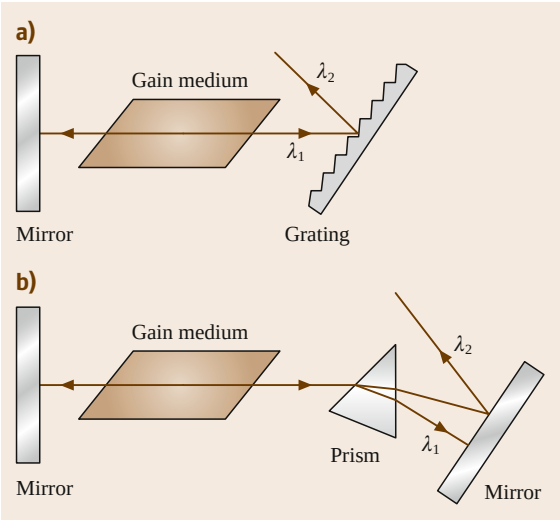

Fig. 11.14 **(a)** Laser tuner based on a diffraction grating in the Littrow configuration. **(b)** Laser tuner based on the use of a dispersive prism

through damped oscillations in both photon number and population inversion. This results in damped oscillations of the output power referred to as *relaxation oscillations*. In solid-state lasers, the frequency of relaxation oscillations typically fall in the 10 kHz–10 MHz region, whereas, in semiconductor lasers, it falls in the GHz region. Relaxation oscillations in slow-gain media (such as in solid-state lasers) triggered by technical noise or by pump power fluctuations are one of the major cause of amplitude noise in the output laser power. Whenever a high degree of intensity stability is required, laser amplitude stabilization may be provided by a suitable active feedback loop.

Laser Tuning

The gain line width of some lasers (e.g., dye lasers or vibronic solid-state lasers) is very wide and, for several applications, one needs to tune the laser output wavelength away from the line center and across the entire available line width. In other cases, different lasing transitions may compete or may potentially be used, and one needs to select one of them. In both circumstances, one can employ a wavelength-selective element inside the laser cavity, which is often referred to as *laser tuner*. For lasers in the middle infrared (such as CO_2 lasers), one generally uses a diffraction grating in the so-called Littrow configuration (Fig. 11.14a) as one of the cavity mirror. Wavelength tuning is simply achieved by grating rotation. In the visible or near-

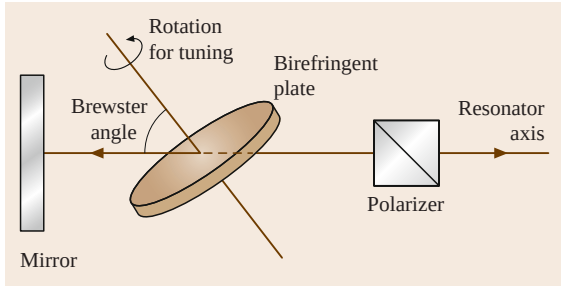

Fig. 11.15 Schematic of a birefringent laser tuner made of an intracavity birefringent plate and polarizer

infrared spectral regions (such as for the Ar^{3+} laser), a dispersive prism is more commonly used and wavelength tuning is simply achieved by prism, or mirror, rotation (Fig. 11.14b). To reduce insertion losses, the two prisms facets are approximately inclined at Brewster angle. A third wavelength-selective element, which is becoming increasingly popular in the visible or near-infrared, uses a birefringent filter inside the cavity. This device exploits a birefringent plate, inclined at the Brewster angle, which generally changes the polarization state of the intracavity laser beam. In the presence of an intracavity polarizer, or just exploiting the polarizing properties of the Brewster-angle filter, the birefringence filter thus generally produces additional cavity losses. However, at certain wavelengths, λ, the birefringent plate does not change the polarization state of the beam and thus allows for laser oscillation with low loss. Upon rotation of the plate around the axis orthogonal to its faces (Fig. 11.15) the direction of the birefringence axes of the plates is changed and this correspondingly changes the wavelength at which low loss occurs.

Single Mode Selection and Limit to Laser Monochromaticity

Most often, lasers tend spontaneously to oscillate on several transverse and longitudinal modes, especially when the gainline is relatively broad. The reasons for multimode oscillations are rather involved and their study goes beyond the scope of the present contribution. For many applications, single-mode operation may be required, and therefore one needs to force the laser to oscillate on a single transverse (usually the fundamental TEM_{00} Gaussian mode) and longitudinal mode. For stable resonators, single transverse mode oscillation is easily achieved by placing an aperture inside the cavity of appropriate size in order to increase diffraction loss of higher-order modes with respect to the TEM_{00} mode.

In some cases, such as in longitudinally pumped solid-state lasers, limitation on the pump spot size lends itself to TEM_{00} mode selection.

Even when a laser is oscillating on a single transverse mode, it can still oscillate on several longitudinal modes. This usually occurs since the longitudinal-mode separation $\Delta\nu = c/(2L)$ is smaller (or much smaller) than the gain line width $\Delta\nu_0$. For some gas lasers, where the gain line width is relatively small (up to a few GHz), single-longitudinal-mode selection is simply obtained by making the cavity length short enough that the longitudinal-mode separation $\Delta\nu$ becomes larger than $\Delta\nu_0/2$. For, e.g., a HeNe laser ($\Delta\nu_0^* \simeq 1.7\,\text{GHz}$), this condition implies $L \leq 17.5\,\text{cm}$. For solid-state lasers with a bandwidth up to a few hundred GHz, this condition requires cavity lengths in the sub-millimeter region (*microchip lasers*). For lasers with much larger bandwidths (e.g., dye lasers or tunable solid-state lasers), the required length is too small to make the technique of practical relevance and to make the gain in the medium large enough to reach threshold. In these cases, different techniques are employed. For solid-state or dye lasers, the simplest method is to use one (or more) Fabry–Pérot etalons within the cavity, which acts as a narrow frequency spectral-selective element (Fig. 11.16). The etalon thickness and finesse should be designed to ensure single mode selection. This implies that:

1. The half width $\Delta\nu_{FP}/2$ of the transmission peaks of the Fabry–Pérot must be smaller than the longitudinal-mode separation $\Delta\nu = c/(2L)$
2. The etalon free spectral range $\Delta\nu_{FSR}$ must be larger than the half width of the gain line $\Delta\nu_0/2$ (Fig. 11.16).

For semiconductor lasers, single mode selection is achieved by using a distributed feedback (DFB) structure, in which a longitudinal corrugation of the refractive index in the semiconductor induces frequency mode selection according to Bragg scattering theory.

A special case of single mode selection that deserves mention is that of a laser with a homogeneously broadened line (e.g., Nd:YAG and dye lasers). In this case, multimode oscillation is mainly due to the standing-wave character of the laser mode arising from the interference of counter-propagating waves established between the two cavity mirrors. The use of a ring resonator instead of a linear cavity, in which unidirectional operation is forced by, e.g., an intracavity optical diode, may be enough in this case to achieve single longitudinal-mode operation.

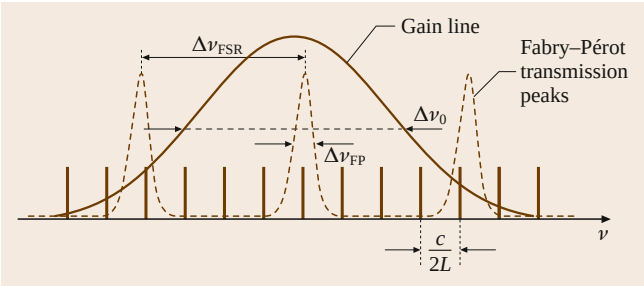

Fig. 11.16 Schematic of single longitudinal mode selection by use of an intracavity Fabry–Pérot etalon

We finally discuss the limit of monochromaticity (and hence of temporal coherence) of a laser. The line width $\Delta\nu_L$ of a laser that oscillates on a single longitudinal mode is ultimately established by spontaneous emission noise. The quantum theory of a laser shows that the spectral shape of emitted light is Lorentzian with a FWHM given by the well-known Schawlow–Townes formula

$$\Delta\nu_L = \frac{N_2}{N_2 - N_1}\frac{2\pi h\nu_L(\Delta\nu_C)^2}{P}\,, \tag{11.62}$$

where P is the output power, $\Delta\nu_C = 1/(2\pi\tau_c)$ is the line width of the cold cavity mode, N_2 and N_1 are the steady-state populations in the upper and lower laser levels, respectively, and ν_L is the emission frequency. Typically the line width predicted by the Schawlow–Townes formula is negligibly small compared to that produced by other cavity disturbances (e.g., fluctuations of cavity length or *technical noise*), except for the very important class of semiconductor lasers. For, e.g., a typical HeNe laser oscillating on its red transition ($\lambda = 632.8\,\text{nm}$), τ_c is of the order of tens of μs, so that $\Delta\nu_L$ is of the order of $\simeq 1\,\text{mHz}$, which turns out to be much smaller than the line broadening due to technical noise. For instance, a small cavity length change ΔL, due to technical noise, contributes to the frequency broadening $\Delta\nu_L$ by an amount given by $|\Delta\nu_L| = (\Delta L/L)\nu_L$; for $L = 1\,\text{m}$ and $\nu_L = 4.7\times10^{14}\,\text{Hz}$ (visible transition), a change of ΔL by just $\approx 10^{-8}$ times the atomic dimension leads to a contribution to $\Delta\nu_L$ comparable to the quantum limit. Conversely, in semiconductor lasers the quantum limit of $\Delta\nu_L$ is considerably larger and typically falls in the MHz range, owing to the much short photon lifetime (τ_c is of the order of few ps). Therefore, the laser line width of a typical semiconductor laser arises from quantum noise.

11.1.5 Pulsed Laser Behavior

In lasers operating in the CW or quasi-CW regimes, the maximum achievable optical output power is limited by the maximum available pump power. For high-power CW lasers (such as CO_2 lasers), power levels up to $\approx 100\,\mathrm{kW}$ can be reached; however larger power levels, which can be of interest for many applications, are prevented in the CW regime. Transient laser behavior allows one to obtain higher peak powers by concentrating the available energy in a single, short optical pulse or in a periodic sequence of optical pulses [11.3, 5]. Additionally, transient laser behavior is a powerful tool for the generation of ultrashort optical pulses, with durations down to $\approx 10\,\mathrm{fs}$ in lasers with a broad gain-line (notably the Ti^{3+}:Al_2O_3 laser). From a dynamical viewpoint, pulsed laser behavior can be divided into two rather distinct categories:

1. Laser transients occurring on a time scale of the order of the cavity photon lifetime τ_c, i. e., appreciably larger than the cavity round-trip time. This includes the so-called Q-switching and gain-switching regimes, which enable the generation of optical pulses as short as a few nanoseconds with optical peak powers typically in the megawatt range. These are basically single-longitudinal-mode regimes and can be described by means of a rate equation model (11.56) and (11.57).
2. Laser transients occurring on a time scale appreciably shorter (and often much shorter) that the cavity round-trip time. These are basically multi-longitudinal-mode regimes, i. e., they involve the simultaneous oscillation of many longitudinal laser modes, and include the so-called mode-locking regime, which enables the generation of trains of ultrashort laser pulses with durations down to a few femtoseconds.

Laser Q-switching: Dynamical Aspects

Q-switching is a technique that enables the generation of a short optical pulse (of the order of the cavity photon lifetime τ_c) by a sudden switching of the cavity Q factor, i. e., of the cavity loss γ. The change of Q is produced, in principle, upon placing inside the laser cavity an opaque shutter which can be opened or closed. When the shutter is closed (i. e., the cavity Q is low), laser action is prevented and the population inversion N can reach a relatively large value (well above the critical value N_c) due to pumping. When the shutter is opened, the Q factor is suddenly switched to a high value and the laser exhibits a gain $g = \sigma l N$ that greatly exceeds the loss γ. Light emission then occurs via the generation of a short and intense laser pulse. The duration of a Q-switching pulse typically ranges from a few nanoseconds to a few tens of nanoseconds, whereas its peak power is in the megawatt range. To achieve sufficient population inversion when laser action is prevented, a long lifetime τ of the upper laser level is required. Thus Q-switching can be effectively used for electric-dipole-forbidden laser transitions, where τ generally falls in the millisecond range. This is the case of most solid-state lasers (e.g., Nd, Yb, Er in different host materials; Cr-doped materials, such as alexandrite, Cr:LiSAF, and ruby) and some gas lasers (e.g., CO_2 or iodine).

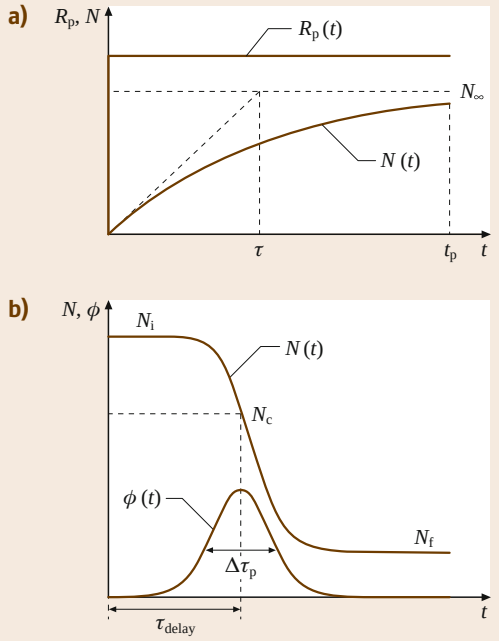

Fig. 11.17a,b Dynamics of fast switching in a four-level laser. **(a)** Temporal behavior of pump rate and population inversion when the cavity Q is low. **(b)** Temporal behavior of population inversion and cavity photons when the cavity Q is suddenly switched to a high value, showing the formation of the Q-switching pulse

To understand the basic dynamics of Q-switching, let us consider a four-level laser and assume that a step pump pulse is applied at time $t = 0$, i. e., $R_p(t) = 0$ for $t < 0$ and $R_p =$ constant for $0 < t < t_p$, where t_p is the duration of the pump pulse; meanwhile the shutter is closed (Fig. 11.17a) and laser action is prevented. From

(11.56) with $\phi = 0$, one then obtains that the transient population inversion increases accordingly to the relation $N(t) = N_\infty[1 - \exp(-t/\tau)]$, where the asymptotic value N_∞ is given by $N_\infty = R_p\tau$ (Fig. 11.17a). After a pump time of about 2τ, the population inversion already reaches a value close to its asymptotic limit N_∞, and therefore the pump pulse can be switched off and the shutter opened. In fact, for t_p larger than $\approx 2\tau$ the energy supplied to the medium is not useful for increasing the population inversion any further but is lost as radiative and nonradiative decay. Suppose now that the shutter is opened very rapidly at time t_p (*fast switching*), and take the origin of time at the instant when switching occurs (Fig. 11.17b). From this time on, the evolution of both population inversion and number of photons in the cavity can be numerically computed by solving the rate equations (11.56) and (11.57) with the initial conditions $\phi(0) \simeq 1$ and $N(0) = R_p\tau[1 - \exp(-t_p/\tau)] \equiv N_i$, where the initial condition $\phi(0) \simeq 1$ accounts for the fact that the laser action is started by spontaneous emission (the so-called *extra photon*). The qualitative transient behavior of both N and ϕ is shown in Fig. 11.17b and can be simply understood by observing that, just after the switching time $t = 0$, the gain $g = \sigma Nl$ in the gain medium greatly exceeds the single-pass cavity loss γ; therefore the number of photons, which increases nearly exponentially with time starting from the extra photon due to spontaneous emission, typically takes from several hundreds to a few thousand cavity round-trips to reach a sufficient value to saturate the laser transition, thus producing a reduction of the available inversion (Fig. 11.17b). This means that the time delay for the peak of the laser pulse, τ_{delay} typically ranges from several tens to a few hundred of nanoseconds. Note that, on such a time scale, the radiative and nonradiative decays of the population N (which typically occur on the millisecond time scale) are negligible, and therefore population decay just occurs by stimulated emission. The decrease of N as ϕ increases leads, in turn, to a decrease of the gain $g = \sigma Nl$. The peak of the pulse occurs at the delay time, τ_{delay}, such that the population inversion N decreases to its critical value, N_c. In this case, in fact, laser gain g equals cavity loss γ and one has from (11.57) $d\phi/dt = 0$. For $t > \tau_{delay}$, one has $N < N_c$ and $d\phi/dt < 0$. This means that the number of photons now decreases towards zero. Meanwhile, due to stimulated emission, the population inversion also keeps decreasing until the photon pulse has decreased to zero. At this time some population inversion, say N_f, is generally left in the medium after Q-switching (Fig. 11.17b). Note that the quantity $\eta_E = (N_i - N_f)/N_i$ represents the fraction of the energy initially stored in the material that goes into stimulated emitted photons, usually referred to as the inversion, or energy, utilization factor. The duration $\Delta\tau_p$ of the Q-switched pulse, the output energy $E = (1/\tau_c)[\int \phi(t)\,dt](h\nu)(\gamma_2/(2\gamma))$, the energy utilization factor η_E, as well as the time τ_{delay} needed for pulse formation can be derived in a closed form by an analysis of the rate equations (11.56) and (11.57) in which pumping and radiative and nonradiative decay are neglected. One obtains

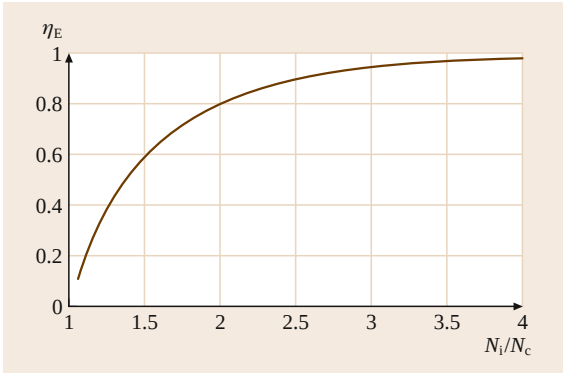

Fig. 11.18 Behavior of the energy utilization factor η_E versus the normalized initial inversion N_i/N_c

$$\Delta\tau_p = \tau_c \frac{(N_i/N_c)\eta_E}{(N_i/N_c) - \ln(N_i/N_c) - 1}\,, \tag{11.63}$$

$$E = \left(\frac{\gamma_2}{2\gamma}\right)(N_i\eta_E V_a)(h\nu)\,, \tag{11.64}$$

$$\tau_{delay} \approx \frac{\tau_c}{(N_i/N_c) - 1}\ln(\phi_p/10)\,, \tag{11.65}$$

where N_i/N_c is the ratio between the initially stored population inversion and critical inversion; ϕ_p is the peak photon number of the Q-switching pulse, given by $\phi_p = V_a(N_i - N_c) - N_c V_a \ln(N_i/N_c)$; and η_E is the energy utilization factor. The value of η_E can be calculated from the implicit equation $(N_i/N_c)\eta_E = -\ln(1 - \eta_E)$ from which a plot of (N_i/N_c) vs. η_E can readily be obtained (Fig. 11.18). Note that (11.64) can readily be obtained by a simple energy-balance argument: the stored energy in the medium released as EM wave is in fact equal to $h\nu(N_i - N_f)V_a = h\nu(\eta_E N_i)V_a$, and, out of this energy, only the fraction $[\gamma_2/(2\gamma)]$ goes into the output beam.

Q-switched lasers may generally be operated in two distinct regimes. In so-called pulsed Q-switching, the pump rate $R_p(t)$ generally consists, as explained above, of a pulse with duration comparable to the upper-state lifetime τ. Of course, the pulsed operation can be pe-

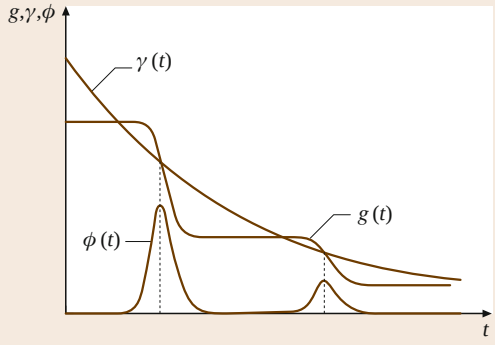

Fig. 11.19 Gain and photon dynamics in a slow-switching laser, showing the formation of multiple pulses

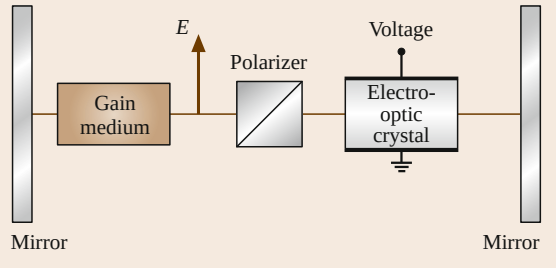

Fig. 11.20 Schematic of a Q-switched laser using a Pockels cell

riodically repeated upon repeating the pulsed pump (generally up to a rate of a few tens of Hz). In so-called CW repetitive Q-switching, the pump rate R_p is held constant and cavity losses are periodically switched from a high to a low value (generally with a rate from a few to a few tens of kHz).

So far we have considered the dynamic behavior corresponding to fast switching, where the switching of the cavity loss is treated as instantaneous (in practice, much shorter than the time τ_{delay}). In the case of *slow switching*, the dynamic behavior is somewhat more complicated and multiple pulses may result, as shown in Fig. 11.19. In the figure, the behavior of the cavity loss γ and laser gain $g = \sigma Nl$ is depicted. The multiple intersections of the slowly decaying curve for the loss $\gamma(t)$ with the gain curve $g(t)$ explain the formation of multiple Q-switching pulses.

Methods of Q-Switching

Several methods have been developed to achieve switching of the cavity Q; the most common are [11.3, 4]:

1. Electrooptic Q-switching
2. Rotating prism
3. Acoustooptical Q-switching
4. Saturable absorber Q-switching.

Electrooptic Q-Switching. In this case the shutter placed inside the laser cavity is made of a Pockels cell and a polarizer in the configuration shown in Fig. 11.20 (electrooptic shutter). The Pockels cell consists of a suitable nonlinear electrooptic crystal (such as KD*P or lithium niobate for the visible-to-near-infrared region or cadmium telluride for middle-infrared), in which an applied DC voltage induces a change in the crystal refractive indices. The induced birefringence turns out to be proportional to the applied voltage. The transmission axis of the polarizer is set at 45° with respect to the birefringence axes of the crystal. When no DC field is applied to the crystal, no polarization losses are introduced in the cavity by the electrooptic shutter, i. e., cavity losses are low. However, when a DC field is applied such that the phase difference $\Delta\varphi$ between the ordinary and extraordinary waves in the birefringent-induced crystal is equal to $\pi/2$, the Pockels cell operates as a $\lambda/4$ birefringent plate. Therefore, the linearly polarized light, coming from the polarizer, is rotated by 90° after a double pass through the cell and it is then fully reflected out of the cavity by the polarizer. The electrooptic shutter is now closed and cavity Q is zero. The DC voltage to the crystal required to produce the phase shift $\Delta\varphi = \pi/2$ is referred to as the quarter-wave voltage and typically ranges from 1 to 5 kV. To avoid multiple pulses, this voltage must be switched off in a time typically smaller than 20 ns.

Rotating Prism. In this simple Q-switching technique, one of the cavity mirror is generally made of a roof-top prism and rotation is made through the axis parallel to the other mirror and orthogonal to the prism edge (Fig. 11.21). The high-Q condition is achieved when the prism edge passes through a position parallel to the other cavity mirror. Although rotating prisms are simple and inexpensive devices which can be used at any wavelength, they suffer the limitation arising from the limited rotation speed ($\approx$ 400 Hz). The Q-switching time is then rather long (typically $\approx$ 400 ns) which often results in the production of multiple pulses (slow switching).

Acoustooptic Q-Switching. In this case the shutter consists of an acoustooptic modulator, driven by a radio-frequency (RF) oscillator, which is placed inside

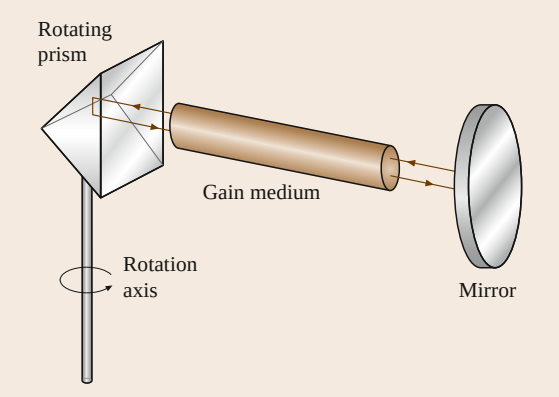

Fig. 11.21 Schematic of a Q-switched laser using a rotating prism

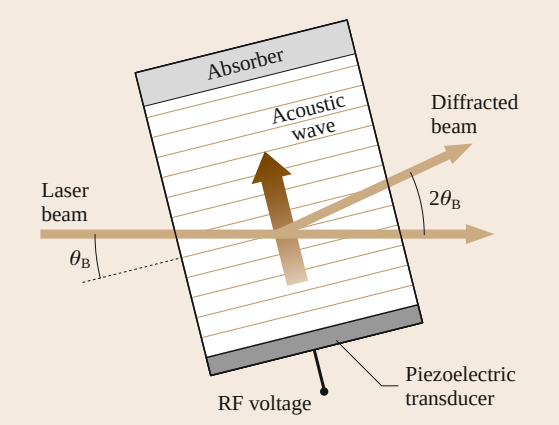

Fig. 11.22 Schematic of an acoustooptic modulator used for laser Q-switching (θ_B is the Bragg angle)

the laser cavity. The modulator consists of a transparent block of material (usually fused quartz in the visible to near-infrared or cadmium selenide in the mid- to far-infrared) bonded on one side to a piezoelectric transducer and to an acoustic absorber on the other (Fig. 11.22). When the transducer is on, traveling sound waves are then produced in the material in the direction orthogonal to the plane of the transducer. Due to the photoelastic effect, the resulting strain in the material results in local changes of the material refractive index, i. e., in the generation of an index grating which is traveling along the material itself. Bragg scattering of the laser beam propagating across such a grating (Fig. 11.22) thus produces a diffracted beam and hence additional losses in the cavity (low-Q condition). Maximum diffraction efficiency is achieved when the incident light angle θ_B satisfies the Bragg condition $\theta_B = \lambda/(2\lambda_a)$, where λ and λ_a are the optical and acoustical wavelengths, respectively. The high-Q condition is simply obtained by switching off the transducer voltage. Acoustooptic modulators have the advantages of introducing low values of optical insertion losses and can be driven at high repetition rates (several kHz). Therefore they are used mainly for repetitive Q-switching of low-gain CW-pumped lasers (e.g., Nd:YAG or Ar-ion lasers).

Saturable Absorber Q-Switching. The Q-switching techniques discussed so far use active Q-switches, in the sense that they need an external control source. A notable passive Q-switching technique, in which no external driving control is required, consists of placing a suitable *saturable absorber* inside the laser cavity. This absorber is basically an unpumped two-level medium which absorbs at the laser wavelength with a comparatively low saturation intensity. Thus, due to the phenomenon of saturation, the absorption coefficient of the absorber decreases as the intensity of the intracavity laser beam increases. To model this phenomenon we write the rate equation for the absorber as $(\mathrm{d}N_2/\mathrm{d}t) = \sigma_a(N_1 - N_2)I/(h\nu) - N_2/\tau$, where N_2 and τ are the population and lifetime of the excited level 2, N_1 is the population in the lower (ground) level 1, and $I = I(t)$ is the intracavity laser intensity. In CW operation or if τ is short enough as compared to the changes of $I(t)$, we may assume that $(\mathrm{d}N_2/\mathrm{d}t) \approx 0$ and therefore obtain $N_1 - N_2 \simeq N_t/(1 + I/I_s)$, where $N_t = N_1 + N_2$ is the total absorber population and $I_s \equiv h\nu/(2\sigma\tau)$ is the *saturation intensity* of the absorber. Since now the absorption coefficient is $\alpha = \sigma_a(N_1 - N_2)$, from the last two equations we obtain

$$\alpha = \frac{\alpha_0}{1 + I/I_s}\,, \tag{11.66}$$

where $\alpha_0 = N_t\sigma_a$ is the unsaturated absorption coefficient of the absorber. Equation (11.66) then shows that, as the intracavity laser intensity I increases, the losses introduced by the saturable absorber decrease and the cavity Q correspondingly increases, i. e., Q-switching is achieved. The detailed dynamics underlying the formation of a Q-switching pulse with the saturable-absorber Q-switch, is however more involved than the one previously discussed. Here we just say that the saturable absorber should have a low value of the saturation intensity so that, when laser action starts, the absorber is bleached earlier (i. e., at lower intensity) than the time

when population inversion in the gain medium starts to decrease appreciably owing to stimulated emission.

Typical absorbers used for passive Q-switching consist of dyes in an appropriate solvent; the main drawback of these absorbers is their photochemical degradation, i. e., poor chemical stability, and inadequate thermal properties. Recently, the advent of solid-state absorbers (notably absorbers based on chromium doped into various crystalline hosts) are replacing dye absorbers, thus avoiding the problem of degradation.

Laser Mode-Locking: Dynamical Aspects

Mode-locking is a laser operation regime in which many longitudinal modes of the cavity are simultaneously forced to oscillate with a precise phase relation so that the output laser beam shows a repetitive train of ultrashort optical pulses [11.3, 5]. To achieve mode-locking operation, a suitable device, which is usually referred to as the *mode locker*, must be placed inside the cavity. For a given laser medium, the lower limit to the achievable pulse duration $\Delta\tau_p$ is set by the gain line width ($\Delta\tau_p \gtrsim 1/\Delta\nu_0$), whereas the pulse repetition rate $1/\tau_p$ is usually equal to the difference frequency between two consecutive longitudinal modes $\Delta\nu$ (or an integer multiple of $\Delta\nu$, as for harmonic mode-locking). Therefore, pulse duration, depending upon the gain line width, usually ranges from about 1 ns, in gas lasers, down to 10 fs in broad-bandwidth solid-state lasers. Pulse repetition rate depends, of course, upon the cavity length and usually ranges from about 100 MHz to a few GHz.

Frequency-Domain Description. The basic principle of laser mode-locking can be explained as follows. Let us consider, for simplicity, a traveling-wave ring laser of optical length L_e, and assume that the separation of the longitudinal cavity modes $\Delta\nu = c/L_e$ be smaller (usually much smaller) than the gain line width $\Delta\nu_0$. In this case, even in the absence of the mode locker, the laser tends spontaneously to oscillate on several longitudinal modes (*free-running* regime). Let $\nu_l = \nu_0 + l\Delta\nu$ be the frequency and $E_l = A_l \exp(i\varphi_l)$ the complex amplitude of the l-th oscillating longitudinal cavity mode, where l is an integer number and $l = 0$ corresponds to the longitudinal mode closest to the center of the gainline (Fig. 11.23). The electric field $E(z, t)$ inside the laser cavity is then given by the superposition of the oscillating longitudinal modes and can be written in the form $E(z, t) = A(t - z/c)\exp[2\pi i\nu_0(t - z/c)]$, where z is the longitudinal coordinate measured along the perimetric axis of the ring and the envelope $A(t')$ is given by

$$A(t') = \sum_l A_l \exp(2\pi i l \Delta\nu t' + i\varphi_l) , \qquad (11.67)$$

where $t' = t - z/c$ is a retarded time. Note that, owing to the dependence of the field on $t - z/c$, the field distribution in the cavity is a traveling wave which propagates with the speed of light; therefore we may limit the discussion to the field behavior at a given reference plane $z = 0$, e.g., at the output coupler of the laser. The output laser power, averaged over the rapidly varying optical cycle, will be then proportional to $|A(t)|^2$. Note that, if the mode amplitudes A_l and phases φ_l are constant or slowly varying in time compared to the cavity round-trip time $\tau_R = L_e/c = 1/\Delta\nu$, the signal $A(t)$ is basically periodic in time with a period equal to τ_R. However, the specific form of the signal in one period depends on the precise distribution of the mode amplitudes A_l and, most importantly, on their phases φ_l.

In a *free-running laser*, the phases φ_l do not have a precise relation to each other; they may also fluctuate in time. The superposition of N modes with, e.g., the same amplitude $A_l = A_0$ but with randomly distributed phases typically leads to a spiking signal $|A(t)|^2$ made of a periodic sequence of irregular pulses (Fig. 11.24a), each with duration approximately equal to $\Delta\tau_p \approx 1/\Delta\nu_L$, where $\Delta\nu_L = N\Delta\nu$ is the oscillating bandwidth. Note that, since the response time of a conventional photodetector is usually much longer than a few picoseconds, the complex temporal behavior shown in Fig. 11.24a is usually not resolved for free-running multimode lasers, instead its average value – proportional to NA_0^2 – is monitored.

In a *mode-locked laser*, the role of the mode locker is to lock the phases of oscillating modes in a precise manner. The most common and interesting case is that of a mode locker that imposes a *linear phase locking* condition, i. e., $\varphi_l = l\varphi$, where φ is a constant. In this

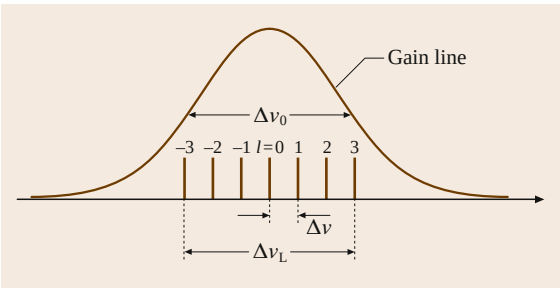

Fig. 11.23 Schematic of a laser oscillating on several longitudinal modes in the frequency domain

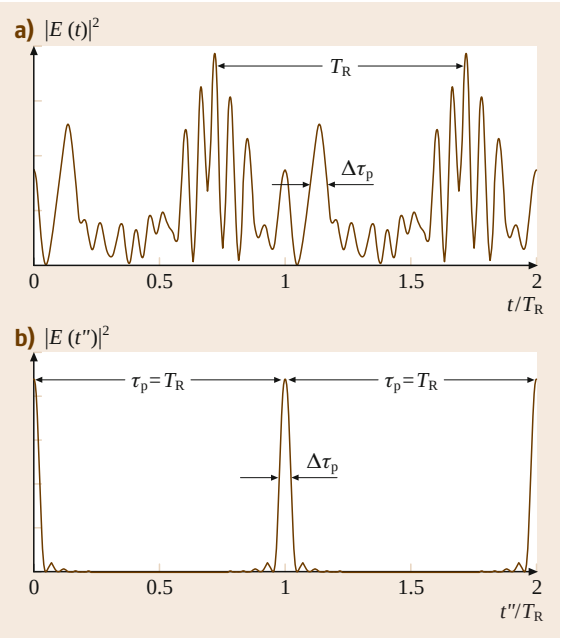

Fig. 11.24a,b Behavior of output power in a laser oscillating on many longitudinal modes with equal amplitude **(a)** Free-running regime, corresponding to random phases ϕ_l. **(b)** Mode-locking regime, corresponding to linear phase locking $\phi_l = l\phi$

case, one has

$$A(t'') = \sum_{l=-\infty}^{\infty} A_l \exp(2\pi i l \Delta\nu t'') \,, \tag{11.68}$$

where t'' is a translated time given by $t'' = t' + \varphi/(2\pi\Delta\nu)$. Usually, in a mode-locked laser the envelope of the mode amplitudes A_l follows the shape of the gainline, i. e., A_l is maximum at the center of the gainline ($l = 0$) and decreases toward zero as $|l|$ increases; for instance, for active mode-locking in a homogeneously broadened medium, one can show that A_l follows a Gaussian distribution. However, to calculate the series in (11.68) simply, we assume that $A_l = A_0 = \text{const.}$ for $|l| \le N$ and $A_l = 0$ for $|l| > N$, i. e., we assume an odd number $2N+1$ of oscillating modes with the same amplitude. In this case one obtains in (11.68) a geometric progression which can be calculated in a closed form, yielding

$$A(t'') = A_0 \frac{\sin\left[(2N+1)\pi\Delta\nu t''\right]}{\sin(\pi\Delta\nu t'')} \,. \tag{11.69}$$

A plot of the squared amplitude of the electric field $|A(t'')|^2$ is reported in Fig. 11.24b. Note that a pulse train, at a repetition rate $\tau_p = 1/\Delta\nu$ equal to the cavity round-trip time τ_R, is obtained. The squared amplitude of the electric field at the peak pulse is given by $(2N+1)^2 A_0^2$, whereas the FWHM pulse duration $\Delta\tau_p$ is approximately given by

$$\Delta\tau_p \simeq \frac{1}{(2N+1)\Delta\nu} = \frac{1}{\Delta\nu_L} \,, \tag{11.70}$$

where $\Delta\nu_L = (2N+1)\Delta\nu$ is again the oscillating bandwidth. Therefore, for broad oscillating bandwidths, phase locking among longitudinal modes leads to the generation of short laser pulses with high peak power. The physical limit to the maximum number of phase-locked modes that can be forced to oscillate is ultimately determined by the gain bandwidth of the active material, i. e., $\Delta\tau_p$ is longer than or equal to $1/\Delta\nu_0$.

In general, when the actual shape (e.g., Gaussian) of the mode amplitudes A_l is taken into account, the overall field amplitude $A(t'')$ can be obtained approximately from (11.68) upon transforming the sum over all modes into an integral, namely $A(t'') \simeq \int_{-\infty}^{+\infty} A(l) \exp(2\pi i l \Delta\nu t'')\, dl$. From this last equation one then sees that the pulse amplitude $A(t'')$ is the Fourier transform of the spectral mode envelope $A(l)$. Therefore, in this case, i. e., under linear phase-locking conditions, the pulse amplitude is said to be transform limited. Note, however, that under phase-locking conditions different from the linear case (e.g., $\varphi_l = \varphi_1 l + \varphi_2 l^2$, as in so-called frequency mode-locking) the mode-locked pulses are no longer transform-limited, i. e., their temporal duration is larger than that predicted by the Fourier limit.

Time-Domain Description. The previous analysis of mode-locking is often referred to as the *frequency-domain* description since the onset of the periodic pulse train is viewed as due to the coherent superposition of longitudinal modes of the laser cavity. A different description of the mode-locking regime, complementary to the frequency-domain approach, is also possible in the *time domain*. In fact, according to the results shown in Fig. 11.24b and since τ_R is the time for a round-trip, a single pulse of duration $\Delta\tau_p$ is circulating within the laser cavity (Fig. 11.25a). Note that the spatial extension of the pulse $\Delta z = c\Delta\tau_p$, according to (11.70) is given by $\Delta z = L_e/(2N+1)$ where L_e is the length of the ring perimeter. For a sufficiently large number $(2N+1)$ of oscillating modes, Δz is then much smaller than the cavity length L_e. The temporal periodicity of the output laser beam then simply results from the successive transits of the intracavity circulating pulse at the out-

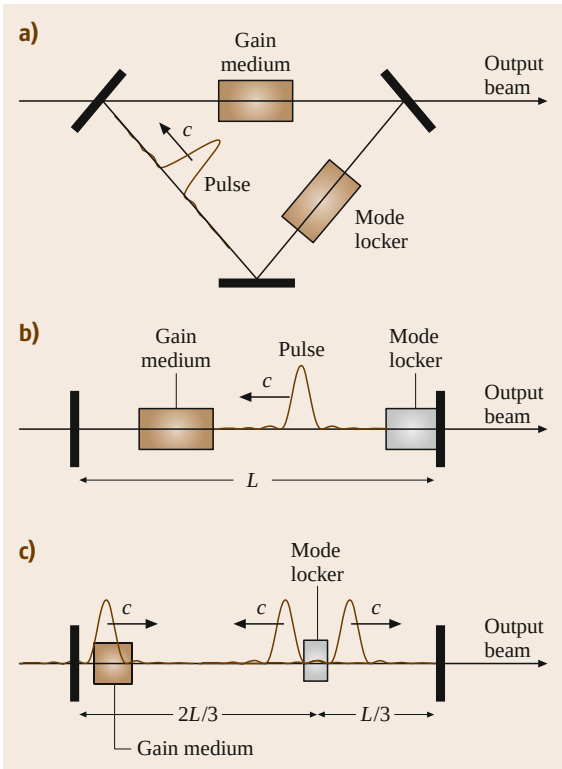

Fig. 11.25a–c Schematic of the mode-locking regime in the time domain. **(a)** Mode-locking in a ring cavity. **(b)** Mode-locking in a linear cavity. **(c)** Harmonic mode-locking in a linear cavity (harmonic order $n = 3$)

put mirror, which occur at intervals $\tau_p = L_e/c$ equal to the cavity transit time. According to this picture, we readily understand that the mode-locking regime can be achieved by placing a suitable fast shutter inside the cavity. In fact, if an initially non-mode-locked beam is present within the cavity, its spatial amplitude distribution can be represented as in Fig. 11.24a, with the time t replaced by z/c. By periodically opening the shutter for a short time interval (of the order $\Delta\tau_p$) with period $\tau_p = L_e/c$, possibly at the time when the most intense noisy pulse in Fig. 11.24a reaches the shutter, then only this pulse will survive in the laser cavity, producing the mode-locking condition of Fig. 11.24b. After a transient leading from the temporal pattern of Fig. 11.24a to that of Fig. 11.24b, the mode-locked pulse will consistently reproduce itself after each transit in the cavity.

It should be noted that all considerations made above for a ring laser resonator apply *mutatis mutandis* to a linear (i. e., Fabry–Pérot) laser cavity. In this case, however, self-consistent propagation of the mode-locked pulse in one cavity round-trip requires that the shutter must be placed close to one end mirror of the cavity (Fig. 11.25b). Note that, if the shutter is placed at a distance $L/2, L/3, \cdots, L/n$ from one end mirror and is opened at intervals $\tau_R/2, \tau_R/3, \cdots, \tau_R/n$, where L is the cavity length, multiple pulses (precisely $2, 3, \cdots, n$ pulses) may be simultaneously generated and the repetition rate of the pulse train is correspondingly increased by a factor of $2, 3, \cdots, n$ (e.g., Fig. 11.25c for the case $n = 3$). Such a mode-locking regime is referred to as *harmonic mode-locking*. Harmonic mode-locking is typically employed in active mode-locked fiber lasers to increase the pulse repetition rate (≈ 1–40 GHz); owing to the relatively long cavity length (≈ 1–10 m), to reach high repetition rates harmonic orders n up to ≈ 1000 are usually needed.

Mode-Locking Methods

The methods to achieve mode-locking can generally be divided into two categories:

1. Active mode locking, in which the mode-locker is driven by an external source.
2. Passive mode locking, in which the mode-locker is not externally driven but exploits some nonlinear optical effect, such as the saturation of a saturable absorber or the nonlinear change of the refractive index in a Kerr medium.

Active Mode Locking. Active mode locking is usually achieved by placing, inside the laser cavity, either an amplitude modulator, which produces a periodic modulation in time of the cavity loss (amplitude-modulation (AM) *mode locking*), or a phase modulator, which periodically varies the optical length of the resonator (frequency-modulation (FM) *mode locking*). In lasers with upper-state lifetimes shorter than the cavity round-trip time (e.g., dye lasers), active mode locking can also be achieved by periodic modulation of the laser gain at a repetition rate equal to the longitudinal mode separation $\Delta\nu$ (*synchronous pumping*). We limit here to describe the basic principle of AM mode locking, since it is the most common among the three mentioned techniques. In AM mode locking, the mode locker is usually a Pockels-cell electrooptic modulator for pulsed and high-gain lasers, or an acoustooptic modulator for low-gain lasers. The electrooptic or acoustooptic modulator sinusoidally varies the cavity loss $\gamma(t)$ at a given modulation frequency ν_m (Fig. 11.26). It is thus ex-

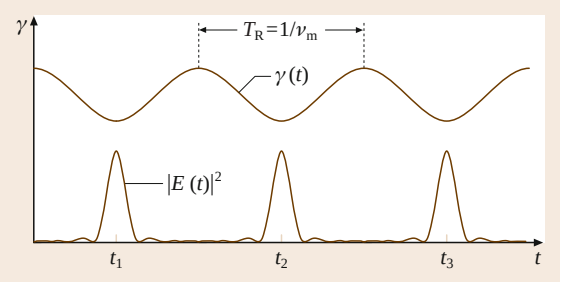

Fig. 11.26 Schematic of AM active mode locking

pected that the mode-locked pulse circulating inside the cavity (Fig. 11.25b) will pass through the modulator at the time t_1 of the cycle where the cavity loss $\gamma(t)$ is minimum. Since the pulse propagating inside the cavity passes again through the modulator at times $t_2 = t_1 + \tau_R$, $t_3 = t_2 + \tau_R$, etc., where $\tau_R = 1/\Delta\nu$ is the cavity round-trip time, a steady mode-locking regime can be reached provided that the synchronization condition $\Delta\nu = \nu_m$ is satisfied. It should be noted that the steady-state pulse duration, $\Delta\tau_p$, is given by the inverse of the oscillation bandwidth, $(2N+1)\Delta\nu$, and, thus, it is ultimately established by the gain bandwidth $\Delta\nu_0$. However, the finite bandwidth of the gain medium influences the steady-state pulse duration in a quite different way for homogeneous or inhomogeneous lines. For an inhomogeneously broadened line, and for a laser well above threshold, the oscillating bandwidth tends to cover the whole gain bandwidth $\Delta\nu_0^*$ even in the absence of AM modulation, and the main role of the mode-locker is just to lock the phases of these oscillating modes. The resulting temporal duration of the mode-locked pulse is therefore given approximately by

$$\Delta\tau_p \simeq \frac{0.44}{\Delta\nu_0^*} \,. \tag{11.71}$$

Conversely, for a homogeneously broadened gain medium the number of longitudinal modes oscillating in the free-running regime is usually rather modest and the role of the mode-locker is both to enlarge the oscillating bandwidth of the laser (by power transfer from the central to lateral longitudinal modes) and to lock the phases of the oscillating modes. Under steady-state conditions, band enlargement due to the modulator is counteracted by band reduction due to the gain medium and the pulse duration is given by [11.14]

$$\Delta\tau_p \simeq \frac{0.45}{\sqrt{\nu_m \Delta\nu_0}} \,. \tag{11.72}$$

As an example, we will consider a mode-locked Nd:YAG laser oscillating on its homogeneously broadened line at $\lambda = 1064\,\text{nm}$. Assuming $\Delta\nu_0 \simeq 126\,\text{GHz}$ ($T = 300\,\text{K}$), a linear cavity of length $L_e = 1.5\,\text{m}$ and an AM mode-locker placed close to one cavity mirror, the modulator loss must be driven at a frequency $\nu_m = \Delta\nu = c/(2L_e) \simeq 100\,\text{MHz}$, and the expected mode-locked pulse duration, according to (11.72), is $\Delta\tau_p \simeq 125\,\text{ps}$.

It should be noted that in AM mode-locked lasers (as well as in the other active mode locking techniques) even small detunings of the modulation frequency ν_m from the cavity axial mode separation $\Delta\nu$ may result in the destruction of the mode-locking operation. In practice a detuning $|\nu_m - \Delta\nu|/\nu_m$ of the order of $\approx 10^{-4}$ is enough to destroy mode-locking. To obtain stable AM mode-locking, active control of the cavity length is sometimes required, especially when relatively long cavities are employed (such as for AM mode-locked fiber lasers).

Passive Mode-Locking. There are two main types of passive mode-locking (ML):

1. Fast saturable-absorber ML, which uses the saturation properties of a suitable absorber (e.g., a dye or a semiconductor) with a very short upper-state lifetime
2. Kerr-lens mode-locking (KLM), which exploits the self-focusing property of a suitable transparent Kerr medium.

Fast Saturable-Absorber ML [11.15]. Consider a saturable absorber with a low saturation intensity and a relaxation time shorter than the duration of the mode-locked pulses. According to (11.66), the absorption loss experienced by a pulse crossing the absorber is dependent on the instantaneous pulse intensity $I(t)$, and decreases as the intensity increases. Thus, starting from the random sequence of light bursts occurring in the unlocked case (Fig. 11.24a), the gain–loss balance will favor the growth and stabilization of the noise pulse with the highest intensity. The steady-state situation, occurring in this case, can be described with the help of Fig. 11.27. Here, gain saturation drives the gain g below the cavity losses $\gamma(t)$ except at those instants where, due to the arrival of the pulse $I(t)$ at the saturable absorber, the losses are reduced due to absorber saturation. During the time intervals corresponding to the hatched regions in Fig. 11.27, the gain is then larger than the instantaneous loss $\gamma(t)$. A so-called window

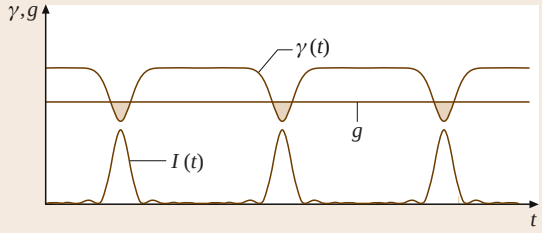

Fig. 11.27 Mode-locking with a fast saturable absorber

of net gain is thus produced, which tends to increase the peak of the pulse and decrease its wings, i. e., it tends to narrow the pulse. This narrowing is again counteracted by pulse broadening due to the finite amplifier bandwidth until a steady-state pulse duration, whose duration again depends on the inverse of the gain bandwidth, is eventually reached. Good candidates for saturable absorbers must have a short relaxation time τ ($\approx$ a few picoseconds or shorter) and a small saturation intensity, given by $I_s = h\nu/(2\sigma_a\tau)$. Thus, very large values for the absorption cross section σ_a ($\approx 10^{-16}$ cm^2 or larger) are needed. Ideal absorbers are therefore dye molecules (e.g., cyanine dyes) or, even better, semiconductors. A particularly interesting saturable-absorber geometry consists of integrating a multiple-quantum-well absorber between two mirrors whose spacing is such that the resulting Fabry–Pérot etalon operates in antiresonance. Such a device has been convincingly proven to generate both picosecond and femtosecond laser pulses from several broadband solid-state lasers.

Kerr-Lens Mode-Locking. This technique is based on the use of a nonlinear loss element simply consisting of a nonlinear Kerr medium placed in front of an aperture (Fig. 11.28). The nonlinear medium shows, via the optical Kerr effect, an intensity-dependent refractive index $n = n_0 + n_2 I$, where n_0 is the linear refractive index of the medium, I is the local light intensity and n_2 is a positive coefficient (for a self-focusing medium) which depends on the strength of the nonlinearity (e.g., $n_2 \simeq 4.5\times10^{-16}$ cm^2/W for fused quartz and $n_2 \simeq 3.45\times10^{-16}$ cm^2/W for sapphire). A light beam with, e.g., a transverse Gaussian intensity distribution $I(r) = I_p \exp[-2(r/w)^2]$ that crosses a thin slice of the Kerr medium of length l thus experiences a transversely varying phase shift $\delta\varphi = 2\pi l n_2 I(r)/\lambda = (2\pi l n_2/\lambda) I_p \exp[-2(r/w)^2]$. Close to the beam center $r = 0$, one can write $\delta\varphi \approx (2\pi l n_2 I_p/\lambda)[1-2(r/w)^2]$, i. e., the thin medium introduces a quadratic phase change of the field and thus acts, for $n_2 > 0$, as a positive lens (called a *Kerr lens*) of dioptric power $1/f = 4n_2 l I_p/(n_0 w^2)$, which increases as the beam intensity I_p increases. If an aperture is placed at some suitable distance from the Kerr medium, a beam with higher intensity will be focused tighter and a higher fraction of the beam will be transmitted through the aperture. Therefore, the Kerr medium with the aperture, like a fast saturable absorber, introduces losses that decrease when the instantaneous pulse intensity is increased, thus leading to mode-locking. Note that, by appropriately controlling the cavity dispersion, the shortest mode-locked pulses ($\approx$ 6 fs) have been achieved by this technique for Ti^{3+}:Al_2O_3 lasers.

11.2 Solid-State Lasers

11.2.1 Basics

Solid-State Lasers Based on Dielectric Insulators

The demonstration of the ruby laser [11.16] (Cr^{3+}:Al_2O_3) in 1960 led to a decade with the realization of a number of crystalline and glass lasers. Especially Nd:YAG [11.17], Nd-doped yttrium aluminum garnet (Nd:$Y_3Al_5O_{12}$), rapidly emerged as one of the most important crystalline dielectric lasers. The first glass laser was a fiber laser [11.18], which decades later led to the development of highly efficient Er-doped

fiber amplifiers (EFDA) with important applications in optical communications.

In the last two decades progress in the area of diode-pumped lasers has contributed very much to a renaissance in the field of solid-state lasers. With diode laser pumping it is possible to obtain higher efficiencies and to build rigid all-solid-state devices with simpler and more compact design. Besides Nd^{3+} various efficient diode-pumped rare-earth lasers have been operated with Er^{3+}, Tm^{3+}, Ho^{3+} [11.19–21], and Yb^{3+} [11.22, 23]. In addition, the successful operation of Cr^{3+}-doped [11.24–27] and Ti^{3+}-doped crystals [11.28, 29] as tunable room-temperature lasers has stimulated further research in transition-metal ions. Interesting new results have been obtained with the Cr^{4+} ion [11.30–33] and recently also with the divalent Cr^{2+} ion [11.34].

Nowadays, average and CW output powers for Nd^{3+}- and Yb^{3+}-doped crystals in the kW range are commercially available. Fiber lasers reach output powers in the 100 W range with nearly diffraction-limited beam quality.

Compact solid-state lasers in the visible spectral region (see for instance [11.35]) are of potential interest, especially for display and high-density optical data storage applications. Optical efficiencies of more than 20% with respect to the pump power can be obtained in Nd lasers by internal frequency doubling with nonlinear crystals. An alternative approach enables the generation of visible laser radiation by upconversion schemes, which incorporate energy transfer processes or two-step pump processes as ground-state and excited-state absorption.

In a most general sense lasers based on solids include both dielectric insulators and semiconductors as gain media. However, the development in the past yielded a subdivision into two laser classes based on solids: solid-state lasers (the topic of this chapter) and semiconductor lasers (Sect. 11.3).

Nearly all modern, important solid-state lasers are based on impurity-doped crystals or glasses. Typically, the impurity ions have unfilled electronic shells. So far, only laser ions from the iron, rare-earth and actinide group are known. The most important laser lines of these ions correspond to 4f–4f, 4f–5d, and 3d–3d transitions. In special cases the laser active ions can also be fully substituted into the lattice (stoichiometric laser materials). It should be noted that in the past lattice defects also have been used as laser-active centers (color center lasers); these lasers are however not included in this chapter.

Spectra of Rare-Earth and Transition-Metal Ions in Solids

4f–4f Transitions in Rare-Earth Ions. In the free rare-earth ion the electrostatic interaction between the 4f electrons creates a splitting of the energy levels of the $4f^n$ configuration into different LS terms. The resultant wave functions are characterized by the quantum numbers L, S, M_L, and M_S. The electrostatic energy splitting of the ${}^{\{2S+1\}}L$ terms is typically $10^4\,\mathrm{cm}^{-1}$, and each level is $(2L+1)(2S+1)$-fold degenerate with respect to M_L and M_S.

In addition, the energy levels are further split by spin–orbit coupling. If the energetic separation between different LS terms is large compared with the spin–orbit coupling energy there is only a small mixing of the LS terms. If this mixing is very small, the Russel–Saunders approximation holds and the wave functions are characterized by the quantum numbers L, S, J, M_J with a degeneration of $(2J+1)$. The typical splitting of ${}^{\{2S+1\}}L_J$ terms is of the order of $1000\,\mathrm{cm}^{-1}$. Although LS coupling is not strictly valid for rare-earth ions, it is usual to describe the 4f energy states with the Russel–Saunders approximation [11.36].

The interaction of the 4f electrons with the crystal field, i. e., the electrostatic field of the surrounding ligands, results in a Stark splitting of the free ion ${}^{\{2S+1\}}L_J$ terms. This interaction can be treated as a perturbation of the free ion levels. The crystal field splitting and the remaining degeneracy depend on the symmetry of the local crystal field. Lower symmetries increase the number of split levels. However, according to Kramers theorem an odd number of electrons always yields at least twofold degeneracy. The Stark splitting is typically in the energy range of several $100\,\mathrm{cm}^{-1}$. The ground state of a special $4f^n$ configuration (the number of 4f electrons $n = 1-14$) can be determined according to Hund's rule. Figure 11.29 shows the $4f^n$ energy levels of rare-earth ions (Dieke diagram [11.37]).

Electric dipole transitions within the 4f-shell are parity forbidden in the free ion. When doped in a solid, acentric perturbations of the crystal field can however create admixtures of wave functions with opposite parity (for instance $4f^{n-1}5d^1$ states) yielding so-called forced electric dipole transitions. Due to the screening of the outer filled $5s^2$ and $5p^6$ orbitals, the crystal field perturbation is small and electron–phonon coupling is very weak. So, for rare-earth ions at acentric sites one observes electric-dipole zero-phonon transitions with very weak vibronic sidebands. When doping occurs at centric sites, parity remains a good quantum number and all 4f–4f transitions remain electric dipole forbid-

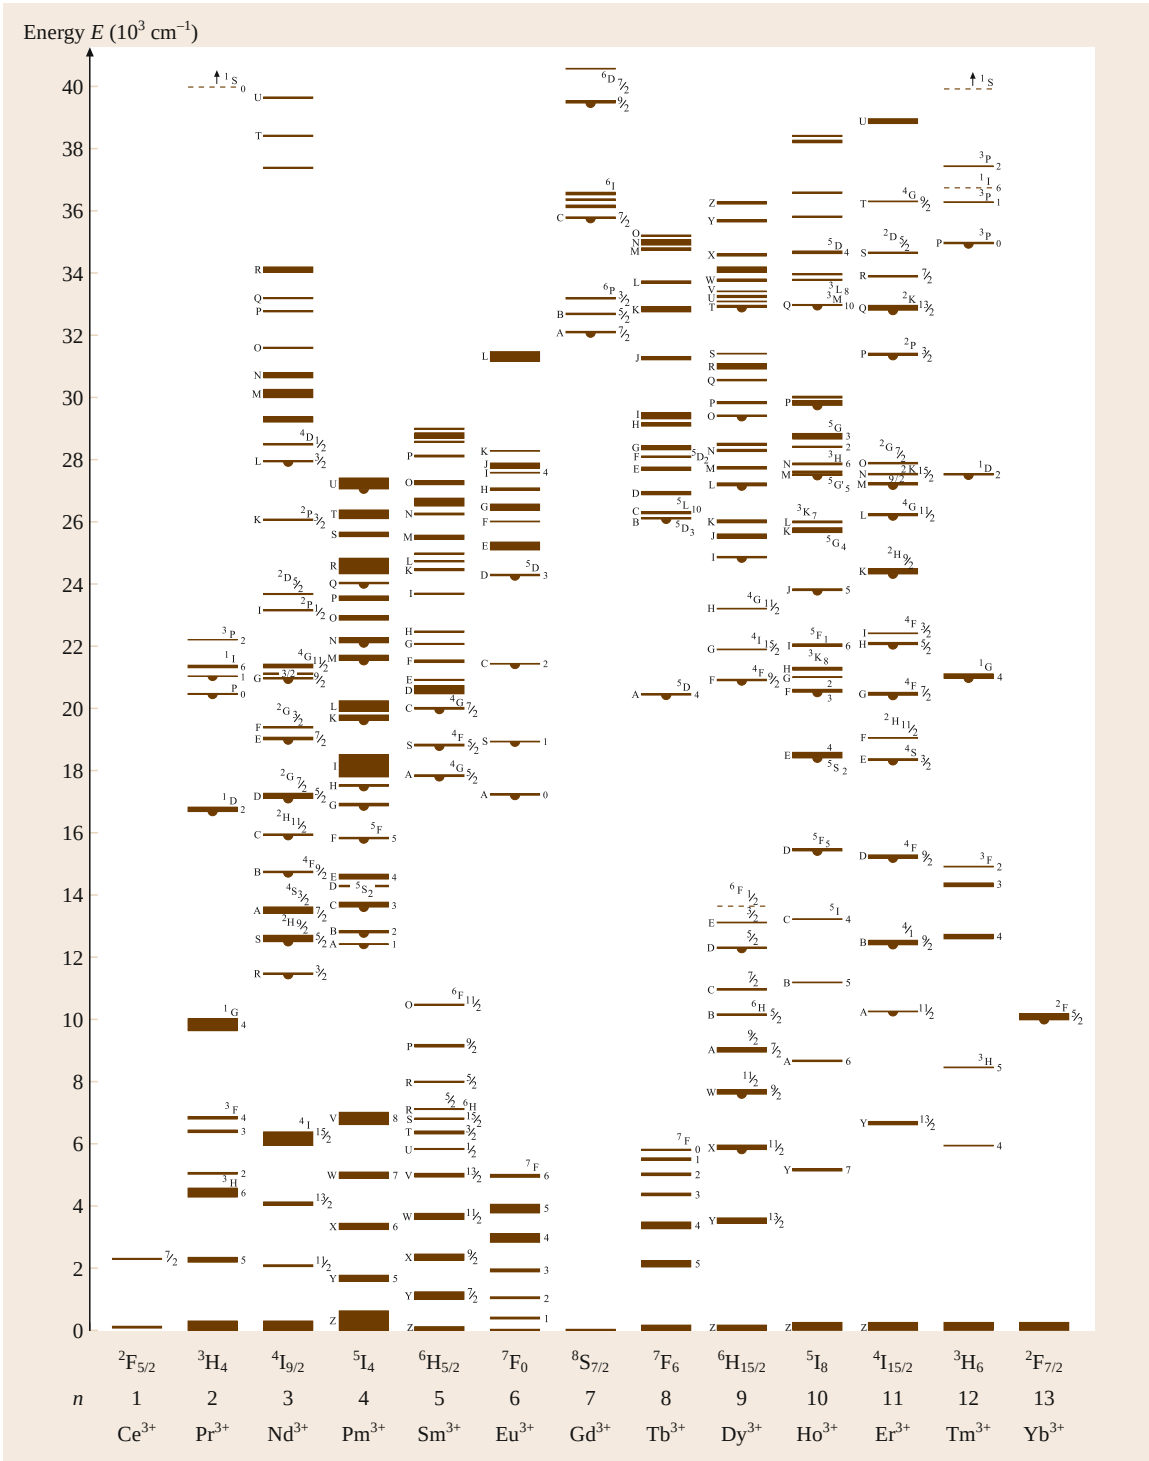

Fig. 11.29 Energy level diagrams of trivalent rare earth ions of RE^{3+} in $LaCl_3$ (*Dieke-diagram*) (after [11.37])

den. The magnetic-dipole emission cross sections are then very small and are not useful for laser applications.

Further selection rules for electric dipole transitions between $4f^n$ states are:

- $\Delta J \leq 6;\ \Delta S = 0,\ \Delta L \leq 6$ (Russel–Saunders approximation)
- $J = 0 \Leftrightarrow J' = 0$ is forbidden.

3d–3d Transitions in Transition-Metal Ions. The 3d electrons of transition-metal ions are not shielded and experience a strong perturbation from the crystal field of the surrounding ligand ions. Therefore, the energy-level scheme and also the spectroscopic characteristics of a transition metal ion depend strongly on the strength and the symmetry of the crystalline field originating from the surrounding ions. The energy-level schemes of the transition-metal ions in crystalline hosts are described by so-called Tanabe–Sugano diagrams [11.38]. These diagrams are distinguished by the number of electrons within the 3d electron shell. In these diagrams the energy levels of the transition-metal ion are presented as a function of the crystal field strength (for some examples, Sect. 11.2.3). For detailed reading appropriate literature can be found in [11.36, 39–42].

Due to the strong interaction with the surrounding ions of the lattice, transition-metal ions mostly exhibit broadband emission because of the electron–phonon coupling between the electronic 3d levels and lattice vibrations. As in the case of 4f–4f transitions, only acentric perturbations can induce electric dipole transitions. Generally the spectra consist of a purely electronic zero-phonon line with vibronic sidebands. In contrast to the situation in rare-earth ions, transition-metal ions at centric sites may also have reasonable transition probabilities due to dynamical admixtures of wave functions with different parity by acentric phonons. On the other hand, strong electron–phonon coupling can yield higher temperature-dependent nonradiative decay rates compared to 4f–4f transitions. The main interest in transition-metal ions is based on their broad tunability.

Interconfigurational 4f–5d Transitions in Rare-Earth Ions. Typically 4f↔5d interconfigurational transitions of rare-earth ions are located in the ultraviolet spectral range. In some cases 4f↔5d transitions are also observed in the visible spectral region. In contrast to 3d↔3d and 4f↔4f transitions, 4f↔5d transitions are electric-dipole allowed, because they obey the parity selection rule. Thus high transition probabilities and hence large absorption and emission cross sections ($\approx 10^{-18}$–10^{-17} cm^2) are observed.

Similar to 3d↔3d transitions strong electron–phonon coupling yields broad absorption and emission spectra with spectral half-widths of more than 1000 cm^{-1}. Therefore 4f↔5d interconfigurational transitions are in principle suitable for the generation of tunable laser oscillation.

However, the difficulty in finding suitable pump sources and often also excited-state absorption processes are major drawbacks with respect to the realization of 5d–4f lasers.

Basic Spectroscopic Properties and Laser Parameters

Ground-State Absorption. The ground-state absorption of an ion is characterized by the absorption coefficient α and the ground-state absorption cross section σ_{GSA}. These values are derived using the Lambert–Beer law

$$I(\lambda) = I_0(\lambda)\, \mathrm{e}^{-\alpha(\lambda)d} = I_0(\lambda)\, \mathrm{e}^{-n_{\mathrm{ion}}\sigma_{\mathrm{GSA}}(\lambda)d}, \tag{11.73}$$

where $I(\lambda)$ is the intensity transmitted through the crystal at wavelength λ, $I_0(\lambda)$ is the intensity in front of the crystal, n_{ion} is the ion concentration, $\alpha(\lambda)$ is the absorption coefficient, $\sigma_{\mathrm{GSA}}(\lambda)$ is the absorption cross section, and d is the crystal thickness.

The ground-state absorption spectrum contains information about the energy-level structure of the ion, the cross sections $\sigma_{\mathrm{GSA}}(\lambda)$ and the oscillator strengths of the observed transitions. Note, that the calculation of cross sections needs a second independent measurement of the ion concentration, which is usually done by x-ray microprobe analysis. The relation between the absorption coefficient and the transition-matrix elements can be derived using Fermi's golden rule [11.36]. The energy-level structure of transition-metal ions is theoretically described by the ligand field theory and the angular overlap model (AOM), see for instance [11.43].

Spontaneous Emission and Emission Cross Section. The spontaneous emission is characterized by the Einstein coefficient A. In an emission measurement, the photon flux (the number of photons per area per time) is usually measured. The normalization process with respect to the instrument response function can be performed either with respect to photon flux or to the spectral intensity distribution $I_\lambda(\lambda)$ (energy per area per time). The relation between the spectral intensity distribution $I_\lambda(\lambda)$, the Einstein coefficient A ($A = \tau_{\mathrm{rad}}^{-1}$)

and the emission cross section $\sigma_{em}(\lambda)$ is given by the Füchtbauer–Ladenburg equation [11.44]

$$\sigma_{em}(\lambda) = \frac{\lambda^5 I_\lambda(\lambda) A}{8\pi n^2 c \int I_\lambda(\lambda)\lambda \, d\lambda} , \quad (11.74)$$

where n is the refractive index and c is the speed of light.

The emission cross sections can also be calculated from the absorption cross sections by the reciprocity method

$$\sigma_{em}(\lambda) = \sigma_{GSA}(\lambda) \frac{Z_l}{Z_u} \exp\left(\frac{E_{zl} - hc/\lambda}{kT}\right) , \quad (11.75)$$

where Z_l and Z_u are the partition functions of the lower and upper energy levels, E_{zl} is the energy of the zero-phonon line of the corresponding transition, k is the Boltzmann constant, and T is the temperature.

For Gaussian band shapes, which are often observed for emission spectra of transition-metal ions, the *McCumber* formula can be used for the determination of the peak emission cross section [11.45, 46]

$$\sigma_{em} = \sqrt{\frac{\ln 2}{\pi}} \frac{A}{4\pi c n^2} \frac{\lambda_0^4}{\Delta\lambda} , \quad (11.76)$$

where λ_0 is the peak emission wavelength and $\Delta\lambda$ is the full width at half-maximum (FWHM).

Excitation Spectra. The excitation spectra allow the determination of those absorption transitions, which yield a specific emission. These measurements are interesting in the case of different absorbing and emitting centers and also for finding energy transfer channels between different optical active centers.

Emission Lifetime. The decay time of the metastable level of an ion in a crystal is usually measured after excitation with a short pulse. The measured decay rate (measured as the number of transitions per unit time) is the sum of radiative and nonradiative decay rates. In general, the nonradiative decay of an ion can consist of intra-ionic multiphonon processes and intra-ionic nonradiative transfer processes (for details of energy transfer processes [11.36]). The equation for the decay is

$$\frac{1}{\tau} = A + \frac{1}{\tau_{nr}} = \frac{1}{\tau_r} + \frac{1}{\tau_{nr}} \quad \text{or}$$
$$W = A + W_{nr} = W_r + W_{nr} , \quad (11.77)$$

where τ, τ_r, and τ_{nr} are the total, radiative, and nonradiative decay times, respectively, and W, W_r, and W_{nr} are the total, radiative, and nonradiative decay rates, respectively.

The determination of the Einstein coefficient A is not an easy task, because in a simple decay measurement the combined lifetime is always measured. An additional measurement of the emission quantum efficiency η_{QE} would allow the determination of the radiative and nonradiative decay rate

$$\eta_{QE} = \frac{\tau}{\tau_r} = \frac{W_r}{W} = \frac{W_r}{W_r + W_{nr}}$$
$$\Rightarrow \quad \tau_r = \frac{\tau}{\eta_{QE}} \quad \text{and} \quad \tau_{nr} = \frac{\tau_r \tau}{\tau_r - \tau} . \quad (11.78)$$

However, a direct measurement of the quantum efficiency is difficult and usually contains a high error.

Another approach is the indirect determination of the quantum efficiency by analysis of the temperature dependence of the emission lifetime. The two most commonly used models are the simple Mott model of the activation energy [11.47] and the more-sophisticated model of *Struck* and *Fonger* [11.48] using the so-called single-configurational-coordinate model, which describes in a simplified way the interaction between the electronic center and the vibrating crystalline environment.

Excited-State Absorption (ESA). Measurements of the excited-state absorption (ESA) spectrum give further insight into the energy-level structure of an ion. In the ground state absorption measurements spin-allowed transitions are mainly observed and often spin-flip transitions are hidden under these absorption bands. Thus the determination of the energy of these spin-flip transitions is often not possible. If the metastable level of the ion has a different spin to the ground state (e.g., Cr^{3+} in strong crystal fields, Mn^{5+}, Fe^{6+}), the ESA spectrum reveals the energetic positions of these states with different spin. By using these data the crystal field parameters can be determined with higher accuracy. The knowledge of ESA processes is also very useful for the determination of their influence on the efficiency of a laser material. ESA may also inhibit gain and hence laser action.

The Laser Aspect. In this section only the case of steady-state conditions for laser oscillation will be discussed. For more details and for the case of pulsed excitation, see e.g. [11.49–52].

The efficiency of a laser system can be described by the laser threshold P_{thr} and the slope efficiency $\eta = dP_{out}/dP_{abs}$, where P_{out} and P_{abs} are the laser

output power and the absorbed pump power, respectively. Under the assumptions of only one metastable level (i. e., the upper laser level), ideal overlap between pump beam and resonator mode, homogeneous pump profile, low mirror transmission and low passive losses as well as the absence of excited-state absorption, the following equations hold for continuous-wave operation [11.49, 50]

$$P_{\mathrm{thr}} = \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\sigma_{\mathrm{se}}(\lambda_{\mathrm{l}})\,\tau} \times \left[T + L + 2d\sigma_{\mathrm{GSA}}(\lambda_{\mathrm{l}})\,(n_{\mathrm{ion}} - n_{\mathrm{thr}})\right]\frac{V}{2d} \quad \text{(3-level system)}\,, \tag{11.79}$$

$$P_{\mathrm{thr}} = \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\sigma_{\mathrm{se}}(\lambda_{\mathrm{l}})\,\tau}(T + L)\,\frac{V}{2d} \quad \text{(4-level system)}\,, \tag{11.80}$$

$$\eta = \eta_{\mathrm{p}}\frac{\lambda_{\mathrm{p}}}{\lambda_{\mathrm{l}}}\frac{T}{T + L}\,, \tag{11.81}$$

where $h\nu_{\mathrm{p}}$ is the energy of pump photon, η_{p} is the pumping efficiency, i. e., the fraction of absorbed pump photons that are converted into excited ions in the upper laser level, σ_{se} is the stimulated emission cross section, τ is the lifetime of the upper laser level, T is the mirror transmission, L is the passive losses, d is the length of the laser crystal, σ_{GSA} is the ground-state absorption cross section, n is the concentration of laser ions, n_{thr} is the threshold inversion density, λ_{p} is the pump wavelength, λ_{l} is the laser wavelength, and V is the pump volume.

In the following, several factors affecting the pump power threshold and the slope efficiency will be discussed.

Influence of the Emission Quantum Efficiency η_{QE}. A quantum efficiency less than unity leads to lifetime shortening and therefore to an increase in the laser threshold, as can be seen from (11.79) and (11.80) after replacing τ by $\eta_{\mathrm{qe}}\tau_{\mathrm{r}}$

$$P_{\mathrm{thr}} = \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\sigma_{\mathrm{se}}(\lambda_{\mathrm{l}})\,\eta_{\mathrm{qe}}\tau_{\mathrm{r}}} \times \left[T + L + 2d\sigma_{\mathrm{GSA}}(\lambda_{\mathrm{l}})\,(n_{\mathrm{ion}} - n_{\mathrm{thr}})\right] \times \frac{V}{2d} \propto \frac{1}{\eta_{\mathrm{qe}}}\,, \quad \text{(3-level)} \tag{11.82}$$

$$P_{\mathrm{thr}} = \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\eta_{\mathrm{qe}}\sigma_{\mathrm{se}}\tau_{\mathrm{r}}}(T + L)\,\frac{V}{2d} \propto \frac{1}{\eta_{\mathrm{qe}}} \quad \text{(4-level)}\,. \tag{11.83}$$

The quantum efficiency does not influence the slope efficiency directly (11.81). However in practice a corresponding, significant contribution of nonradiative transitions increases the temperature in the pump volume and usually leads to a lower slope efficiency due to further lifetime reduction and other problems such as thermal lensing.

Influence of Passive Losses L. Passive losses in a laser system are due to imperfect optical components in the laser resonator. This can be due to, e.g., stray centers and residual absorptions. Passive losses influence both the threshold and the slope efficiency (11.79, 80, 81). In a four-level system, the passive losses can be determined by the Findlay–Clay method [11.53]. For such an analysis, the laser threshold is measured as a function of the output mirror transmission. The following equation holds

$$P_{\mathrm{thr}} = \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\sigma_{\mathrm{se}}\tau}\frac{V}{2d}T + \frac{h\nu_{\mathrm{p}}}{\eta_{\mathrm{p}}\sigma_{\mathrm{se}}\tau}\frac{V}{2d}L = mT + b\,, \tag{11.84}$$

with slope $m = h\nu_{\mathrm{p}}/(\eta_{\mathrm{p}}\sigma_{\mathrm{se}}\tau)V/(2d)$ and axis parameter $b = mL$. From a linear fit to $P_{\mathrm{thr}} = P_{\mathrm{thr}}(T)$ both m and b are determined and thus the value of the passive losses L. An alternative way to determine the passive losses is to rewrite (11.81) for a so-called *Caird plot* [11.54]:

$$\frac{1}{\eta} = \frac{\lambda}{\eta_{\mathrm{p}}\lambda_{\mathrm{p}}}\frac{L}{T} + \frac{\lambda}{\eta_{\mathrm{p}}\lambda_{\mathrm{p}}} = m'\frac{1}{T} + b'\,, \tag{11.85}$$

with slope $m' = \lambda/(\eta_{\mathrm{p}}\lambda_{\mathrm{p}})L = b'L$. From a linear fit to $1/\eta = 1/\eta\,(1/T)$ both m' and b' can be determined and thus the value of the passive losses L.

Influence of Excited-State Absorption. ESA at the pump wavelength reduces the number of pump photons converted into excited ions in the metastable laser level according to

$$\eta_{\mathrm{p}} = \eta_{\mathrm{p},0} \times \left(1 - \frac{n_1\sigma_{\mathrm{ESA}}(\lambda_{\mathrm{p}})}{n_1\sigma_{\mathrm{ESA}}(\lambda_{\mathrm{p}}) + (n_{\mathrm{ion}} - n_1)\sigma_{\mathrm{GSA}}(\lambda_{\mathrm{p}})}\right), \tag{11.86}$$

where $\eta_{\mathrm{p},0}$ is the pumping efficiency without ESA, n_{ion} is the concentration of active ions, and n_1 is the population density in the upper laser level. Therefore the pump threshold is increased and the laser slope efficiency is reduced according to (11.79) and (11.81).

ESA on the laser wavelength also affects the laser threshold and the slope efficiency. The stimulated emission cross section $\sigma_{\mathrm{se}}(\lambda_{\mathrm{l}})$ in (11.79) and (11.80) is

replaced by $\sigma_{EFF}(\lambda_l) = \sigma_{se}(\lambda_l) - \sigma_{ESA}(\lambda_l)$ and (11.81) has to be extended [11.54]

$$\eta = \eta_p \frac{\lambda_p}{\lambda_l} \frac{\sigma_{se}(\lambda_l) - \sigma_{ESA}(\lambda_l)}{\sigma_{se}(\lambda_l)} \frac{T}{T+L} \propto \frac{\sigma_{EFF}}{\sigma_{se}} . \quad (11.87)$$

If $\sigma_{ESA}(\lambda_l) > \sigma_{se}(\lambda_l)$ laser oscillation is not possible.

11.2.2 UV and Visible Rare-Earth Ion Lasers

Lasers Based on 5d ↔ 4f Transitions of Trivalent and Divalent Rare-Earth Ions

In this section an overview of lasers oscillating in the ultraviolet and visible spectral range based on transitions of rare-earth ions is given. The first part deals with laser and possible laser systems based on interconfigurational transitions, i. e., $4f^{n-1}5d \rightarrow 4f^n$. In the second part, visible and UV lasers based on intraconfigurational ($4f^n \rightarrow 4f^n$) transitions will be discussed. Both parts deal with crystals as host materials. Finally, in the third part an overview of fiber lasers in the visible spectral range is given.

The 4f ↔ 5d interconfigurational transitions of some divalent (RE^{2+}) and trivalent (RE^{3+}) rare-earth ions are located in the visible and ultraviolet spectral range. They are in principle suitable for the realization of (tunable) laser oscillation. The transitions are electric-dipole allowed and have high transition probabilities and large absorption and emission cross sections of the order of 10^{-17} to $10^{-18}\,cm^2$. Due to their strong electron–phonon coupling, the observed absorption and emission transitions are broad ($> 1000\,cm^{-1}$). Difficulties with respect to laser operation are the non-availability of efficient and simple excitation sources and the high probability of excited-state absorption and solarization (photoionization), e.g., Ce^{3+}:$LiCaAlF_6$ and Ce^{3+}:$LiSrAlF_6$ depicted in Fig. 11.30.

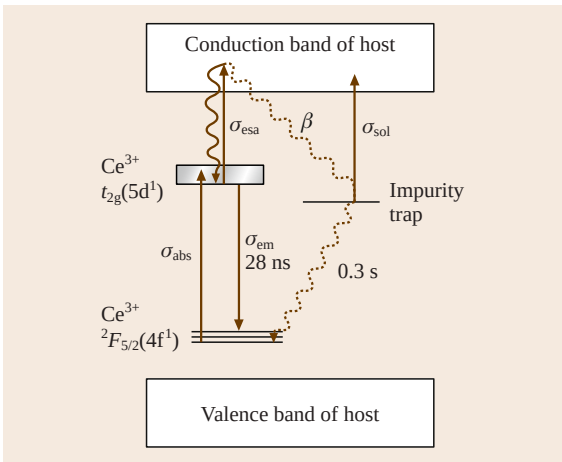

Fig. 11.30 Scheme of the energy levels in Ce^{3+}-doped $LiCaAlF_6$ and $LiSrAlF_6$, where s_{ABS}, s_{EM}, s_{ESA}, and s_{SOL}, are the absorption, emission, ESA, and solarization cross sections, respectively (after [11.55])

In the following the trivalent and divalent rare-earth ions exhibiting short-wavelength emission will be briefly discussed together with a summary of the obtained laser results.

Ce^{3+} Lasers. The Ce^{3+} $4f^1$ ground-state configuration splits into the $^2F_{5/2}$ ground state and the $^2F_{7/2}$ excited-state multiplet with an energy separation of $\approx 2000\,cm^{-1}$. The 5d excited configuration consists in an ideal octahedral or cubic symmetry of a threefold orbital degenerated $^2T_2$ state and of a twofold orbital degenerated ^2E level, from which the $^2T_2(^2E)$ state is at lower energy in octahedral (cubic) symmetry. In Fig. 11.31 the room-temperature absorption and emission spectrum of Ce^{3+}:$LiYF_4$ is shown. In general, in the absorption spectrum two to five broad bands are expected, depending on the crystal field symmetry. In emission two bands corresponding to the $5d \rightarrow {}^2F_{5/2}$ and $5d \rightarrow {}^2F_{7/2}$ transitions with an energetic separation of approximately $2000\,cm^{-1}$ are observed. The high cross sections of the electric-dipole- and spin-allowed $4f^1 \leftrightarrow 5d^1$ transitions correspond to an emission lifetime in the ns range. Ce^{3+}-doped materials were therefore thoroughly investigated for application as tunable solid-state lasers and scintillators, see e.g., the overview articles by *Coutts* et al. [11.56] and *Dorenbos* [11.57]. Laser oscillation was thus far achieved in $YLiF_4$ [11.58], $LuLiF_4$ [11.59], $LiCaAlF_6$ [11.60], $LiSrAlF_6$ [11.55, 61], LaF_3 [11.62], and BaY_2F_8 [11.63] crystals. The laser data are summarized in Table 11.2. For Ce^{3+}-doped materials the main obstacle with respect to laser oscillation is excited-state absorption assigned to transitions to the conduction band, e.g., as is the case for Ce^{3+}:YAG [11.64, 65]. For Ce^{3+}-doped $LiCaAlF_6$ and $LiSrAlF_6$ the ESA transition leads to a *solarization*, i. e., impurity traps with long lifetimes are populated (Fig. 11.30). With the help of an *anti-solarent* pump, these traps are depleted and higher efficiencies are obtained [11.66, 67].

Pr^{3+} ($4f^2$). The energy-level scheme of Pr^{3+} is shown schematically in Fig. 11.32. Pr^{3+} has a $4f^2$ ground-state configuration. In this configuration 91 energy levels ex-

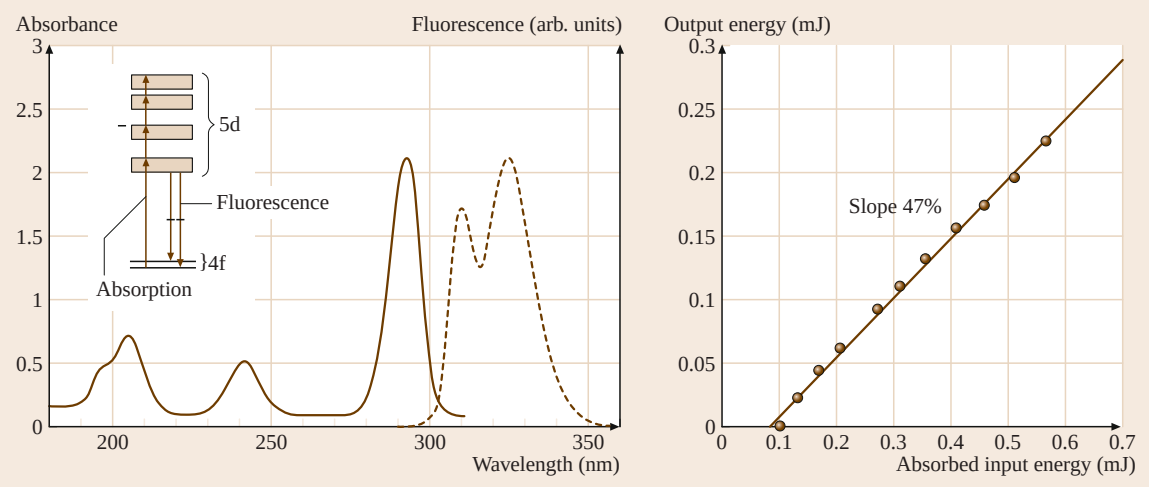

Fig. 11.31 *Left*: Absorption (*solid line*) and emission (*dotted line*) spectra of Ce^{3+}:$LiYF_4$. The *inset* shows the schematic energy level diagram (after [11.58]). *Right*: Input–output characteristic of a 2% Ce^{3+}, 2% Na:$LiSrAlF_6$

Table 11.2 Overview of lasers based on the 5d→4f transitions of trivalent and divalent rare-earth ions (CVL: copper vapor laser, RS: Raman-shifted)

Laser material	λ_{las} (nm)	E_{out}, P_{out}	η_{sl}	Tuning range (nm)	Pump source	References
Ce^{3+}:$LiYF_4$	325.5				KrF, 249 nm	[11.58]

Nd^{3+}:LaF_3	172				Kr, 146 nm	[11.87, 88]
					F_2 Laser, 157 nm	[11.89, 90]
Sm^{2+}:CaF_2	708.5 (20 K)			708.5–745 nm (20–210 K)	Xe flash lamp	[11.91, 92]

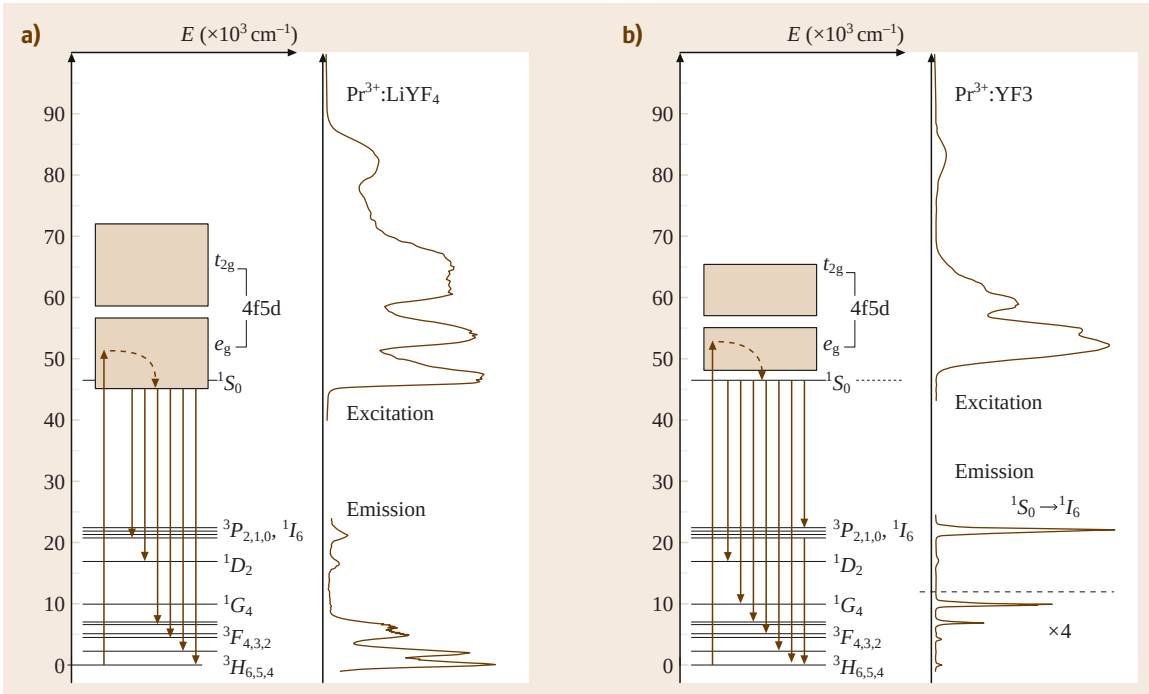

Fig. 11.32a,b Energy-level schemes of Pr^{3+} **(a)** Pr^{3+}:$LiYF_4$, $E(4f^15d^1) < E(^1S_0)$, **(b)** Pr^{3+}:YF_3, $E(4f^15d^1) > E(^1S_0)$. (after [11.93])

ist, distributed over 11 manifolds, from which the $^3H_4$ level is the ground state and $^1S_0$ is the highest level at approximately 46 500 cm^{-1}. In the $4f^15d^1$ configuration, 140 energy levels exist. Depending on the crystal field strength and splitting, either the lowest $4f^15d^1$ level or the $^1S_0$ state is lower in energy. Thus after UV excitation, emission occurs either from the $4f^15d^1$ level as a $4f^15d^1 \rightarrow 4f^2$ transition or from the $^1S_0$ level as a $4f^2 \rightarrow 4f^2$ transition. In any case, the emission spectrum consists of several bands, because several $4f^2$ terminal levels exist. Spectroscopic investigations of the $4f \leftrightarrow 5d$ transitions have so far been carried out for a number of materials, e.g., $Y_3Al_5O_{12}$ [11.68, 69], $YAlO_3$ [11.68, 70, 71], CaF_2, $LiYF_4$ [11.71–73], and $K_5PrLi_2F_{10}$ [11.71]. Thus far laser oscillation based on the $4f^15d^1 \rightarrow 4f^2$ or on the $^1S_0 \rightarrow 4f^2$ emission of Pr^{3+} has not achieved. The main reason seems to be excited-state absorption into the conduction band, e.g., for $YLiF_4$ [11.73], and into higher-lying $4f^15d^1$ levels, e.g., for $Y_3Al_5O_{12}$ [11.74].

Other RE^{3+} Ions. The lowest $4f^{n-1}5d^1$ energy levels for ions from Nd^{3+} to Yb^{3+} are at even higher energies and therefore in the vacuum ultraviolet (VUV) spectral region. Thus the corresponding transitions are not easy to access spectroscopically. A systematic study and detailed analysis of the VUV spectroscopy of trivalent rare-earth ions were performed by *Wegh* et al. [11.94]. The exploitation of these VUV transitions for laser oscillation still requires much experimental efforts. Laser oscillation on a 5d→4f transition besides for Ce^{3+} has thus far only been realized with Nd^{3+}:LaF_3 at 172 nm with a Kr_2 laser at 146 nm as the pump source [11.87].

Divalent Rare-Earth Ions. Rare-earth ions have a strong tendency to be incorporated into crystals in the trivalent state. In order to obtain the divalent state, the RE^{3+} ion needs to be reduced. Eu^{2+}, Yb^{2+}, Sm^{2+} and, with some limitations, Tm^{2+} can already be obtained in significant amounts during crystal growth by using suitable lattices containing divalent cation sites, appropriate codopants, and a reducing growth atmosphere. The other RE^{2+} ions are rather difficult to obtain in crystals; usually special growth conditions as well as pre- and post-treatments are necessary, e.g., the use of sealed Ta ampoules during crystal growth, presynthesis of REF_2 and $RECl_2$, electron-beam irradiation etc.

5d→4f transitions are expected to occur for systems in which the $4f^{n-1}5d$ level is energetically located within a large energy gap between $4f^n$ multiplets. These ions are Sm^{2+}, Eu^{2+}, Tm^{2+}, and Yb^{2+}.

Sm^{2+} ($4f^6$). The $4f^6$ energy-level scheme of Sm^{2+} is spectroscopically similar to that of Eu^{3+} (Fig. 11.29). For most crystals, Sm^{2+} emission occurs as a $4f^6 \rightarrow 4f^6$ transition from the metastable $^5D_0$ level, which is located at about $15\,000\,cm^{-1}$. In CaF_2, the lowest $4f^55d^1$ level is located just below the $^5D_0$ level and broadband emission occurs. Laser oscillation based on a $4f^55d^1 \rightarrow 4f^6$ transition was realized with Sm^{2+}:CaF_2 [11.91, 92]. The laser wavelength is 708.5 nm at 20 K and increases with temperature to 745 nm at 210 K, which is the highest operation temperature of the Sm^{2+}:CaF_2 laser. This laser is affected by excited-state absorption assigned to transitions to the conduction band and to high-lying $4f^6$ levels [11.95,96].

Eu^{2+} ($4f^7$). The $4f^7$ energy-level scheme of Eu^{2+} is spectroscopically similar to that of Gd^{3+} (Fig. 11.29). A large energy gap between the $^8S_{7/2}$ ground state and the $^6P_{7/2}$ first excited state exists. Depending on the crystal field strength, the lowest $4f^65d^1$ energy level is located above or below the $^6P_{7/2}$ level. Therefore, either narrow line emission due to the $^6P_{7/2} \rightarrow {}^8S_{7/2}$ transition in the UV region or broadband emission due to the $4f^65d^1 \rightarrow {}^8S_{7/2}$ transition in the blue to yellow spectral range occurs. Laser oscillation based on a $4f^65d^1 \rightarrow 4f^7$ transition of Eu^{2+} has not been realized thus far due to excited-state absorption from the lowest $4f^65d^1$ level to the conduction band and to high-lying $4f^7$ levels [11.96].

Tm^{2+} ($4f^{13}$). The $4f^{13}$ energy-level scheme of Tm^{2+} is spectroscopically similar to that of Yb^{3+} (Fig. 11.29). Laser oscillation of Tm^{2+} was realized in CaF_2 on the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition at 1116 nm at temperatures below 27 K [11.97, 98] (Table 11.9). Laser oscillation based on the $4f^{12}5d^1 \rightarrow 4f^{13}$ transition has not been obtained thus far. However, Tm^{2+} is an interesting candidate for laser oscillation on a $4f^{12}5d^1 \rightarrow 4f^{13}$ transition, because there are no high-lying $4f^{13}$ energy levels, which could interfere with the $4f^{12}5d^1$ energy levels and thus act as possible terminal levels for excited-state absorption transitions or quenching processes. The transition between the lowest $4f^{12}5d^1$ level and the ground state is parity allowed, but spin forbidden. Thus the emission cross sections are expected to be about one to two orders of magnitude smaller compared to, e.g., those of the 5d→4f transitions of Ce^{3+}. The $Tm^{2+} \rightarrow Tm^{3+}$ conversion observed under UV/VIS lamp excitation [11.98] indicates the strong tendency of the Tm ion towards the trivalent state and has to be considered as a possible major drawback for laser applications.

Yb^{2+} ($4f^{14}$). The ground-state configuration of the Yb^{2+} ion is $4f^{14}$. This completely filled shell leads to a $^1S_0$ ground state of the free ion and other $4f^{14}$ levels do not exist. In an octahedral crystal field, this state transforms like the $^1A_1$ irreducible representation. The excited $4f^{13}5d^1$ configuration consists in total of 140 energy levels. The $4f^{13}5d$ level splits in a highly symmetric crystal field into a threefold degenerated T_2 and a twofold degenerated E level. The $4f^{13}$ electrons can be considered as a Yb^{3+}-ion configuration with the two manifolds $^2F_{7/2}$ and $^2F_{5/2}$ separated by about $\Delta E_{4f} \approx 10\,000\,cm^{-1}$. The spin of the 5d electron can either be parallel or antiparallel to that of the $4f^{13}$ core, thus the whole energy-level scheme exists for singlet and for triplet states, from which, according to Hunds' rule, the triplet states are energetically lower. Note furthermore that for the Yb^{2+} free ion the 6s level is energetically lower than the 5d level. Therefore it might be the case that in some materials the $4f^{13}6s$ level is also the lowest excited state. This would lead to a parity- and spin-forbidden transition requiring $\Delta L = 3$ and $\Delta S = 1$. The emission spectra of Yb^{2+}-doped materials consists of a broad band ($\approx 6000\,cm^{-1}$) with the peak emission wavelength strongly dependent on the host material ($\lambda_{peak} \approx 390$–$575$ nm) [11.99–103]. Laser oscillation has not been obtained thus far. The main reason is excited-state absorption. In Yb^{2+}:MgF_2 strong ESA transitions in the whole spectral range of absorption and emission are observed, preventing laser oscillation. The ESA cross section is about one order of magnitude larger than the absorption cross section and three orders of magnitude larger than the stimulated emission cross section [11.102, 103].

Lasers Based on 4f ↔ 4f Transitions of Trivalent and Divalent Rare-Earth Ions

This section deals with UV and visible lasers based on the 4f↔4f transitions of trivalent and divalent rare-earth ions. Laser oscillation has been realized under flashlamp pumping, direct laser pumping into the upper laser level or higher-lying energy levels and under upconversion pumping.

Pr^{3+} *Lasers.* The Pr^{3+} ion is a very interesting and promising ion for obtaining efficient visible laser oscil-

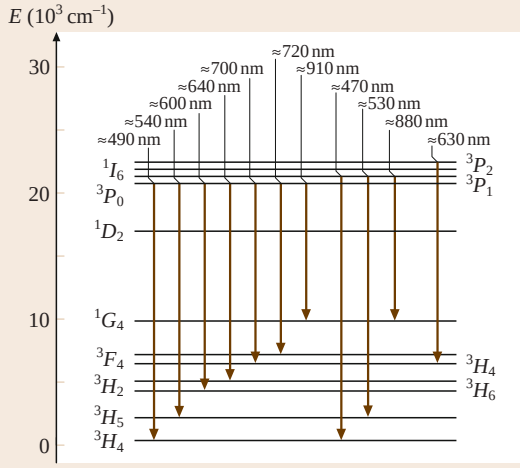

Fig. 11.33 Energy-level scheme of the Pr^{3+} ion. The observed laser transitions in the visible spectral range are indicated by *arrows*

lation. Its energy-level scheme is shown in Fig. 11.33. Laser transitions in the visible spectral range occur from the $^3P_0$ and the thermally populated $^3P_1$ and $^3P_2$ levels. In Fig. 11.34 the emission spectrum of the Pr^{3+}:BaY_2F_8 as an example is shown. The peak cross sections are in the range of ≈ 1 to 5×10^{-19} cm^2 and thus comparable to the values of the Nd^{3+} $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition. The highest cross sections are in the orange and red spectral range, therefore the most efficient lasers are expected there. The first Pr^{3+} laser ($\lambda = 1047$ nm) was realized in $CaWO_4$ as early as 1962 by *Yariv* et al. [11.104]. Since then, laser oscillation has been obtained in more than 20 materials on several transitions and under different pumping conditions, see e.g., the review article by *Kaminskii* [11.105]. The major drawback of Pr^{3+} lasers is their excitation; see the discussion in section on Pr^{3+} laser.

Directly Pumped Pr^{3+} Lasers. In Fig. 11.35 the absorption spectrum of Pr^{3+}:BaY_2F_8 for the spectral range between 420 and 500 nm is shown. Direct pumping of the $^3P_0$ upper laser level is possible for several wavelengths in the blue spectral range corresponding to the $^3H_4 \rightarrow {}^3P_2$, $^3P_1$, $^3P_0$, and $^1I_6$ transitions. In principle the following pumping schemes for direct excitation are possible:

1. Ar^+-ion laser pumping. Ar^+-ion lasers offer the possibility of continuous-wave pumping with a high-quality pump beam. Therefore it allows the characterization of a Pr^{3+}-doped laser material. For Pr^{3+}:$LiYF_4$, laser oscillation on several transitions has been obtained with slope efficiencies up to $\approx 26\%$ and output powers up to ≈ 270 mW [11.106] (Figs. 11.36 and 11.37). However, the wavelength match between the Ar^+ pump and Pr^{3+} absorption is bad (Fig. 11.35). Furthermore Ar^+-ion laser

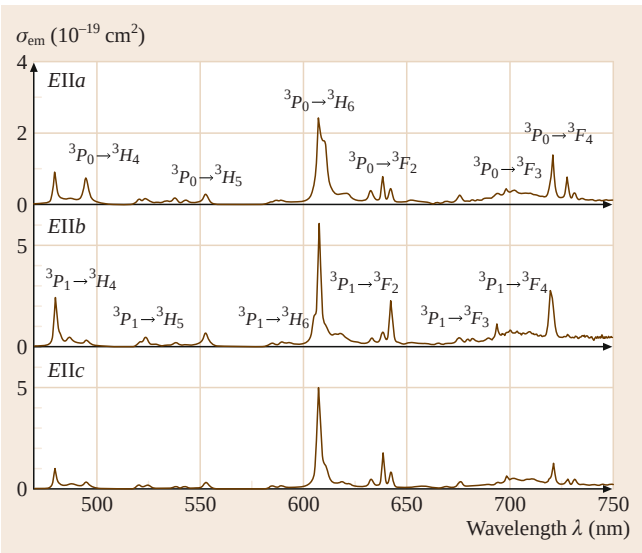

Fig. 11.34 Emission spectra of Pr^{3+}:BaY_2F_8 at room temperature for different polarizations

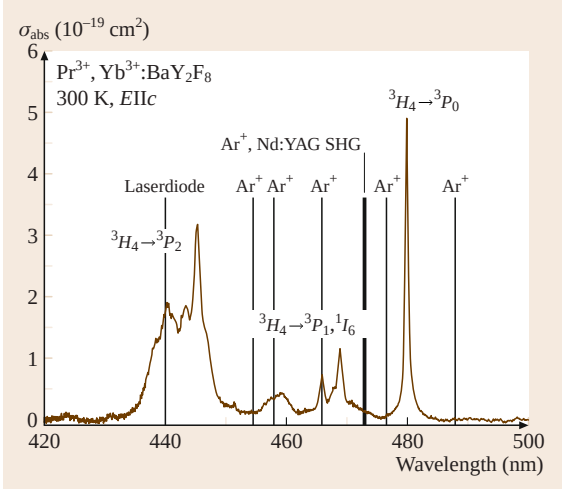

Fig. 11.35 Absorption cross section spectrum of Pr^{3+}, Yb^{3+}:BaY_2F_8 at room temperature. The relevant transitions are assigned. The possible pump laser wavelengths are also shown

pumping itself is very inefficient, therefore the overall efficiency of a gas-laser-pumped Pr^{3+} laser is very low.

2. Pumping with a frequency-doubled Nd^{3+} laser operating on the ${}^4F_{3/2} \rightarrow {}^4I_{9/2}$ ground-state transition. These ground-state lasers operate, depending on the host material, between 910 and 960 nm, i. e., the frequency doubling yields wavelengths between 455 and 480 nm. A Pr^{3+} laser directly pumped by a frequency-doubled Nd^{3+}:YAG ground-state laser operating at 473 nm has been successfully demonstrated by *Heumann* et al. [11.108]. Pr^{3+} laser oscillation occurred at 639.5 nm on the ${}^3P_0 \rightarrow {}^3F_2$ transition with an output power of nearly 100 mW and a slope efficiency of 12%. Also for frequency-doubled Nd^{3+} ground-state lasers the match between the pump and absorption wavelength is crucial.
3. Frequency-doubled optically pumped semiconductor lasers (OPS). These lasers are commercially available with powers up to several watts [11.109]. In principle, the laser wavelength is adjustable (by choosing the material parameters of the semiconductor) and can be tuned to match the absorption line of the Pr^{3+} ion. Continuous wave laser operation using an OPS operating at around 480 nm

was realized [11.107, 110–113]. Slope efficiencies up to 56% and output powers of about 600 mW were obtained for Pr^{3+}:$YLiF_4$ and Pr^{3+}:$YLuF_4$. Also active Q-switching experiments were performed, leading to 1.5 W and 0.75 W of output power for Pr^{3+}:$YLiF_4$ and Pr^{3+}:$YLuF_4$, respectively; pulse lengths were about 100 ns and the repetition rate was 200 Hz. It is worth noting that intracavity frequency doubling leads to continuous-wave UV radiation ($\approx$ 320 mW) of about 360 mW for Pr^{3+}:$YLiF_4$, 260 mW for Pr^{3+}:$YLuF_4$, and 19 mW for Pr^{3+}:BaY_2F_8 [11.107, 111, 112]. Due to the multi-wavelength operation of Pr^{3+} lasers, UV generation at 360 nm, 303 nm, and even 261 nm seems possible. These pump lasers are still expensive; however further power scalability of OPS lasers can be expected, which will making these pump sources very attractive for Pr^{3+} lasers.

4. Blue and UV GaN laser diodes. Currently, these diodes operate in the spectral region below 450 nm and with output powers in the mW range. Laser oscillation at room temperature under pumping with a 442 nm GaN laser diode was obtained in recent years with Pr^{3+}:$YLiF_4$, Pr^{3+}:$YLuF_4$, Pr^{3+}:$GdLiF_4$, KY_3F_{10}, Pr,Mg:$SrAl_{12}O_{19}$ [11.35, 107, 112, 131–135]. The Pr^{3+} laser emits up to 930 mW at $\approx$ 640 nm. Slope efficiencies up to 63% were obtained. Laser oscillation has been realized also on other transitions around 522 nm, 545.9 nm, 607 nm, and 720 nm. If the development of these diodes towards higher output powers proceeds, laser diodes

will certainly be one of the best choices for the direct pumping of Pr^{3+} lasers.

5. Flashlamp pumping [11.114]. Under flashlamp excitation only a small fraction of the emitted radiation of the lamp can be used for the excitation of the Pr^{3+} $^3P_0$ level, because of the narrow line width of the Pr^{3+} absorption lines and of the small spectral range of these lines. Output energies up to 87 mJ and slope efficiencies of 0.3% have been obtained [11.114].
6. Dye-laser pumping. The pump laser wavelength is tunable and thus can be adjusted to match the absorption lines of the Pr^{3+} ion. Therefore, the obtained lasers exhibit a high efficiency. For Pr^{3+}:$LiGdF_4$ lasers, oscillation on several wavelengths and transitions with slope efficiencies up to 37% have been reported [11.122]. However, dye lasers are limited in their practical use.

Table 11.3 lists Pr^{3+} lasers operating in the visible spectral range under direct excitation. In Table 11.4 an overview of the room-temperature laser data for visible Pr^{3+} lasers is given.

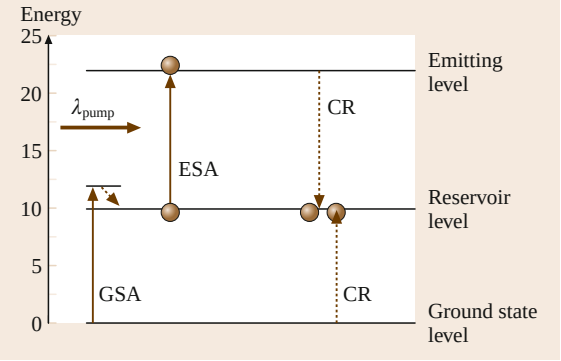

Fig. 11.38 Scheme of the photon-avalanche process (GSA: ground-state absorption, ESA: excited-state absorption, CR: cross-relaxation)

Upconversion Pumped Pr^{3+} Lasers. Because of the former difficulties of direct excitation, other pumping schemes using upconversion processes are under investigation for Pr^{3+} lasers. Upconversion describes a process in which the photon energy of the excitation light (pump light) is converted via interaction with the active ions inside the optical material into higher-energy photons [11.156–159]. For Pr^{3+} with its high-lying energy levels upconversion is a suitable way to obtain visible laser oscillation under infrared pumping. Especially the photon-avalanche pumping scheme, which is a combination of different upconversion and energy transfer processes, has been efficiently exploited for the Pr,Yb codoped system. For crystals the Ti:Al_2O_3 laser is mainly used as the excitation source, but investigations are being performed on the use of commercially available laser diodes. In fibers, efficient laser operation has already been achieved under laser-diode pumping (see page 694, Visible fiber lasers).

The principle scheme of the photon-avalanche process is shown in Fig. 11.38. A weak ground-state absorption yields the excitation of a few ions into the intermediate (*reservoir*) level. The strong ESA process efficiently brings these ions to the emitting level. An effective feedback mechanism for the reservoir level (in our system a cross-relaxation process) is necessary, which couples the emitting level, the reservoir level and the ground-state level. After these two steps there are two ions in the reservoir level. This cycle repeats and thus the population of the emitting (upper laser) level increases like an avalanche. If the threshold population is reached, the laser oscillation on any transition from the upper laser level may start. The general characteristics are described in detail in [11.156, 157, 160–162]; here only the main points are given for the example of Pr^{3+}, Yb^{3+}:BaY_2F_8 [11.155, 163]. The pump-power dependence of the emission intensity exhibits a threshold-like behavior. At this threshold, the slope increases significantly. A second characteristic of the avalanche mechanism is the temporal *S*-shaped evolution of the upconverted emission (Fig. 11.39).

The photon-avalanche process has already been observed in a variety of materials, see e.g. [11.156, 157]. However, laser oscillation has only been obtained in a few materials, see Table 11.5 for Pr^{3+} systems and Table 11.6 for other rare-earth-ion-doped systems. The reason is that there exist special requirements for an effi-

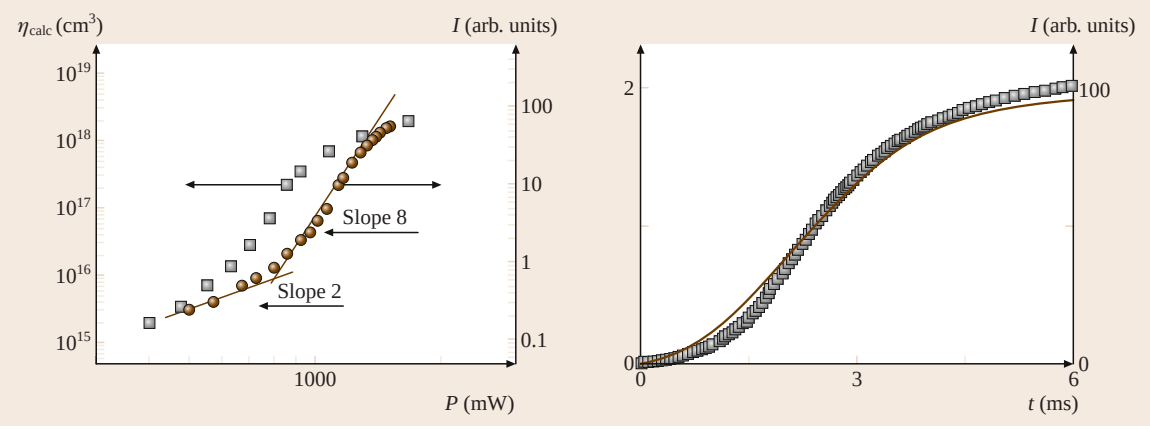

Fig. 11.39 Characteristics of the photon-avalanche excitation mechanisms. *Left*: pump-power dependence of the upconverted emission intensity (experiment, *open circles*) and $^3P_0$ population (calculated, *filled squares*). *Right*: temporal evolution of the upconverted emission intensity (*solid line*: experiment, *squares*: rate equation model). (After [11.155])

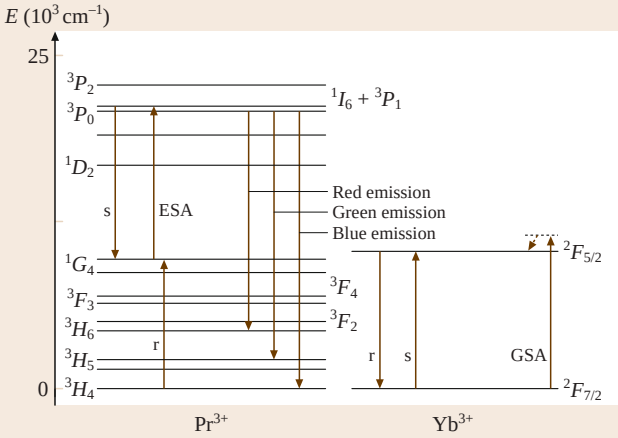

Fig. 11.40 Scheme of the avalanche mechanism in Yb-Pr-doped systems

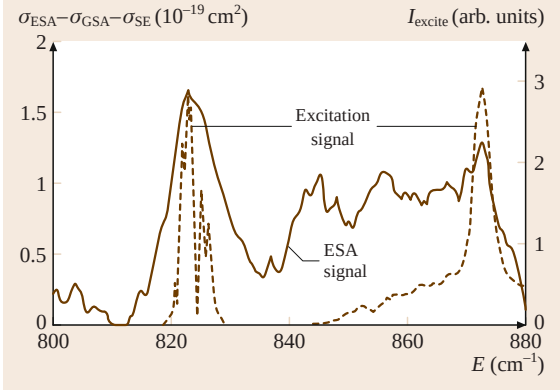

Fig. 11.41 Upconverted emission excitation spectrum and excited-state absorption spectrum of Pr^{3+}, Yb^{3+}:BaY_2F_8. (After [11.155])

cient avalanche process; its efficiency depends strongly on the transfer rates between the ions, the ground- and excited-state absorption cross sections, the ionic concentration, the emission branching ratios and the lifetimes of the energy levels involved. In principle it is possible to describe the photon-avalanche excitation mechanism for Pr,Yb-doped systems with rate equation systems [11.155–157, 160, 161]. However, due to its complexity, it is not possible to predict the overall efficiency solely from knowledge of the spectroscopic parameters.

In Table 11.5 an overview of photon-avalanche pumped Pr^{3+} laser systems is given. Room-temperature avalanche-pumped laser oscillation in bulk crystals was obtained for the Pr^3, Yb^{3+} codoped system, a so-called sensitized photon avalanche, in $YLiF_4$ (YLF) [11.164–166] and BaY_2F_8 (BYF) [11.163]. The principle scheme of the Pr-Yb system is shown in Fig. 11.40 [11.167–171]. The excitation around 840 nm corresponds to a very weak ground-state absorption process (very probable into a phonon tail of the Yb^{3+} absorption), followed by energy transfer (process r in Fig. 11.40) from Yb^{3+} to Pr^{3+} ($^2F_{5/2}$, $^3H_4$) → ($^2F_{7/2}$, $^1G_4$). The ESA process ($^1G_4$ → ($^1I_6$, $^3P_1$)), followed by fast phonon deexcitation [($^1I_6$, $^3P_1$) → $^3P_0$] feeds the $^3P_0$ level (i. e., the emitting level). The cross-relaxation process s ($^3P_0$, $^2F_{7/2}$) → ($^1G_4$, $^2F_{5/2}$) followed again by the transfer process r re-feeds the reservoir level. In this way, at each step, an increase of the population in the $^1G_4$ level is obtained and consequently a strong population will be build up in the $^3P_0$ level (because of the strong $^1G_4$ → ($^1I_6$, $^3P_1$) ESA process). The upconverted emission excitation spectrum and the excited-state absorption spectrum are shown in Fig. 11.41 indicating the good match between these two spectra. The peak excited-state absorption cross section of the $^1G_4$ → ($^1I_6$, $^3P_1$) transition is about 1.5×10^{-19} cm^2.

The laser input–output curves for Pr,Yb:YLF and Pr,Yb:BYF under Ti:sapphire pumping are shown in Fig. 11.42; the results are summarized in Table 11.5. The realization of diode pumping using commercially available infrared laser diodes is under investigation in several research groups. However, at the moment ion-doped fibers as materials for upconversion and avalanche pumped lasers are more efficient, because they allow waveguiding of both the pump and the laser beam. Therefore high pump intensities over a long distance are possible, increasing the overall efficiency of the avalanche pumping mechanism, see the section on visible fiber lasers in Sect. 11.2.2.

Er^{3+} Lasers. The problem for the realization of directly pumped visible Er^{3+} lasers is the lack of efficient pump sources that have a good spectral match to the absorption lines of the Er^{3+} ion. Therefore most visible Er^{3+} laser schemes have been realized by upconversion pumping in the near-infrared spectral range, as shown in Fig. 11.43. Table 11.7 summarizes a few results of direct pumping of Er^{3+} obtained with Xe lamps and a dye laser.

The energy-level schemes of Erbium-doped crystals such as $LiYF_4$ and $LiLuF_4$ [11.120, 121] offer the feasibility of realizing an upconversion laser emitting in the green spectral region ($^4S_{3/2}$ → $^4I_{15/2}$ transition). As shown in Fig. 11.43 the upconversion excitation of the upper laser level $^4S_{3/2}$ requires sequential two-photon

absorption (STPA) either at 810 nm or 970 nm. With a pump wavelength of 810 nm, the ground-state absorption (GSA) $^4I_{15/2} \rightarrow {}^4I_{9/2}$ is followed by nonradiative decay to the $^4I_{11/2}$ level. From there, population is taken to the $^4F_{5/2}$ level by excited-state absorption (ESA). Finally, the $^4S_{3/2}$ level is populated by nonradiative decay. With a pump wavelength around 970 nm, the upconversion excitation scheme of the upper laser level is very similar, however, it involves the GSA process $^4I_{15/2} \rightarrow {}^4I_{11/2}$ and the ESA process $^4I_{11/2} \rightarrow {}^4F_{7/2}$.

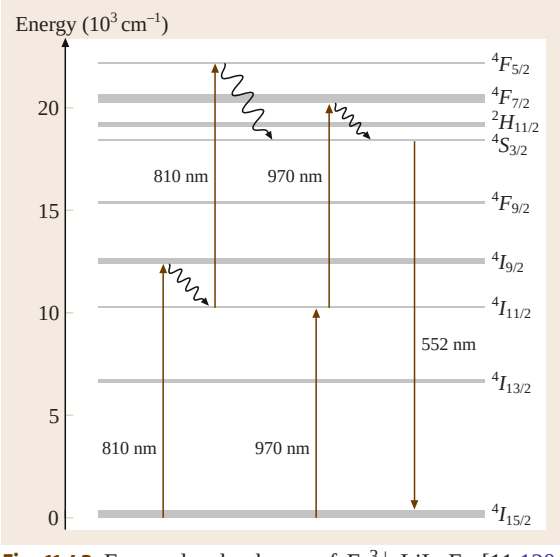

Fig. 11.43 Energy-level scheme of Er^{3+}:$LiLuF_4$ [11.120, 121] with two possible upconversion excitation routes of sequential two-photon absorption (STPA) at 810 nm or 970 nm [11.189, 190] and emission at 552 nm

Using a Ti:sapphire laser for excitation, various rare-earth-doped fluoride crystals have shown room-temperature CW upconversion lasing in the visible spectral range, e.g., Er^{3+}:$LiYF_4$ [11.191] and Er^{3+}:$LiLuF_4$ [11.189]. Diode pumping of a green erbium-doped upconversion laser in Er^{3+}:$LiLuF_4$ [11.190] and in the mixed fluoride crystal Er^{3+}:$LiKYF_5$ [11.192] has been demonstrated. In the latter case, however, laser operation could only be achieved under chopped excitation with a duty cycle of 20%.

Table 11.8 presents an overview Er-based upconversion lasers in different crystals and at various wavelengths.

Besides $YAlO_3$ most of the interesting candidates are fluorides, due to their relatively small phonon energies and correlated long lifetimes of intermediate states. Rare-earth-doped $LiLuF_4$ exhibits a larger splitting of the manifolds by the crystal field compared to $LiYF_4$ and $LiGdF_4$, which tends to produce more-favorable thermal occupation factors of both the upper and lower laser levels [11.193, 194]. A reasonable overlap between GSA and ESA enables two-step excitation to the $^4S_{3/2}$ level of Er^{3+} using just a single pump wavelength. The emission cross section σ_{em} at 552 nm (π polarization) is $\sigma_{em} = 3.5 \times 10^{-21}\,cm^2$. This value as well as the GSA cross sections around 970 nm are slightly larger than the corresponding cross sections in Er^{3+}(1%):$LiYF_4$. The lifetime τ of the upper laser level $^4S_{3/2}$ $\left[\tau(^4S_{3/2}) = 400\,\mu s\right]$ is slightly longer in $LiLuF_4$ than in $LiYF_4$.

Table 11.8 Visible Er^{3+} lasers (ETU: energy transfer upconversion, STPA: sequential two-photon absorption, CT: cooperative transfer, PA: photon avalanche, CW: continuous wave, p: pulsed, SP: self-pulsed, QS: *Q*-switched, ML: mode-locked, IR-fl: infrared flashlamp, OPS: optically pumped semiconductor, RT: room temperature)

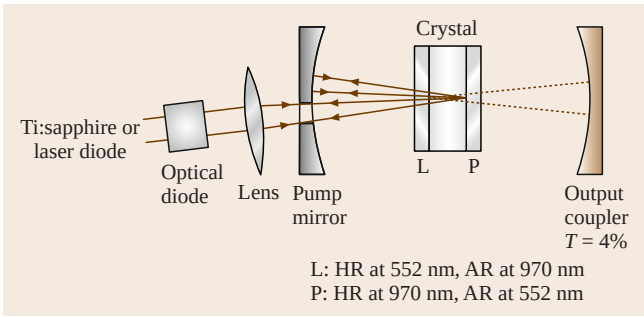

Fig. 11.44 Experimental setup for fourfold-pass pumping [11.190] (HR: high reflection, AR: antireflection)

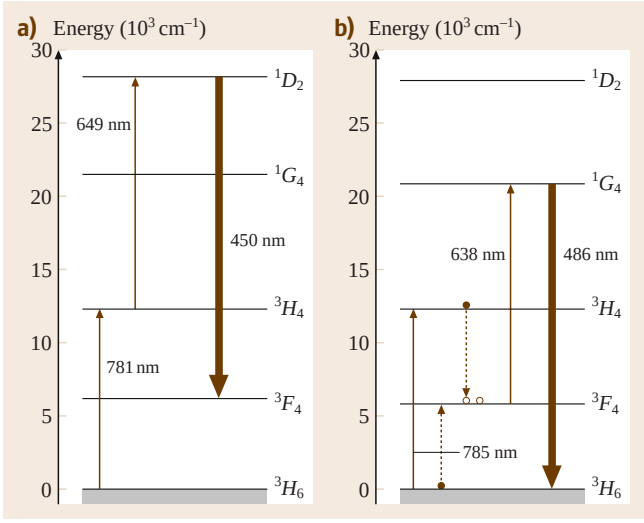

Fig. 11.45a,b Upconversion pump mechanisms for Tm^{3+}. **(a)** Sequential two-photon absorption, **(b)** sequential two-photon absorption with additional cross-relaxation (*dashed line*)

A multipass pumping setup has been used in order to increase the absorbed pump power (Fig. 11.44). Both end faces of the 1.6 mm-long Er^{3+}(1%):$LiLuF_4$ crystal have been prepared with directly coated dielectric mirrors [11.190]. One of these mirrors is highly transmitting for the pump wavelength and highly reflecting for the laser wavelength, while the other mirror is highly transmitting for the laser wavelength and highly reflecting for the pump wavelength (Fig. 11.44, coatings L and P, respectively). An additional concave mirror with a hole drilled slightly off axis is used to realize up to four passes of the pump radiation through the active volume of the laser crystal. The collimated pump beam is focused through the mirror hole into the crystal. With respect to single-pass pumping significant improvement of the performance of the Er^{3+}:$LiLuF_4$ upconversion laser could be achieved under Ti:sapphire laser excitation by using this setup. The maximum CW output power was 213 mW at an incident pump power of 2.6 W. The slope efficiencies with respect to incident and absorbed pump power were 12% and 35%, respectively. When replacing the Ti:sapphire laser by a 3 W diode, it was possible to realize laser-diode-pumped CW operation of this erbium-doped upconversion laser at room temperature for the first time [11.190]. The maximum output power was 8 mW at an incident pump power of 2.5 W. The absorbed power under four-pass pumping was small and estimated to be between 10% and 12%. The slope efficiency with respect to the absorbed pump power was 14%. Pumped with an optically pumped semiconductor laser operating at 970 nm, continuous-wave laser oscillation at 550 nm with Er^{3+}:$LiLuF_4$ has been achieved with an output power of 500 mW and a slope efficiency of about 30% [11.120, 121, 189, 190].

Other 4f–4f Divalent and Trivalent Rare-Earth Ion Lasers. Besides visible lasers based on 4f–4f transitions of Pr^{3+} and Er^{3+} several other lasers with 4f–4f transitions in the visible spectral region have been realized as shown in Table 11.6. When compared to Pr^{3+} and Er^{3+} lasers, the laser performance of all listed systems in Table 11.6 is worse. However, at least the upconversion pumped Tm^{3+} and Ho^{3+} lasers seem to have some potential for improvement of laser performance in the visible spectral region.

Blue upconversion laser emission in Tm-doped crystals can be achieved with STPA pumping. The energy levels and upconversion pump mechanisms in Tm^{3+} are illustrated in Fig. 11.45.

Figure 11.45a shows a pure STPA-pumped upconversion laser scheme, whereas in Fig. 11.45b, upconversion pumping also requires an additional cross-relaxation step between two Tm^{3+} ions. This cross-relaxation process populates the intermediate $^3F_4$ state which is the starting level for the second step of the STPA process.

In sensitized upconversion lasers a donor ion D (the sensitizer) absorbs the pump light and transfers its excitation energy to an acceptor ion A. In many cases Yb^{3+} has been used as the donor D for trivalent rare-earth-ion activators A. Through an upconversion energy transfer (ETU), two donor ions transfer their excitation energy successively to an acceptor. Finally the excitation energy of the donor is higher than the energy of an excited Yb^{3+} ion.

Table 11.9 Visible and UV lasers based on divalent and trivalent rare-earth ions

Ag^+	KI, RbBr, CsBr		335	5	[11.228]

Figure 11.46 shows a system with $D = Yb^{3+}$ and $A = Tm^{3+}$. In this case a three-step STPA process is also possible, yielding a variety of laser transitions in the visible region.

Figure 11.47 illustrates the STPA and ETU upconversion mechanisms in Ho^{3+} and in the donor–acceptor system Yb^{3+}-Ho^{3+}. Laser emission can be generated near 750 nm and 550 nm, originating from the metastable $^5S_2$, $^3F_4$ states.

It can be seen in Table 11.6 that, besides STPA and ETU pumping, photon avalanche (PA) pumping has also been used in a few cases (Nd^{3+} and Tm^{3+}).

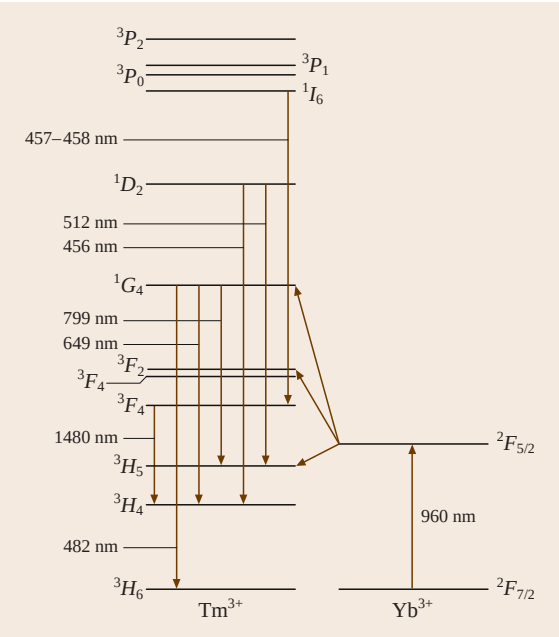

Fig. 11.46 Sensitized upconversion in Yb^{3+},Tm^{3+}-doped BaY_2F_8 after *Trash* and *Johnson* [11.182] with two and three steps in the STPA process

In Table 11.9 other rare-earth-ion lasers in the visible spectral range based on 4f–4f transitions are listed. The data are taken from [11.229].

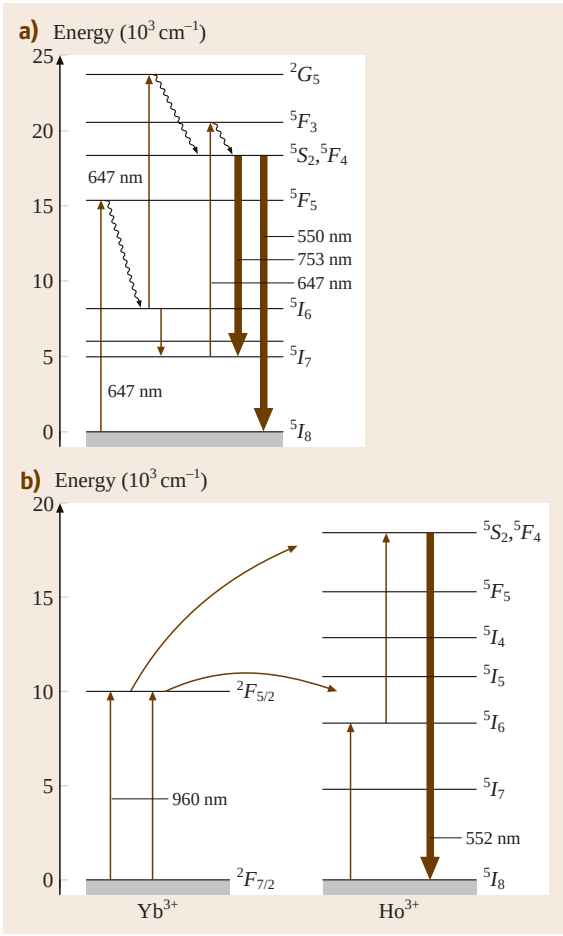

Fig. 11.47a,b STPA (**a**) and ETU (**b**) pumping of Ho^{3+} upconversion lasers

Visible Fiber Lasers

A different and very promising approach to realize efficient upconversion room-temperature laser oscillation is the use of rare-earth-ion-doped fibers. The geometry of the fiber provides waveguiding of both the pump radiation and the stimulated emission, thus long interaction lengths can be realized, yielding high intensities over a long distance, a critical requirement for upconversion lasers. This is one advantage of the fiber concept (for a detailed description of the fiber concept, see the description of Yb fiber lasers in Sect. 11.2.2) compared to bulk materials. Another requirement for visible upconversion lasers is the existence of metastable intermediate levels to act as initial levels for an excited-state absorption or an energy transfer process. Like in crystals, fluoride materials are preferred because of their low phonon energies and generally larger bandgaps. The fiber material of choice is the fluorocirconate glass

ZBLAN (ZrF_4-BaF_2-LaF_3-AlF_3-NaF). Another advantage of fibers compared to bulk crystals is that the transitions in glass are broadened and therefore the possibility for resonant transitions or energy transfer is enhanced. An overview of visible fluoride fibers is given in [11.244].

Nearly all rare-earth-ion-doped fluoride fiber lasers can be pumped in the 0.63–1.2 μm region and thus take advantage of the mature semiconductor technology, e.g., AlGaInP (0.63–0.69 μm), GaAlAs (0.78–0.88 μm) and InGaAs (0.90–1.2 μm) and of the highly developed solid-state laser technology, e.g., Nd^{3+} and Yb^{3+} lasers in the near-infrared spectral region.

Visible Pr^{3+} Fiber Lasers. As in crystals, the praseodymium ion is very attractive for visible fiber lasers because of its energy-level scheme (Fig. 11.33) and the possibility of upconversion pumping by two-step absorption, photon avalanche or energy transfer processes. Laser oscillation at room temperature has been achieved in the red, orange, green and blue spectral ranges. Some of these transitions have even been operated simultaneously [11.235]. Laser oscillation at room temperature originates from the $^3P_0$, $^3P_1$ and $^1I_6$ levels, which are thermally coupled. In Pr^{3+}:ZBLAN, the lifetime of these coupled multiplets is in the range 40–50 μs [11.245, 246]. *Richter* et al. and *Okamoto* et al. obtained laser oscillation of a Pr^{3+}-doped ZBLAN fiber under direct pumping with a blue semiconductor laser [11.243, 247]. Output powers of 94 mW and a slope efficiency of 41.5% at 635 nm were obtained. Broad tunability (479–497 nm, 515–548 nm, 597–737 nm, 849–960 nm) of a Pr^{3+}:ZBLAN fiber pumped by a GaN laser diode was shown by *Okamoto* et al. [11.248].

In Table 11.10 the results to date with Pr^{3+}-doped ZBLAN fibers are summarized. The best results obtained thus far, at the most efficient wavelength of 635 nm, are output powers up to 2 W and slope efficiencies up to 45% [11.238]. The efficiencies in the green and blue wavelength regions are about one order of magnitude smaller.

Generally, a double-clad fiber can be used to couple highly divergent pump radiation of near-infrared high-power laser diodes into the large-numerical-aperture inner cladding and propagate it along the fiber axis. On its way down the fiber, the pump radiation is gradually absorbed in the embedded small-numerical-aperture active core. Since the number of transverse radiation modes supported in a cylindrical fiber core depends only on the wavelength of the radiation, the core diameter, and its numerical aperture, the geometry and material of the active fiber core can be chosen to support just one or a few transverse modes of the radiation generated in the active core by near-infrared pumping. Thus, an upconversion double-clad fiber with a suitably chosen rare-earth-ion-doped active core can be used to convert the highly multimode radiation of high-power near-infrared laser-diode arrays into single-mode or few-mode visible laser emission with excellent beam quality. The best results in terms of upconversion laser output power, however, have been achieved when the pump radiation of a high-beam-quality laser source was launched directly into the active core of the described fiber. This is due to the high pump intensities required locally for photon-avalanche upconversion, which can be best provided by diffraction-limited pump radiation focused onto the fiber end face and guided in the rare-earth-ion-doped active core.

For example, Fig. 11.48 shows a demonstration of high-power upconversion laser operation under pumping with two dichroic coupled Ti^{3+}:Al_2O_3 lasers tuned to pumping wavelengths near 850 nm [11.170]. The maximum upconversion-laser output power was 1020 mW at an incident near-infrared total pump power of 5.51 W (Fig. 11.49). The overall slope efficiency with respect to the incident pump power was 19% [11.170].

Also, near-infrared high-power diode-laser bars with beam-shaping optics have been used to pump a Pr^{3+},Yb^{3+}-doped ZBLAN fiber with the common single-clad structure and a large-area multimode active core. In this case, 4.5 W of pump power were launched into the fiber core, generating red output powers in excess of 2 W at 635 nm [11.238]. In the blue spectral range, a Pr^{3+},Yb^{3+}-doped ZBLAN-based upconver-

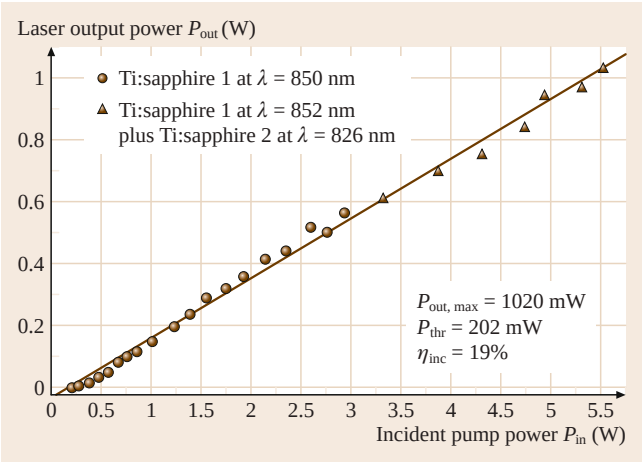

Fig. 11.49 Input–output characteristics of the Pr^{3+},Yb^{3+}-doped upconversion ZBLAN fiber laser [11.170]

sion fiber laser has been demonstrated at an emission wavelength of 491 nm ($^3P_0 \rightarrow {}^3H_4$ transition of Pr^{3+}). The pump source was a single-mode diode laser emitting at a wavelength of 840 nm. The maximum blue output power was 8 mW at an incident pump power of 200 mW [11.240].

Other Visible Fiber Lasers. Laser oscillation in the visible spectral range has also been obtained with other rare-earth ions in ZBLAN. In Table 11.11 an overview of these laser systems is given. A detailed description of these systems and their prospects is given in [11.244].

11.2.3 Near-Infrared Rare Earth Lasers

Nd Lasers

The most intensively investigated class of solid-state lasers is based on Nd^{3+}-ion-doped materials. The Nd^{3+}-ion offers various groups of laser lines in the near-IR spectral region.

Energy-Level Scheme. Figure 11.50 shows transitions from the $^4F_{3/2}$ upper laser level into the $^4I_{13/2}$, $^4I_{11/2}$, and $^4I_{9/2}$ manifolds. The specific absorption and emission wavelengths depend on the crystal field, which influences the splitting within a manifold and between different manifolds. As shown in Fig. 11.50 the splitting between the ^4I (and also between ^4F) manifolds is dominated by LS coupling of the 4f electrons and is only affected to second order by covalency effects caused by the crystal field. The energetic splitting between the ^4F and ^4I levels is dominated by Coulomb interaction of the 4f electrons, which is also only effected to second order by covalency effects of the crystal field. Therefore, the transition wavelengths of Nd-doped crystals vary in a certain range near the values given for Nd:$Y_3Al_5O_{12}$ (Nd:YAG) in Fig. 11.50. The strongest and most commonly used laser transition $^4F_{3/2} \rightarrow {}^4I_{11/2}$ emits near 1060 nm (Fig. 11.50).

Figures 11.51 and 11.52 show as an example the absorption and emission spectra of Nd:YAG, measured at 300 K. The strongest absorption is located near 808 nm and the strongest laser transition at 1064 nm.

Longitudinal and Transversal Diode Pumping. Nd lasers are usually pumped by lamps or diode lasers. The first generation of Nd-doped solid-state lasers were pumped with CW krypton or pulsed xenon lamps. These lamps have high electrical-to-optical efficiencies of about 70% and are available at reasonable costs. Unfortunately, the overlap of their emission spectra with the narrow 4f–4f absorption spectra of Nd-doped solid-state laser materials is usually poor; thus the electrical to optical pump efficiency is low – typically a few percent.

In modern Nd lasers, diode lasers at 808 nm are employed as pump sources. Laser diodes typically have efficiencies of about 50% and offer several advantages over lamp pumping. Diodes emit spectrally narrowband radiation (≈ 1–5 nm). Therefore, a much better overlap with the 4f–4f absorption spectra of Nd can be achieved. Because of the good spectral match, the total pump efficiency of diode pumping is much higher than for lamp pumping. In addition the transfer efficiency of pump light into the crystal is much better in the case of diode pumping, so that a total efficiency of 10% to 30% for the conversion of electrical power into laser power is achievable.

The selective spectral pumping with diodes also leads to reduced heat deposition in the laser crystal with reduced thermal lensing effects, giving rise to improved beam quality. Diffraction-limited beams can be realized easier.

However, there are also disadvantages of diode lasers. Because of their small active laser cross-sectional area and their relatively large refractive index, laser diode beams have a large divergence. Their beams also possess large beam-quality differences in the transversal and sagittal directions since the active area dimensions are usually $\approx 1\,\mu\text{m} \times 100\,\mu\text{m}$ and confinement is given only in one dimension. For power scaling, bars or arrays of diodes must be used. This can lead to output powers of up to several tens of watts. Unfortunately, combination of many single diode stripes also broadens the emission spectrum, while the beam quality of the combined radiation is further decreased. So, sophisticated pump optics such as beam shaping must often be employed [11.275].

Several pump geometries can be used with diode laser excitation. The common geometry to pump lasers, which are capable of generating several watts of output power with excellent beam quality, is end pumping (Fig. 11.53). In this geometry, pump radiation is focused into the laser crystal along the laser resonator axis. A very good overlap of pump and laser modes can be provided. Gain media of small volume and with short absorption lengths can be used, and high population inversions at low pump power levels can be achieved. Because most of the pump power is deposited

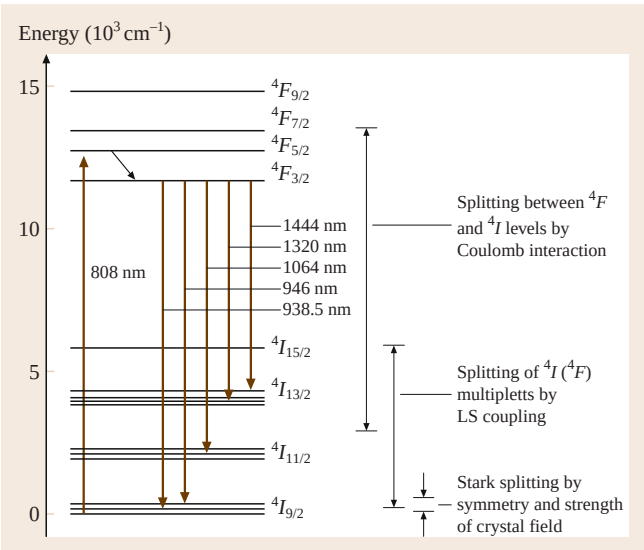

Fig. 11.50 Level scheme, pump and laser transitions of Nd^{3+} in YAG

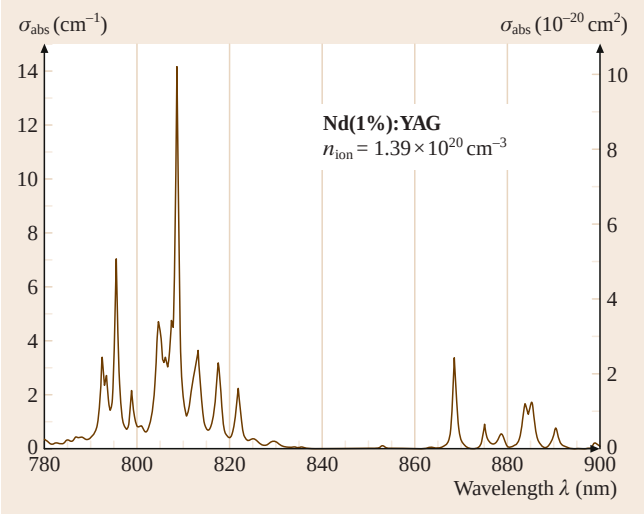

Fig. 11.51 Absorption spectrum of Nd(1%):YAG and absorption cross sections

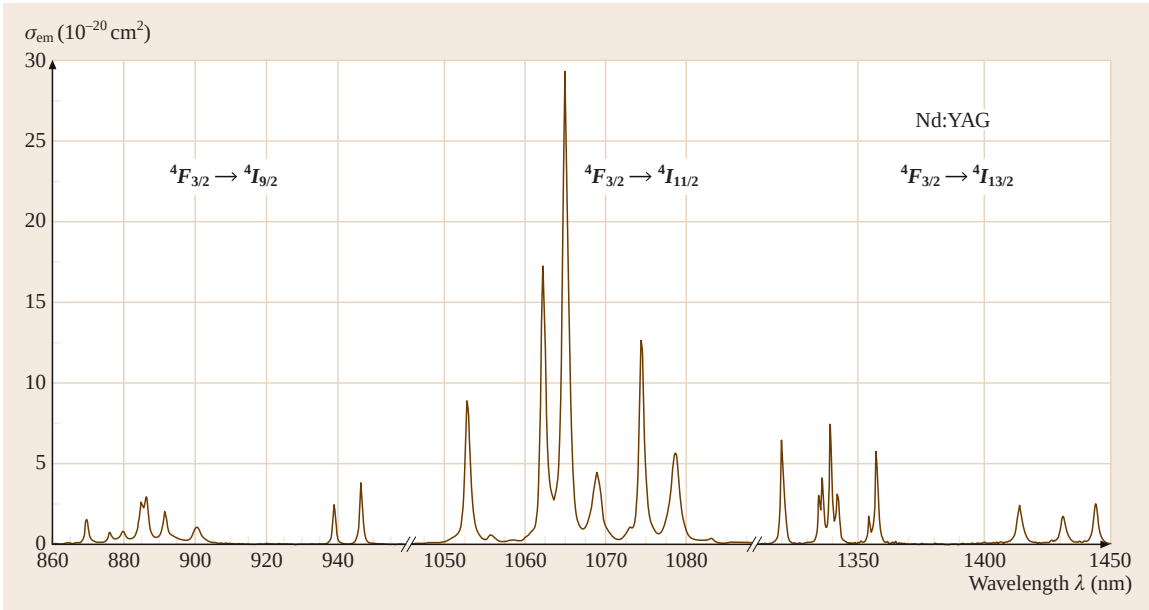

Fig. 11.52 Emission cross section spectra of Nd:YAG

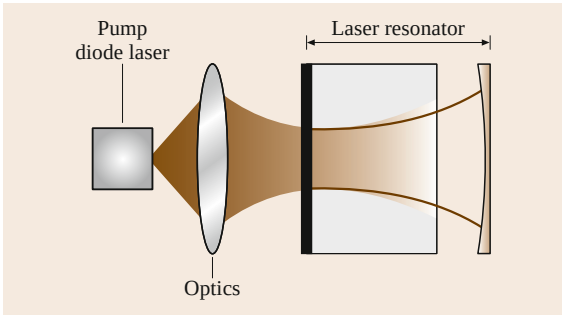

Fig. 11.53 Diode end-pumping scheme

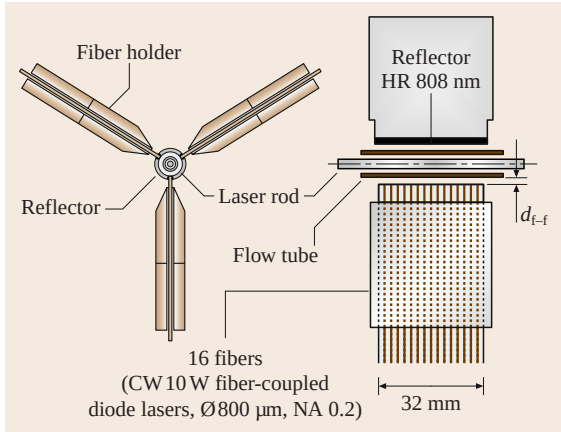

Fig. 11.54 Diode side (transversal) pumping scheme [11.276]

within the volume of the TEM_{00} laser mode, higher-order modes usually cannot oscillate. Excellent beam quality is therefore inherent. However, scaling of end-pumped lasers to output powers above 20 W is difficult to achieve due to possible thermally induced fracture of the laser crystal within the small volume of pump absorption.

An alternative diode pumping method is side pumping (Fig. 11.54, [11.276]). In this approach, the pumping geometry is principally similar to the arrangement for lamp pumping. One or several linear pump diode bars are positioned around the side surface of the laser crystal. Pump radiation is then usually imaged into the crystal perpendicular to the laser resonator axis. The crystal is relatively homogeneously pumped throughout its total volume, and a smaller excitation density is usually realized than in diode laser end pumped systems. Because of the use of larger gain media, however, more energy can be deposited into the laser crystal and therefore higher output powers can be achieved. Since a larger laser mode is present inside the crystal, higher-order modes also usually oscillate in these lasers. Therefore beam quality is often rather low.

Nd-doped fiber lasers can also be operated in specific configurations, see for example [11.277–288], and

Table 11.12 Important host materials for Nd^{3+} [11.293]

Host	YAG	YAlO (FAP)	YVO	GVO	YLF

[a] The published data of heat conductivities of the vanadates YVO and GVO differ considerably [11.289–292]

are used in many applications. For high-power laser generation, double-clad fibers are usually used. Basic aspects are described later in this chapter.

The Most Important Nd Lasers. The most important Nd-doped laser materials feature relatively high emission cross sections, a relatively long upper-state lifetime of Nd^{3+}, a high damage threshold, high mechanical and chemical stability, good thermal conductivity and very good optical quality, see Table 11.12. Many host crystals have been investigated, including yttrium aluminum garnet (YAG), yttrium aluminum perovskite (YAP or YALO), yttrium lithium fluoride (YLF) and yttrium vanadate (YVO). Very efficient and compact diode-pumped lasers with slope efficiencies of over 60% have been demonstrated in many Nd-doped laser materials.

Nd:YAG is still regarded as the most important solid-state laser. Due to their very good optical and mechanical properties, diode-pumped Nd:YAG lasers are robust and reliable. They are in use in many applications. Within the last few years Nd:YAG have also become available as ceramics with high optical quality.

The vanadates Nd:YVO and Nd:GVO emit polarized radiation and exhibit large cross sections and gain.

Nd Laser Wavelength and Materials. A variety of Nd lasers have been reported so far. Tables 11.13–11.15 list

Table 11.13 Laser wavelengths of the $^4F_{3/2} \rightarrow {}^4I_{9/2}$ transition at 300 K [11.229]

Wavelength (nm)	Material
0.8910	$Y_3Al_5O_{12}$
0.8999	$Y_3Al_3O_{12}$
0.901	$Sr_{1-x}La_xMg_xAl_{12-x}O_{19}$ [11.294]
0.9106	$Ba_3LaNb_3O_{12}$

0.941	$CaY_2Mg_2Ge_3O_{12}$
0.9458–0.9464	$Y_3Al_5O_{12}$ [11.304]
0.946	$Y_3Al_5O_{12}$ [11.229, 305–313]
0.946	$Y_3Al_5O_{12}$ ceramic [11.314]
0.966	Sc_2O_3 [11.315]

laser materials and their laser wavelengths which have been observed at 300 K on the transitions $^4F_{3/2} \rightarrow {}^4I_{9/2}$, $^4I_{11/2}$ and $^4I_{13/2}$. The tables also list Nd-doped ceramics, which have been developed with very good optical quality and low scattering losses. So, the efficiency of ceramic lasers can be as high as for crystals.

If not specified otherwise, the references for the laser materials can be found in [11.229].

Yb Lasers

Coherent oscillation of Yb^{3+} was first observed in YAG at 77 K [11.316]. In 1991 the first realization of a diode-pumped Yb:YAG laser [11.317] at room temperature initialized an intensive renaissance of research on Yb-doped laser materials for laser diode pumping at 300 K. Yb^{3+}-doped solid-state lasers feature several important advantages compared with other rare-earth lasers:

1. Yb^{3+} ions have only two states, the ground state $^2F_{7/2}$ and the excited state $^2F_{5/2}$, which are separated by an energy of about 10 000 cm^{-1}. Thus, there is no excited-state absorption of the pump and laser radiation (Fig. 11.55).
2. The quantum efficiency of Yb^{3+} is close to unity.
3. Due to the small Stokes shift and the related small quantum defect (typically 500 cm^{-1}) heat generation in the lasing process of Yb^{3+} is small and makes it a suitable ion for high-average-power lasers.
4. The small ionic radius of Yb^{3+} compared to that of other rare-earth ions favors its incorporation into Y-based host crystals such as YAG, allowing higher dopant concentration and thus shorter gain elements such as discs.
5. Yb^{3+} ions exhibit a relatively broad emission band which leads to tunability and the generation of ultrashort pulses.
6. The radiative lifetime of the laser level ranges in different crystals from a few hundred microseconds to a few milliseconds, which implies greater energy storage efficiency, especially for Q-switched operation with diode pumping.

One disadvantage of Yb^{3+}-doped lasers is that they operate in a quasi-three-level scheme with temperature-dependent reabsorption at the laser wavelength. This leads to an increased threshold compared to a four-level scheme, because the pump must bleach the reabsorption losses (see the section on basic spectroscopic properties in Sect. 11.2.1).

Figures 11.56 and 11.57 show as an example the absorption and emission cross section spectra of Yb:YAG [11.318]. When pumped near the absorption peaks at 940 nm or 970 nm, the Stokes shift to the lasing wavelength at 1030 nm corresponds to less than 10%, which allows in principle a slope efficiency of more than 90%.

Yb^{3+} Thin-Disc Lasers. In connection with the power scaling of diode-pumped Yb lasers *Giesen* et al. [11.319] invented the thin-disc laser concept as a pump and resonator design for high-power lasers (Fig. 11.58).

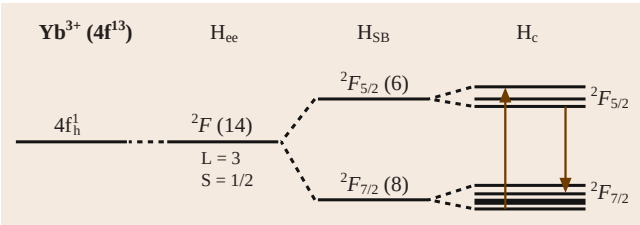

Fig. 11.55 Level scheme of Yb^{3+}: free-ion state (one 4f hole $4f^1_h$), electron–electron interaction (H_{ee}), splitting by spin–orbit interaction H_{SB}, and crystal field H_c. Pump and laser transitions are indicated by *arrows* ◀

The active medium is a thin circular disc, which is coated for both the pump and laser wavelengths with a highly reflecting (HR) dielectric mirror on the rear side and with an antireflection coating on the front side. The disc is then bonded with the rear HR side to a heat sink. The resonator is formed by the coated crystal and an output coupler. The pump light is provided by fiber-coupled laser diodes which are focused onto the crystal. Since the thin crystal disc only absorbs a small fraction of the pump light during one pass through the crystal, the pump light is reflected back into the disc several times by a parabolic mirror and the folding prism [11.320]. Up to a total of 32 pump light passes may be used.

Due to the geometrical setup a nearly one-dimensional thermal gradient along the laser axis can be reached within the crystal. This setup minimizes the formation of thermal lenses, and therefore yields better beam quality at high powers compared to a rod laser. Multiple passes of the pump radiation through the crystal increase the absorption efficiency and also the effective pump power density in the crystal. Therefore, the thin disc design is suitable for quasi-three-level systems such as Yb^{3+}. Figure 11.59 shows the input versus output power of a thin-disc Yb:YAG laser [11.320]. CW output powers in the kilowatt range from one disc are possible. Further power scaling with several discs in the cavity is also possible [11.320].

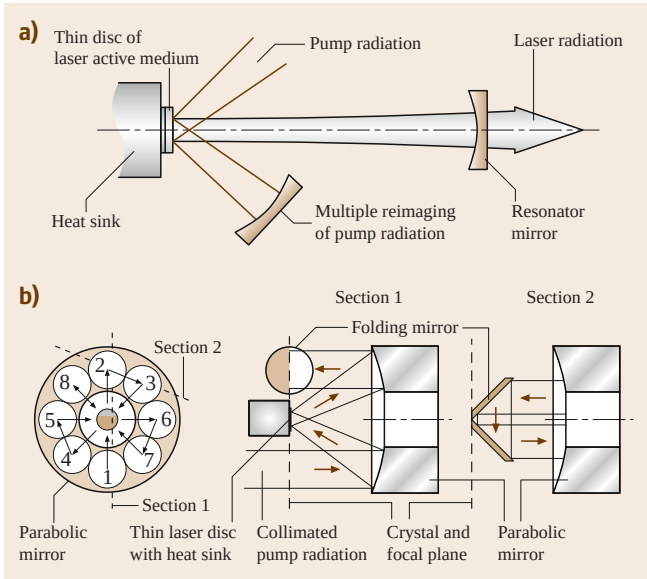
Yb *Fiber Laser*. Fiber lasers present another approach for the generation of high powers with diffraction-limited beam quality. Since the introduction of the double-clad fiber more than two decades ago and with the recent technological advances in the fields of fiber fabrication and beam-shaped high-power diode lasers, the performance of diode-pumped fiber lasers has dramatically improved. Today, fiber lasers can compete with their corresponding bulk crystalline systems in certain applications, especially when fundamental-transverse-mode continuous-wave (CW) laser operation at output powers in the milliwatt to kilowatt range is required.

Basic Aspects of Fiber Lasers. The invention of the double-clad fiber geometry and the holey fiber concept has accelerated the scaling of the output power and hence the success of high-power Er, Nd and Yb fiber lasers. For more-detailed reading a comprehensive introduction to the field of rare-earth-doped fiber lasers can be found in [11.398].

The choice of the fiber material involves a number of considerations: The maximum phonon energy, environmental durability, the drawability and the rare-earth solubility. The maximum phonon energy of the glass sets the overall infrared transparency range of the fiber and the multiphonon relaxation rates that influence the quantum efficiency of radiative electronic transitions by nonradiative decay. The important physical properties of the popular glasses used for optical fibers are shown in Table 11.16:

- Silicate glass. This glass is the most important material used for optical fiber production [11.398, 399]. However, the maximum phonon energy is high ($\approx 1100\,cm^{-1}$) and has so far limited the emission wavelength for infrared fiber lasers using this material to approximately 2.2 μm [11.400]. Silica is robust and fibers fabricated from this material involve the very effective modified chemical vapor deposition (MCVD) technique. Reducing the OH^- content in the glass, which has two main absorption peaks in the range 1.3–2.0 μm, reduces the background absorption of fibers [11.401].
- Fluoride glass. These glasses, especially the heavy-metal fluorides [11.402, 403], are used as host materials for mid-infrared fiber lasers. The most widespread fluoride fiber material is ZBLAN [11.404] with a mixture of 53 mol % ZrF_4,

Fig. 11.58 (a) Thin-disc laser setup, (b) multiple-pass pump optics for 16 passes ▶



20 mol % BaF_2, 4 mol % LaF_3, 3 mol % AlF_3, and 20 mol % NaF. Since it can be readily drawn into single-mode optical fiber [11.405] it is particularly important to mid-infrared fiber lasers [11.406] and allows for high infrared transparency up to $\approx 6\,\mu m$. Nonradiative decay by multiphonon relaxation, however, becomes significant for transitions at wavelengths longer than $\approx 3\,\mu m$. In addition to mid-infrared applications, ZBLAN is mostly also used for upconversion fiber lasers which need metastable intermediate pump levels with low multiphonon relaxation rates. An overview of the spectroscopic properties of rare-earth ions doped into ZBLAN is given in [11.407].

- Chalcogenide glasses. Chalcogenides are composed of the chalcogen elements S, Se and Te [11.413, 414]. When rare-earth ions are doped into these glasses [11.415], the radiative transition probabilities, and therefore the absorption and emission cross sections, are high as a result of the high (≈ 2.6) refractive index and the high degree of covalency of the glass. Small phonon energies of 300–450 cm^{-1} produce low rates of multiphonon relaxation for mid-infrared transitions. The low thermal conductivity (Table 11.16) is, however, an important factor to be considered in the design of chalcogenide-based lasers. So far, the most important glasses are the sulfide glasses GaLaS (GLS) [11.416] and GeGaS [11.417] because of the reasonably high rare-earth solubility.

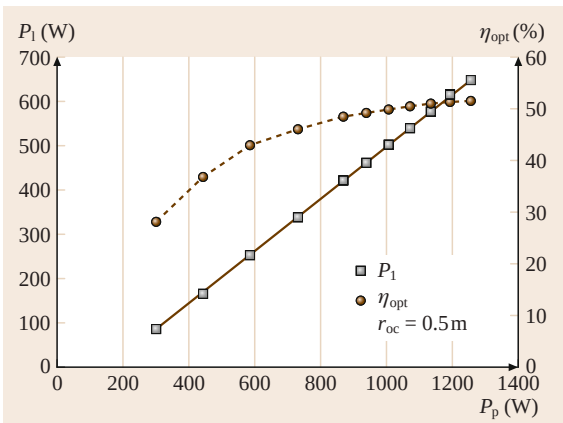


Fig. 11.59 Output power and optical efficiency for a thin-disc Yb:YAG laser using a single disc. (P_p = pump power, P_l = laser output power, η_{opt} = optical-optica efficiency)

Fiber, Pump and Resonator Geometries. As bulk lasers, fiber lasers can be operated continuous wave, pulsed (including Q-switching) and mode-locked. These operation modes have been investigated intensively for the common laser transitions near 1 μm in Nd^{3+} and Yb^{3+}, and near 1.5 μm in Er^{3+}. However, the small fiber diameter limits the peak power by the damage threshold intensity and, hence, crystalline lasers in bulk geometries are mostly preferred when high-energy short pulses are needed. In an analogous way to the optical excitation of bulk gain media (see the section on longitudinal and transversal pumping

Table 11.16 Properties of popular fiber materials

Fiber material	Max. phonon energy (cm^{-1})	Infrared transparency (μm)	Propagation losses (λ at minimum) (dB/km)	Thermal conductivity (W/m · K)
Silica	1100 [11.408]	< 2.5	0.2 (1.55 μm)	1.38 [11.409]
ZBLAN	550 [11.407]	< 6.0	0.05 (2.55 μm)	0.7–0.8 [11.410]
GaLaS	425 [11.411]	< 8.0	0.5 (3.50 μm)	0.43–0.5 [11.412]

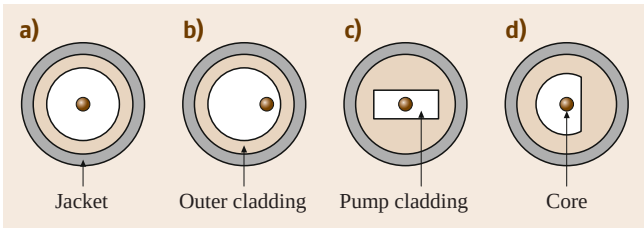

Fig. 11.60a–d Principal double-clad fiber geometries which include **(a)** circular-shaped pump cladding with axially positioned core, **(b)** circular-shaped pump cladding with off-axially positioned core, **(c)** rectangular-shaped pump cladding and **(d)** D-shaped pump cladding

in this Sect. 11.2.2), doped optical fibers can be either end pumped (core pumped) or side pumped (cladding pumped). The former method is less scalable since it relies on the use of expensive high-beam-quality pump sources because core areas are usually $< 100\,\mu m^2$. On the other hand, the larger cladding area ($> 10^4\,\mu m^2$) allows for high-power diode-array pumping [11.418–421]. We will here describe the cladding-pumping technique, which is one of the most important developments in high-power fiber-laser technology:

- Fiber designs for cladding pumping. In the design of cladding pumping, the core of the fiber is generally made to guide a single transverse LP_{01} mode. The shape of the multimode pump cladding (Fig. 11.60), however, can be shaped with a number of geometries. The pump cladding, which in turn is surrounded by a low-refractive-index transparent polymer or glass, provides a high numerical aperture (NA) of typically 0.3–0.55. Photonic crystal structures can be also used to improve cladding pumping [11.422] for the operation of fiber lasers at the multi-hundred-watt level. There are three main double-clad-fiber layouts: circular, circular with offset core, and rectangular, as shown schematically in Fig. 11.60. In the case of circular pump cladding [11.53] a portion of the launched pump light is skew to the fiber axis and produces an inner pump beam caustic that never crosses the core. Asymmetric configurations significantly improve the pump beam absorption in the core [11.423,424]. Double-clad pump schemes have been demonstrated with holey or photonic crystal fibers [11.425]. In such fibers single-mode guiding and very large mode areas are possible [11.426].
- Fiber-laser resonators. Typical free-running fiber-laser resonators are shown schematically in Fig. 11.61. In the simplest resonator (Fig. 11.61a), the pump light passes through a dichroic mirror that is highly reflective for the oscillating laser light. Fresnel reflection at the cleaved output end facet of the fiber can provide sufficient feedback for laser oscillation, although with an output-coupler mirror at the output end of the fiber the optical efficiency can be maximized. In an alternative arrangement, the pump light can be launched into the output end of the fiber (Fig. 11.61b). In order to scale the output power, each end of the fiber can be pumped (Fig. 11.61c). Due to its geometry, the fiber provides potentially high pump- and signal-beam intensities without the drawbacks of significant thermal and thermo-optical effects. Its large surface-area-to-volume ratio means that the heat generated in the core is dissipated effectively by radiation and convection from the outer surface of the fiber.

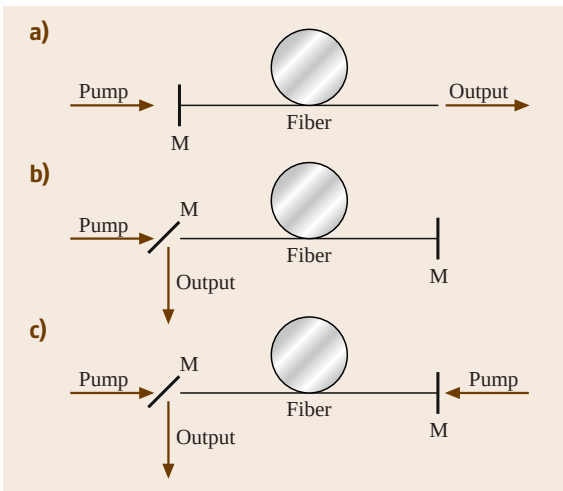

Fig. 11.61a–c Schematic diagram of resonators used for free-running fiber lasers with **(a)** a single-end co-propagating pump, **(b)** a single-end counter-propagating pump and **(c)** dual-end pumps. M represents a mirror

High-Power Yb Fiber Lasers. Yb-doped fiber-lasers have been operated at CW and average output powers in excess of 10 W [11.427–432], in excess of 100 W [11.433–439] and above 1 kW [11.440]. Also, a 30 μm Yb-doped large-mode-area fiber has been used for the amplification of Q-switched Nd:YAG pulses at repetition rates between 3 and 50 kHz with average output powers up to 100 W. Pulse energies as high as 4 mJ with diffraction-limited beam quality have been obtained in this case [11.441].

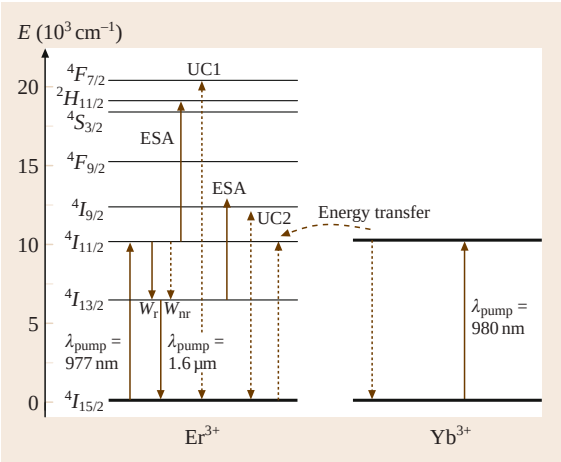

Fig. 11.62 Energy-level diagram of Er^{3+} and Yb^{3+} in a YVO_4 crystal

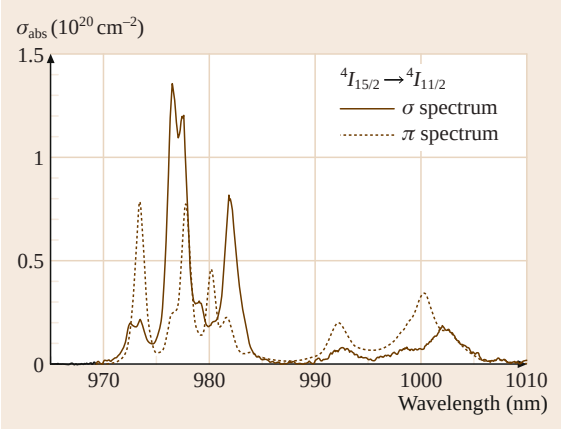

Fig. 11.63 Polarized absorption spectra at room temperature of an Er^{3+}:YVO_4 crystal in the spectral range of the ${}^4I_{15/2} \rightarrow {}^4I_{11/2}$ transition. (After [11.446])

Yb^{3+} Crystalline Lasers. The properties and laser parameters of Yb:YAG are listed in Table 11.17. In the meantime, besides Yb:YAG, a lot of Yb-doped laser materials have been explored and tested in CW, Q-switched and mode-locked operation. Table 11.18 shows an overview of Yb-doped laser crystals.

Er Lasers at 1.5 µm (${}^4I_{13/2} \rightarrow {}^4I_{15/2}$)

For many years Er^{3+}-doped materials have been widely investigated for laser applications in the spectral range around 1.6 µm [11.447]. This laser transition (${}^4I_{13/2} \rightarrow {}^4I_{15/2}$, see Er^{3+} energy-level scheme depicted in Fig. 11.62) is used for eye-safe lasers for medicine, telecommunication, remote sensing and light detecting and ranging (LIDAR). Suitable erbium-doped materials for the 1.6 µm laser transition should be at first characterized by a high phonon energy, which enables fast depopulation of the pump level ${}^4I_{11/2}$ via nonradiative decay in order to prevent excited-state absorption (ESA, ${}^4I_{11/2} \rightarrow {}^2H_{11/2}, {}^4S_{3/2}$) and upconversion $\left(\text{UC1}, ({}^4I_{11/2}, {}^4I_{11/2}) \rightarrow ({}^4I_{15/2}, {}^4F_{7/2})\right)$ from the ${}^4I_{11/2}$ level and to populate efficiently the ${}^4I_{13/2}$ upper laser level (Fig. 11.62). The second important condition is that the ESA transition ${}^4I_{13/2} \rightarrow {}^4I_{9/2}$ should not spectrally overlap with the range of stimulated emission around 1.6 µm and that the upconversion process $\left[\text{UC2}, ({}^4I_{13/2}, {}^4I_{13/2}) \rightarrow ({}^4I_{9/2}, {}^4I_{15/2})\right]$ is weak. Additionally, a significant splitting of the ground-state multiplet is advantageous to achieve a quasi-four-level system. These conditions are best fulfilled by Er^{3+}-doped glasses and fibers, which are to date the most efficient lasers at this transition. However, glasses suffer from poor thermal and mechanical stability, thus Er^{3+}-doped crystalline matrices are still being intensively investigated in order to find suitable crystals for this laser transition.

For most applications of Er^{3+}-doped laser materials, laser diodes operating in the wavelength range

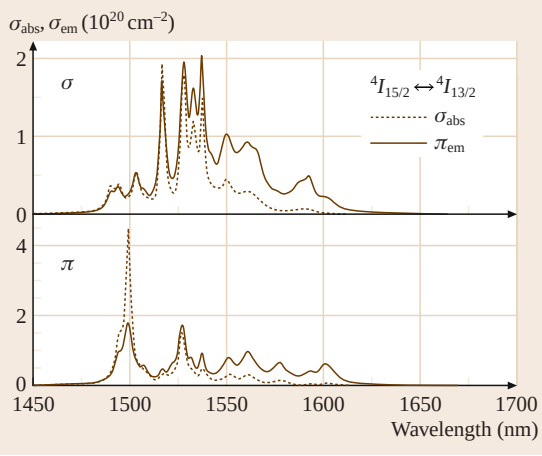

Fig. 11.64 Spectra of absorption cross sections due to the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ transition of Er^{3+} in YVO_4 crystal (*dotted lines*) and emission cross sections ($^4I_{13/2} \rightarrow {}^4I_{15/2}$) (*solid lines*) for σ and π polarization. (After [11.446])

around 975 nm (the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ transition) are used as a pump source, thus enabling all-solid-state laser systems. With Ti:sapphire pump lasers in general better laser results are obtained, however, the overall efficiency is low. Another possible pump wavelength lies around 1.5 μm, i. e., directly into the upper laser multiplet. However, for this wavelength region high-power laser diodes are not yet available, therefore usually Er-glass lasers as pump sources are used. In any case, the Er absorption at these wavelengths is rather small, because the absorption cross sections are in the order of 1 to 2×10^{-20} cm^2 (Figs. 11.62, 63). Doping levels higher than 1 to 2% are critical, because of increased reabsorption losses and higher rates for energy transfer processes, which depopulates the upper laser level ($^4I_{13/2}$, $^4I_{13/2}$) → ($^4I_{15/2}$, $^4I_{9/2}$). Therefore, to keep the Er^{3+} concentration low but achieve higher absorption, the usual approach is to codope the Er^{3+}-doped laser material with Yb^{3+}, which can be very efficiently pumped around 975–980 nm. Then, the energy transfer process ($^2F_{5/2}$, $^4I_{15/2}$) → ($^2F_{7/2}$, $^4I_{11/2}$) is exploited (Fig. 11.62). The main task for the optimization of Er lasers around 1.55 μm is thus to find the optimum concentration for both dopant ions.

Crystals. The absorption spectra of Er^{3+}:YVO_4 for the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ and $^4I_{15/2} \rightarrow {}^4I_{13/2}$ transitions are shown in Figs. 11.63 and 11.64, respectively [11.446]. The peak absorption cross section for the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ transition around 970 nm is up to 2×10^{-20} cm^2, for the $^4I_{15/2} \rightarrow {}^4I_{13/2}$ transition around 1500 nm cross sections are higher, approximately up to 4×10^{-20} cm^2. The emission spectrum is shown in Fig. 11.64. The peak emission cross sections of the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ emission in Er^{3+}:YVO_4 are up to 2×10^{-20} cm^2, in the long-wavelength tail, where the laser oscillation occurs, the peak cross sections are around 0.5×10^{-20} cm^2. These values are typical for Er^{3+}-doped crystals, e.g., the peak emission cross section around 1550 nm is 0.31×10^{-20} cm^2 for Er:$YAlO_3$ [11.447],

0.33×10^{-20} cm^2 for Er:Y_2SiO_5 [11.595], 0.45×10^{-20} cm^2 for Er:YAG [11.447], 0.42×10^{-20} cm^2 for Er:YLF [11.447], and 0.59×10^{-20} cm^2 for Er:$LaGaO_3$ [11.596].

From the absorption and emission spectra the gain coefficient curves (Fig. 11.65) can be calculated by

$$g = N[P\sigma_{em} - (1-P)\sigma_{abs}] ,$$

where N is the ion concentration and P is the inversion coefficient, defined as the ratio between the populations in the $^4I_{13/2}$ and the $^4I_{15/2}$ levels. It can be seen that for Er^{3+}:YVO_4 already for an inversion coefficient of $P \approx 0.2$ laser oscillation should be possible within a spectral range from approximately 1530 to 1610 nm.

In Fig. 11.66a the input–output characteristics of Ti:sapphire-pumped Er^{3+}:YVO_4 crystals with 0.5% Er and 1% Er doping, operating at 1604 nm, are shown. The slope efficiency with respect to the incident power is about 7–8%. It should be noted that with respect to the absorbed power the 0.5% Er:YVO_4 crystal exhibits a higher slope efficiency. This indicates that for the more highly doped sample (1% Er) the aforementioned loss mechanism of reabsorption and upconversion already take place. The laser threshold is below 200 mW of incident power and below 100 mW of absorbed pump power.

These values for the slope efficiency, the laser threshold and the output power are typical for well-performing Er^{3+}-doped crystals, such as for $Y_3Al_5O_{12}$ [11.597] and $LaSc_3(BO_3)_4$ [11.598].

Recently, high-power and ultra-efficient laser operation of an Er:YAG laser near 1645 nm with approximately 60 W [11.599–602] of output power was demonstrated using a high-power fibre laser at 1532 nm as a pump source (so-called in-band pumping (Fig. 11.66b). This work demonstrates that the small Stokes shift between the pump and laser radiation (1532 nm/1645 nm) yields very efficient Er lasers with slope efficiencies up to 80%.

In Table 11.19 an overview of crystalline room-temperature Er^{3+} lasers is given. Note that lasers on the $^4S_{3/2} \rightarrow {}^4I_{9/2}$ transition are also listed.

Glass. Laser oscillation in Er^{3+}-doped and Yb^{3+},Er^{3+}-codoped silicate and phosphate glasses was investigated as early as the mid-1960s [11.603–605]. The three-level behavior of the Er^{3+} system and the weak absorption of pump radiation caused by the requirement of low dopant concentration (usually approximately 2 to 5×10^{19} cm^{-3}) makes it difficult to obtain efficient laser operation in singly Er^{3+}-doped glasses. Therefore, Yb^{3+} codoping is necessary in order to absorb the pump light efficiently at wavelengths around 1 μm. Continuous-wave laser oscillation, Q-switched [11.606, 607] and quasi-CW operation with pulse energies up to 35 J and average output powers up to 20 W have been obtained [11.608–612]. The pulse duration of the Xe flashlamps is several milliseconds, thus matching the upper-laser-level lifetime of the Er^{3+} $^4I_{13/2}$ level. Also laser diodes can be efficiently applied as pump sources. *Wu* et al. [11.613] used pulsed laser diodes in a transversal excitation scheme. Using a repetition rate of 50 Hz, a pump pulse duration of 2.5 ms and a peak pump power of ≈ 1.5 kW, an average output power of 8.5 W was obtained, corresponding to an output energy of 170 mJ per pulse. A comparison and discussion of different pumping schemes is given in [11.614]. In all experiments, the main problem of glass materials compared to crystals is the low heat conductivity (for Kigre QE7 0.82 W/(m K) [11.611] versus 13 W/(m K) for YAG). Thus, the introduced heating power and therefore also the extractable output power and/or repetition rate is limited and high-power continuous-wave excitation of Er^{3+}-doped glasses is difficult. Despite this, the overall performance of the Kigre QE7 and QX glasses is better than that of Er^{3+}-doped crystals. *Obaton* et al. [11.615] obtained a slope efficiency of 21% in a diode end-pumped setup for a QX glass. *Diening* [11.616] compared Kigre QE7 glass with Er^{3+}:$LaSc_3(BO_3)_4$ and $Y_3Al_5O_{12}$ in the same setup

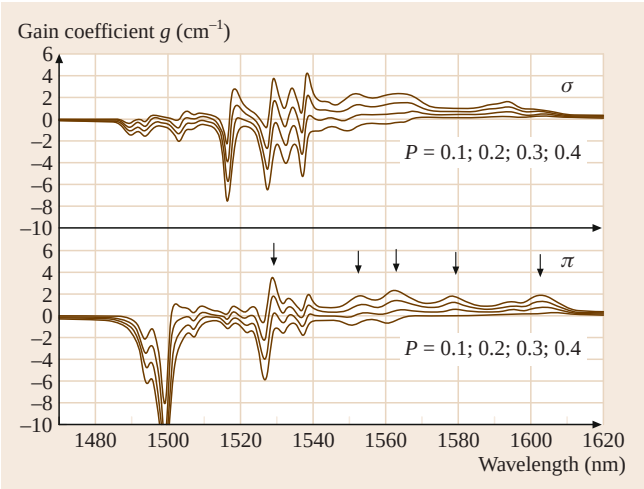

Fig. 11.65 Gain coefficient curves derived for both polarizations for Er^{3+}:YVO_4 in the spectral range of the $^4I_{15/2} \rightarrow {}^4I_{11/2}$ laser transition for four values of the inversion parameter P (larger gain values for larger P). *Arrows* denote the wavelengths for which laser oscillation was realized. (After [11.446])

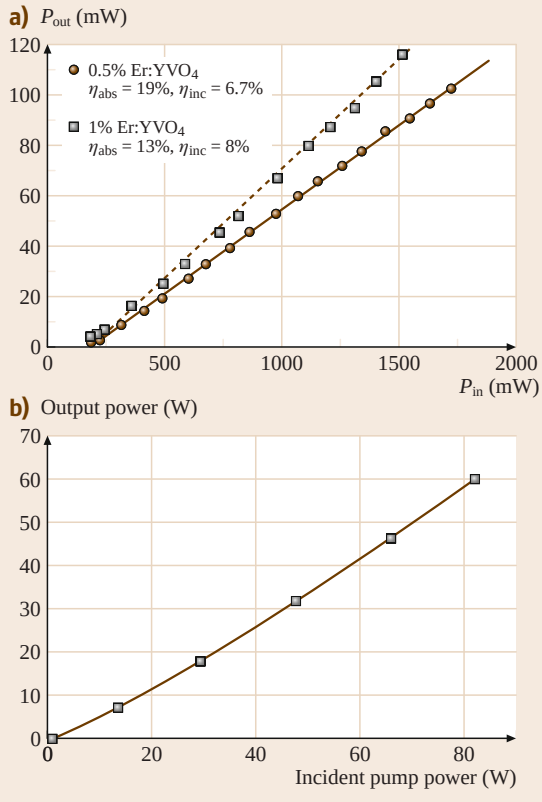

Fig. 11.66 (a) Input–output curve of the CW laser oscillation of Er^{3+} (0.5%):YVO_4 crystal ($\lambda_{laser} = 1604$ nm, output mirror transmission = 1%). The slope efficiencies are given with respect to the absorbed (η_{abs}) and incident (η_{in}) power. (Results from [11.446]). (b) In-band pumping of Er:YAG with a fiber laser at 1532 nm and lasing at $\lambda_{laser} = 1645$ nm (after [11.599])

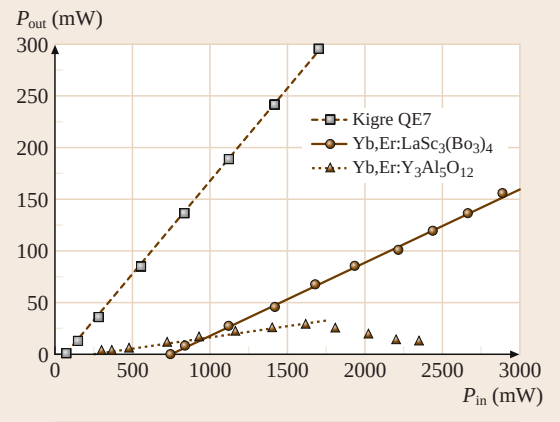

Fig. 11.67 Results of the laser experiments with Kigre QE7 glass, Yb^{3+}(10%), Er^{3+}(0.5%):$LaSc_3(BO_3)_4$ and Yb^{3+}, Er^{3+}(0.5%):$Y_3AL_5O_{12}$. (After [11.616])

(Fig. 11.67). The achieved output power and slope efficiency for the QE7 glass are about twice as high as for Er^{3+}:$LaSc_3(BO_3)_4$.

Fibers. Erbium-doped fiber lasers have been extensively studied for their potential use as sources in communication systems operation in the third communication window around 1.55 μm. All these lasers oscillate on the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition, either in continuous-wave or pulsed mode. In singly Er^{3+}-doped fibers, suitable pump wavelengths for using laser diodes are 810 nm ($^4I_{15/2} \rightarrow {}^4I_{9/2}$), 980 nm ($^4I_{15/2} \rightarrow {}^4I_{11/2}$) and 1480 nm ($^4I_{15/2} \rightarrow {}^4I_{13/2}$). Other possible pump bands are around 660 nm ($^4I_{15/2} \rightarrow {}^4F_{9/2}$), 532 and 514.5 nm ($^4I_{15/2} \rightarrow {}^4H_{11/2}$). The pump wavelengths at 810 and 514.5 nm suffer from strong excited-state absorption, yielding a loss of pump photons [11.617]. The gain coefficient of Er-doped fibers is rather high (11 dB/mW [11.618]) due to the fairly high peak emission cross section of $4–7 \times 10^{-21}$ and the long lifetime of the $^4I_{13/2}$ level (8–10 ms) in silica fibers, despite the three-level laser character causing ground-state absorption at this wavelength. Like in Er^{3+}-doped crystals and glasses, concentration quenching occurs. In order to enhance the absorption efficiency without increasing the Er^{3+} concentration and/or fiber length, Yb^{3+} codoping is used, especially when diode pumping between 900 and 1000 nm is used. The requirement for efficient operation is – as in the crystals and glasses – efficient energy transfer from the Yb^{3+} $^2F_{5/2}$ level to the Er^{3+} $^4I_{13/2}$ level (Fig. 11.62). In Table 11.20, some of the Er-fiber lasers around 1.55 μm are summarized. For a very detailed discussion of Er^{3+}-doped fiber lasers and amplifier see [11.619]. In summary, Er^{3+}-doped fiber lasers operating around 1.55 mm are extremely efficient. Output powers in the watt range are possible. Nowadays up to 100 W of output power are commercially available [11.620]. Most efficient pumping occurs at 1480 nm, here slope efficiencies close to the quantum limit of 95% are possible. Pumping at 980 nm is less efficient due to the higher quantum defect, however, at this wavelength highly efficient and reliable high-power laser diodes are available.

Other Near-Infrared Er^{3+} Lasers. Room-temperature laser oscillation in Er^{3+}-doped crystals in the near-infrared spectral range has also been observed at

Table 11.19 Overview of room-temperature Er^{3+}-doped laser operating around 1.6 μm on the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ and on the $^4S_{3/2} \rightarrow {}^4I_{9/2}$ transition

other wavelengths. In Yb^{3+}-codoped Er^{3+}:$YLiF_4$ an upconversion pumping scheme was realized for the $^4S_{3/2} \rightarrow {}^4I_{11/2}$ transition at 1234 nm, which allowed continuous-wave room-temperature Ti:sapphire- and diode-pumped laser oscillation [11.621, 622]. Under Ti:sapphire excitation around 966 nm output powers of 160 mW and slope efficiencies of up to 22% were obtained. Note, that without the Yb codoping, the output powers were an order of magnitude lower. Under diode laser pumping at 966 nm, Yb^{3+},Er^{3+}:$YLiF_4$ exhibited output powers of 80 mW and slope efficiencies of 7%.

For this transition Xe flashlamp excitation is also possible allowing room-temperature laser oscillation in $YLiF_4$ [11.663–665], $LuLiF_4$ [11.666] and $YAlO_3$ [11.667]. In $BaYb_2F_8$, the $^4F_{9/2} \rightarrow {}^4I_{13/2}$ transition at 1260 nm exhibited laser oscillation under pulsed Nd laser or Xe flashlamp excitation [11.668]. Laser oscillation on the $^4F_{9/2} \rightarrow {}^4I_{11/2}$ transition was obtained around 1.96 μm in $BaYb_2F_8$ [11.669–671] under pulsed Nd laser and Xe flashlamp excitation.

11.2.4 Mid-Infrared Lasers

Basics

The mid-infrared wavelength range ≈ 1.9–5.0 μm is of interest for a number of applications. Mid-infrared solid-state lasers serve as light sources for spectroscopy, e.g., in remote sensing of the atmosphere, as the frequencies of internal vibrational motion of many molecules can be found in this spectral region. Other applications include medicine, e.g., microsurgery and dentistry in the region of high water absorption around

Table 11.20 Overview over Er^{3+} and Yb^{3+}:Er^{3+}-doped silica fiber lasers. λ_{laser}: laser wavelength, λ_{pump}: pump wavelength, l_{fiber}: fiber length, P_{thr}: laser threshold, η: slope efficiency, P_{out}: output power, P_{pump}: pump power, Ref.: reference, (l): launched, (inc): incident, (abs): absorbed, NA: not available. 2.7–3 μm. Laser wavelengths near 2 μm are suitable for tissue welding and lithotripsy.

The first mid-infrared laser was operated in 1960, shortly after the invention of the laser itself. It was operated at 2.6 μm in a calcium fluoride crystal doped with trivalent uranium [11.691]. Pulsed excitation and cooling to low temperatures were typically required for novel laser transitions in the early years. Two years later, a Dy^{2+}-doped CaF_2 laser at 2.36 μm was also demonstrated in continuous-wave operation [11.692, 693]. Among the lasers based on trivalent rare-earth ions, the transitions near 2 μm in Tm^{3+} and Ho^{3+} were operated in $CaWO_4$ in 1962 [11.694, 695]. The first observation of coherent emission near 3 μm from erbium ions was reported in 1967 [11.696]. Since those early years, a large number of new host materials has been developed and various new laser transitions in the mid-infrared spectral region have been demonstrated (for a comprehensive overview of ion–host combinations, [11.697]). Around 1990, Tm^{3+}- and Ho^{3+}-doped solid-state laser systems in $Y_3Al_5O_{12}$ (YAG), $YLiF_4$ (YLF), YVO_4, and $Y_3Sc_2Ga_3O_{12}$ (YSGG) were shown to operate between 1.86 and 2.46 μm [11.698–701], and Er^{3+}-doped lasers in similar host systems cover the wavelength range of 2.66–2.94 μm. Short-pulse lasers at these wavelengths have been demonstrated [11.702, 703].

Nowadays, mid-infrared laser transitions ranging from 1.8 μm up to 7.2 μm [11.704] are known in divalent Dy, trivalent Tm, Ho, Er, Dy, Pr, Tb, and Nd, as well as in trivalent U. The current state of the art in solid-state lasers occurring in rare-earth ions such as Tm^{3+}, Ho^{3+}, Er^{3+} and others and their population mechanisms are discussed in this section on the basis of the spectroscopic properties of these ions. Continuous-wave fundamental-mode power levels ranging from a few mW near 4 μm up to ≈ 100 W near 2 μm have

been demonstrated in recent years. Power-scaling methods and their limitations, the possibilities to optimize the population mechanisms and increase the efficiencies of these lasers, as well as the prospects of future mid-infrared lasers in a number of rare-earth ions at transitions in the wavelength range beyond 3 μm and extending to 5 μm are described.

The aspects relevant to rare-earth-ion-doped mid-infrared solid-state lasers, such as the competition between radiative and multiphonon decay and the consequent choice of host materials for these wavelengths will be introduced next. The performance of the most important mid-infrared laser transitions in the wavelength range 2–3 μm will then be discussed in detail: Tm^{3+}-doped lasers at 1.9 and 2.3 μm, Ho^{3+}-doped lasers at 2.1 and 2.9 μm, Er^{3+}-doped lasers at 2.7–2.9 μm, and Dy^{3+}-doped lasers at 2.9–3.4 μm. At wavelengths beyond 3 μm, it becomes increasingly difficult to find suitable host materials for actively doped laser systems. This statement holds true for glass fibers in the same way as for crystalline materials. The prospects for future mid-infrared solid-state lasers in this wavelength range will be discussed at the end of the section.

Introductions to the fields of mid-infrared solid-state crystalline and fiber lasers can be found in [11.707] and [11.708], respectively.

Decay Mechanisms, Host Materials, and Thermal Issues

Here a few fundamental aspects of lasers are discussed with emphasis on their impact on mid-infrared solid-state lasers.

Radiative Versus Multiphonon Decay. The choice of host material for mid-infrared solid-state lasers involves a number of considerations. The maximum phonon energy is the most important aspect. The optical transparency range relates to both the size of the bandgap and also the infrared absorption cut-off, hence to the vibrational frequency ν of the anion–cation bonds of the material. For an ordered structure,

$$\nu = \left(\frac{1}{2\pi}\right)\sqrt{\frac{k}{M}}\,, \tag{11.88}$$

where $M = m_1 m_2/(m_1 + m_2)$ is the reduced mass for two bodies m_1 and m_2 vibrating with an elastic restoring force k. The relative cation–anion bond strength is intimated by the field strength Z/r^2, where Z is the valence state of the cation or anion and r is the ionic radius. Generally, materials composed of large anions and cations with low field strengths display high transparency in the mid-infrared spectral region.

Radiative decay of excited states is in competition with nonradiative multiphonon decay. The maximum phonon energy of the material sets the multiphonon relaxation rates, which influence the quantum efficiency. The rate constant of a multiphonon relaxation process decreases exponentially with the energy gap to the next lower-lying state and with the order of the process, i. e., the number of phonons required to bridge the energy gap [11.705, 709]. As an example, the multiphonon relaxation rates for the common fiber glasses as a function of the energy gap between energy levels are shown in Fig. 11.68.

The influence of multiphonon decay is stronger in oxides than in fluorides because of the smaller atomic mass m_2 of the anion and the larger elastic restoring force k (11.88), due to the stronger covalent bonds in oxides [11.706], both resulting in larger maximum phonon energies in oxides. Typically, nonradiative decay becomes dominant if five or fewer phonons are required to bridge the energy gap [11.710]. Since an energy gap of $\approx 3300\,\mathrm{cm}^{-1}$ corresponds to a transition wavelength of 3 μm, radiative decay prevails for phonon energies below $\approx 600\,\mathrm{cm}^{-1}$, which is roughly the maximum phonon energy of fluorides. Fluorides are, therefore, preferred over oxides as host materials for most mid-infrared laser transitions.

In the example of Fig. 11.69, dominant laser (solid lines) and multiphonon (dotted lines) transitions from

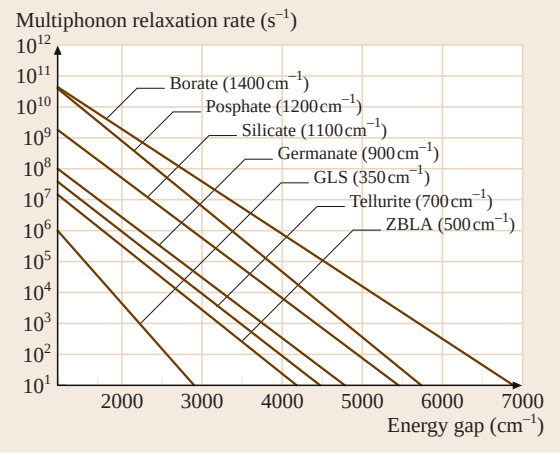

Fig. 11.68 Calculated and measured multiphonon relaxation rates as a function of the energy gap between energy levels for glasses with different maximum phonon energies. (After [11.705, 706])

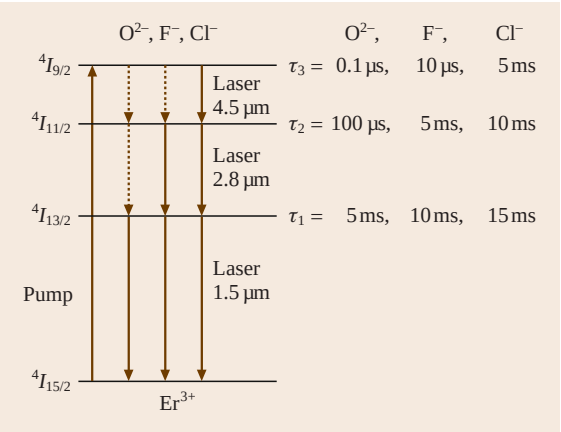

Fig. 11.69 Radiative and laser (*solid lines*) versus nonradiative (*dotted lines*) decay of the lowest three excited states of Er^{3+} in oxide, fluoride, and chloride host materials [11.710]

the three lowest-energy levels of Er^{3+} are indicated, together with the corresponding lifetimes of the levels in different classes of host materials. In high-phonon-energy oxide host materials, only the 1.5 µm laser transition possesses sufficiently high frequency and large energy gap, resulting in a long $^4I_{13/2}$ lifetime. On the other hand, the $^4I_{11/2}$ lifetime is significantly quenched by multiphonon relaxation and the 2.8 µm laser originating in this level is more easily operated in fluoride host materials. Finally, low-phonon host materials such as chlorides are required to ensure a long $^4I_{9/2}$ lifetime in order to operate the 4.5 µm laser.

Host Materials for Mid-Infrared Lasers. Crystalline oxide materials have been the laser host materials of choice for several decades, as many oxide crystals are comparatively easy to grow, environmentally stable, and possess high heat conductivities [11.711], fracture limits, and refractive indices, the latter resulting in large absorption and emission cross sections. Most prominent is $Y_3Al_5O_{12}$ (YAG), together with other garnets, but in recent years materials such as mixed garnets, the vanadates YVO_4 and $GdVO_4$, the double tungstates $KY(WO_4)_2$ and $KGd(WO_4)_2$, the sesquioxides Y_2O_3, Sc_2O_3, and Lu_2O_3 and others have shown great promise for efficient lasing when doped with various rare-earth ions. Their performance decreases significantly when lasers are operated at wavelengths above ≈ 2.5–3 µm because of their high maximum phonon energies (≈ 700–$900\,cm^{-1}$). Silicate glass is perhaps the most important material used for optical fiber production [11.706, 712], however, in this material the maximum phonon energy of $\approx 1100\,cm^{-1}$ [11.713] is even higher and has so far limited the emission wavelength of mid-infrared fiber lasers using this material to ≈ 2.2 µm [11.714]. Silica is robust and involves the very effective modified chemical vapor deposition (MCVD) technique for fiber fabrication. Reducing the OH^- content in the glass, which has two main absorption peaks in the range 1.3–2.0 µm [11.715], improves the near-to-mid-infrared utility. Rare-earth ions such as Nd^{3+} and Er^{3+} which have high field strengths have low solubility in silicate glass, which can lead to clustering and microscale phase separation.

The use of fluoride crystals and glasses as host materials for mid-infrared solid-state lasers has found wide acceptance. The heavy-metal fluorides [11.716, 717] are preferred as fiber materials, especially ZBLAN [11.718, 719], a mixture of 53 mol % ZrF_4, 20 mol % BaF_2, 4 mol % LaF_3, 3 mol % AlF_3, and 20 mol % NaF. Since it can be readily drawn into single-mode optical fiber [11.720] it is particularly important to mid-infrared fiber lasers [11.721]. The large atomic weight of the zirconium atom combined with relatively weak bonding provides a maximum phonon energy for ZBLAN of $\approx 550\,cm^{-1}$ [11.722] and allows for high infrared transparency up to ≈ 6 µm. Multiphonon relaxation, however, becomes significant for transitions at wavelengths longer than ≈ 3–3.5 µm. Compared to silica, ZBLAN has a lower damage threshold. The crystal field strength is also weaker [11.723]. An overview of the spectroscopic properties of rare-earth ions doped into ZBLAN is given in [11.722] and a summary of ZBLAN fiber lasers has recently appeared in [11.724]. On the crystalline side, the host materials $LiYF_4$, BaY_2F_8, and their respective isostructural relatives have become the workhorses for many mid-infrared laser transitions [11.725, 726]. Because of their fluoride content, these materials have to be grown under an atmosphere which excludes oxygen.

Among the low-phonon host materials, many compounds naturally possess low heat conductivity and are hygroscopic. This accounts for most of the halides, with increasing hygroscopicity from chloride to iodide. On the other hand, these materials provide phonon energies in the range of 350–150 cm^{-1} [11.727]. Recently, KPb_2Cl_5 and related compounds have emerged as non-hygroscopic, hence promising candidates for mid-infrared lasers [11.728–730]. Chalcogenide glasses are composed of the chalcogen elements S, Se and Te [11.731–733]. They are environmentally durable and have reasonably large glass-forming regions. When the

rare-earth ions are doped into these glasses [11.734], the radiative transition probabilities and, therefore, the absorption and emission cross sections are high as a result of the high refractive index (≈ 2.6) of the glass and the high degree of covalency of the rare-earth ion with the surrounding medium. Maximum phonon energies of $300-450\,\mathrm{cm}^{-1}$ [11.735] produce low rates of multiphonon relaxation (Fig. 11.68), and therefore high quantum efficiencies. The most important glasses are the sulfide glasses GaLaS (GLS) [11.736] and GeGaS [11.737] because of the reasonably high rare-earth solubility.

Studies into the use of ceramics as host materials for the rare-earths have recently made a lot of progress [11.738]. These ceramics are composed of nanocrystallites of materials such as YAG and can be produced in a simple cost-efficient process at relatively low temperatures. This allows the fabrication of materials with very high melting points [11.739] that are difficult to grow by other techniques such as the Czochralski method. This class of materials is also available in a fiber geometry [11.740]. Ceramic fibers combine the characteristics of crystalline materials such as high absorption and emission cross sections, large thermal conductivity, and even the possibility of doping with transition-metal ions [11.740] with the convenience of guiding the pump and signal light in a fiber. While bulk ceramics have already matured as laser host materials, the losses of ceramic fibers are still comparatively high.

Specific Aspects of Operating Mid-Infrared Lasers. As higher pump powers become available from laser-diode systems, it is generally recognized that thermal and thermo-optical issues set limitations to the power scalability of end-pumped bulk laser systems. Owing to the unfavorable temperature dependence of thermal and thermo-optical parameters [11.711], the large heat load in the crystal leads, firstly, to a significant temperature increase in the rod, secondly, to strong thermal lensing with pronounced spherical aberrations, and ultimately, to rod fracture in a high-average-power end-pumped system. Thermal management will be required when very high output powers are desired. In particular, for high-power mid-infrared operation, thermal management may be very important because of the decreased quantum efficiency and the consequently higher amount of heat dissipation [11.741].

Due to its geometry, the fiber provides potentially high pump and signal beam intensities without the drawbacks of significant thermal and thermo-optical effects. Its large surface-area-to-volume ratio means that the heat generated from multiphonon relaxation in the core is dissipated effectively by radiation and convection from the outer surface of the fiber. This is especially true for single-clad, core-pumped single-mode fibers where this ratio is highest [11.742]. The larger cladding area ($> 10^4\,\mu\mathrm{m}^2$) of double-clad fiber lasers allows for high-power diode-array pumping [11.418,743–746]. On the other hand, double-clad fibers have a smaller surface-area-to-volume ratio and thermal issues need to be taken into account [11.747–750].

While bulk crystalline mid-infrared lasers matured already during the 1990s, the high costs of fabricating fibers with sufficiently low losses in the mid-infrared region of the spectrum has impeded the necessary research efforts in the field of mid-infrared fiber lasers. However, with the introduction of the double-clad fiber and recent technological advances in the fields of fiber fabrication and beam-shaped high-power diode lasers, the performance of diode-pumped fiber lasers has dramatically improved. Today, mid-infrared fiber lasers can compete with the corresponding bulk crystalline systems in certain applications, especially when fundamental-transverse-mode, CW laser operation at output powers in the milliwatt to the hundred watt range is required.

A large number of techniques for pulsed operation including Q-switching and mode locking of fiber lasers have been explored. These techniques have been investigated intensively for the common laser transitions at $1\,\mu\mathrm{m}$ in Nd^{3+} and Yb^{3+}, and at $1.5\,\mu\mathrm{m}$ in Er^{3+}, and are usually described in combination with these lasers. The small fiber size limits the peak power through the damage-threshold intensity (propagating power per core area) and, hence, crystalline lasers in bulk geometries or optical parametric processes are often preferred when high-energy short pulses are needed. This argument accounts especially for mid-infrared ZBLAN-based fiber lasers, because these fibers possess a lower damage threshold compared to silica fibers. The description of mid-infrared fiber lasers is, therefore, confined to CW operation and specific techniques for pulsed operation of fiber lasers are not discussed in this chapter.

Thulium-Doped Solid-State Lasers at 1.9–2.0 µm and 2.3–2.5 µm

The use of the Tm^{3+} ion for mid-infrared solid-state laser applications has been widespread, partly as a result of the convenient absorption band near $0.79\,\mu\mathrm{m}$, which allows for direct AlGaAs diode-laser pumping. The primary luminescent transitions of Tm^{3+} relevant to mid-infrared laser emission are the ${}^3F_4 \rightarrow {}^3H_5$ transition at $\approx 2.3\,\mu\mathrm{m}$ and the ${}^3H_4 \rightarrow {}^3H_6$ ground-state

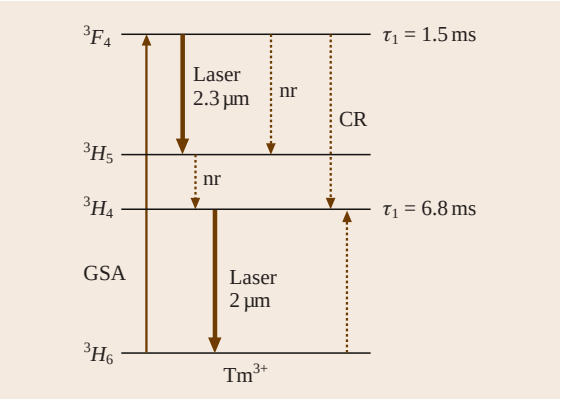

Fig. 11.70 Partial energy-level scheme of Tm^{3+} displaying the measured lifetimes when doped into fluoride glass [11.751], NR and CR represent nonradiative decay and cross-relaxation, respectively

transition at ≈ 1.9 μm; see the energy-level scheme in Fig. 11.70. The $^3F_4$ level is excited by the 0.79 μm pump wavelength.

Three-Level Lasers at 1.9–2.0 μm. The first laser emission from Tm^{3+} ions was reported on the phonon-terminated 2 μm transition $^3H_4 \rightarrow {}^3H_6$ in $CaWO_4$:Tm^{3+} in 1962 [11.694]. In 1975, pulsed operation at room temperature was demonstrated in Cr^{3+}-codoped YAG and $YAlO_3$ [11.752]. Cr^{3+} codoping allowed the experimentalist to improve the absorption of flashlamp or ion-laser pump light in the visible spectral range by the active medium and subsequent energy transfer from Cr^{3+} to the Tm^{3+} lasing ions [11.753, 754]. The cross-relaxation process $(^3F_4, {}^3H_6) \rightarrow (^3H_4, {}^3H_4)$ can transform one pump photon absorbed in the $^3F_4$ or a higher-lying energy level into two excitations in the $^3H_4$ upper laser level of the 2 μm transition [11.699, 755] (Fig. 11.70), thereby enhancing the quantum efficiency of this laser by a factor of 2. Laser emission under diode pumping of the $^3F_4$ level at 780–790 nm was achieved in YAG in the late 1980s [11.756]. A single-frequency monolithic laser has also been reported in YAG:Tm^{3+} [11.757].

Recently, 14 W, 18 W, and 36 W of output power with high beam quality has been achieved with diode pumping at room temperature in YAG:Tm^{3+} [11.758] and in $LiYF_4$:Tm^{3+} in slab [11.759] and bulk [11.760] geometries, respectively. The latter approach could be scaled to 70 W, however currently with low beam quality [11.761]. Two research groups reported about 115 W and 120 W, respectively, of multimode output power from diode-pumped YAG:Tm^{3+} lasers [11.762, 763]. A microchip laser was demonstrated in $GdVO_4$:Tm^{3+} [11.764]. A thin-disc laser has also been demonstrated in YAG [11.765]. In Lu_2O_3:Tm^{3+}, when pumping at 796 nm, a slope efficiency of 68% was obtained under Ti-sapphire pumping [11.766] and 75 W of output power were demonstrated under diode pumping [11.767].

The large degree of Stark splitting of the $^3H_6$ ground state, combined with vibronic broadening of the spectrum [11.768], provides the $^3H_4 \rightarrow {}^3H_6$ transition with a very broad emission, spanning ≈ 400 nm in many hosts, which represents one of the broadest luminescent transitions available from any rare-earth ion. Accordingly, its tunability is rather large, ranging from 1.87–2.16 μm in YAG [11.769], 1.84–2.14 μm in YSGG [11.769], 1.93–2.00 μm in $YAlO_3$ [11.770], 1.93–2.09 μm in Y_2O_3 [11.771], 1.93–2.16 μm in Sc_2O_3 [11.771], 1.92–2.12 μm in Lu_2O_3 [11.767], 1.83–1.97 μm in CaF_2 [11.772], 1.91–2.07 μm in $LiYF_4$ [11.759], 1.85–2.06 μm in BaY_2F_8 [11.773], 1.86–1.99 μm in $GdVO_4$ [11.774], 1.84–1.95 μm in $LuVO_4$ [11.775], 1.79–2.04 μm in $KGd(WO_4)_2$ [11.776], and 1.81–2.03 μm in $NaGd(WO_4)_2$ [11.777]. As for many other transitions, shifts in the center emission wavelength can be achieved by substitution of host ions, e.g., from $Y_3Al_5O_{12}$ to $Lu_3Al_5O_{12}$ [11.778]. The vanadate crystals $GdVO_4$ and YVO_4 as well as double tungstates possess comparatively high absorption coefficients [11.764, 779, 780], allowing pumping also at 805–810 nm, where cheaper and more-reliable pump diodes than at 780–790 nm are available. Exploiting the large gain bandwidth, mode-locked operation of Tm^{3+} 2 μm lasers with pulse durations of 35 ps and 41 ps has been reported in YAG:Tm^{3+} [11.781] and YAG:Cr^{3+},Tm^{3+} [11.782], respectively. Actively [11.783, 784] or passively [11.785] Q-switched laser operation is useful in microsurgery [11.786].

Recent progress in the fields of crystalline epitaxial growth and in-bulk refractive-index modification processes in glasses and crystals has enabled novel solid-state lasers in the waveguide geometry [11.787]. The first 2 μm dielectric waveguide laser was demonstrated in a thulium-doped lead-germanate glass [11.788]. Planar waveguide lasers with slope efficiencies up to 68% [11.789] and to 15 W of output power under high-power diode side pumping [11.790] were operated in YAG:Tm^{3+}. The first $KY(WO_4)_2$ planar waveguide laser [11.791] did not show a performance as good as for the same material in bulk geometry [11.792] or in a waveguide geometry but doped with Yb^{3+} and las-

ing at 1 μm [11.793] which delivered slope efficiencies of 69 and 80%, respectively. Channel waveguide geometries provide better control over the beam shape, as well as better confinement and overlap of the pump and laser modes in the doped region. Tm^{3+}-doped channel waveguide lasers were demonstrated in oxides [11.794] and glasses [11.795], but the output powers and slope efficiencies were inferior. In Tm^{3+}-doped $KY(WO_4)_2$, via improved refractive-index contrast by co-doping the epitaxial layer with optically inert Gd^{3+} and Lu^{3+} ions [11.796] and micro-structuring by Ar^+ beam milling [11.797] channel waveguide lasers were demonstrated with slope efficiencies of 13% [11.798] and 31.5% [11.799]. By increasing the Tm concentration to 8%, thereby efficiently exploiting the cross-relaxation process and generating close to two excitations in the upper laser level for each absorbed pump photon, slope efficiencies up to 70% and output powers up to 300 mW have recently been demonstrated [11.800]. A channel waveguide inscribed by femtosecond-laser writing into Tm^{3+}-doped ZBLAN bulk glass produced lasing with a slope efficiency of 50% [11.801]. Epitaxial layers of $Tm:KLu(WO_4)_2/KLu(WO_4)_2$ have also been operated with the laser cavity perpendicular to the layer in the 2 μm spectral range [11.802].

The first explorations into fiber lasers utilizing the 1.9 μm ground-state transition related to the dye-laser pumping at 797 nm of a Tm^{3+}-doped silica fiber laser [11.803]. Overlap of the main absorption band with the emission wavelength of AlGaAs diode lasers quickly resulted in diode-laser pumping of these fiber lasers based on either silica [11.804] or fluoride [11.805] glass hosts. The cross-relaxation process $(^3F_4, {}^3H_6) \rightarrow ({}^3H_4, {}^3H_4)$ and enhancement of excited ions in the $^3H_4$ upper laser level of the 2 μm transition (Fig. 11.70), is highly dependent on the overall concentration of Tm^{3+} ions and competition from multiphonon relaxation from the $^3F_4$ level. Although generally high concentrations of Tm^{3+} in low-phonon-energy glasses enable full exploitation of this beneficial process, that this cross-relaxation process is resonant in a silica host and hence only moderate (2–3 wt %) Tm^{3+}-ion concentrations are required to utilize the cross-relaxation [11.806]. Nevertheless, according to a recent study, for moderate pump powers the output power and efficiency under 800 nm pumping appear to be higher in fluoride than in silica fibers [11.807].

Also in fibers, the broad emission spectrum allows a large degree of wavelength tunability [11.808]. Recently, tuning ranges of 230 nm from 1.86–2.09 μm [11.809] and 250 nm from 1.72–1.97 μm [11.810] have been demonstrated. Since its higher peak-power damage threshold compared to ZBLAN fiber favors silica fiber for pulsed operation of the Tm^{3+} 1.9 μm transition, pulses in the range of 190–500 fs have been obtained in additive-pulse [11.811] or passive [11.812] mode-locking arrangements using this broad emission spectrum. Mode-locking with high average power of nearly 12 W, pulse durations of < 40 ps, and pulse energies of > 300 nJ has recently been reported [11.813]. The smaller emission cross section and the three-level nature of the laser transition resulted in higher pump thresholds compared to standard Nd^{3+}-doped silica fiber lasers. Reabsorption from the ground state of the Tm^{3+} ion has to be overcome because the ground-state multiplet is the lower laser level. Reducing the population of the higher Stark levels of the ground state by cooling the fiber causes emission at shorter wavelengths. Tunability to longer wavelengths can be obtained by variation of the fiber length because of the increased level of reabsorption by the ground state with longer lengths of fiber [11.814]. Passive Q-switching of a diode-pumped double-clad Tm^{3+}-doped silica fiber has been demonstrated with a Ho^{3+}-fiber saturable absorber [11.815]. In an actively Q-switched fluoride fiber, 90 μJ pulse energy from 160 ns pulses with 100 kHz repetition rate, resulting in 9 W of average output power, have been obtained [11.816]. The same technique applied to silica fiber provided 270 μJ, 41 ns pulses with 30 W of average power [11.817].

Early power-scaling experiments involved the use of the convenient 1.064 μm YAG:Nd^{3+} laser which core-pumped the short-wavelength side of the $^3H_5$ level [11.818]. Pumping the long-wavelength side of the $^3H_5$ level with a high-power 1.319 μm YAG:Nd^{3+} laser also yielded efficient output [11.819]. Also diode pumping at 1150 nm has been investigated [11.820]. In-band pumping of the transition at 1.57 μm in silica [11.821] and at 1.58–1.60 μm in fluoride glass [11.822, 823] has also been demonstrated. Whilst theoretical modeling of Tm^{3+}-doped silica fiber lasers [11.824] indicates that in-band pumping is the most efficient pump method for silica-based fiber lasers because of the high Stokes efficiency, nevertheless, the wide availability of high-power AlGaAs diode lasers at 790–800 nm and the strong level of cross-relaxation in Tm^{3+}-doped silica means that such diode-cladding-pumped systems in both standing-wave [11.814, 825] and ring-resonator [11.826] arrangements are perhaps the most practical ways of producing high output power from this ion (Fig. 11.71). With Yb^{3+} sensitization and pumping at 975 nm, 75 W of output power has been demonstrated [11.827]. The max-

imum output power from a Tm^{3+}-doped silica fiber laser is now ≈ 85 W [11.825]. Recently, 64 W of output power with a slope efficiency of 68%, equivalent to a quantum efficiency of 1.8, and an output power of 104 W, albeit with lower efficiency, has been demonstrated in a Tm^{3+}-doped germanate fiber pumped at 800 nm [11.828]. In-band Er^{3+}-fiber-laser-pumped, narrow-linewidth distributed-feedback laser operation has been obtained in a Tm^{3+}-doped, photosensitive alumino-silicate fiber [11.829] and power amplification to 100 W of single-frequency output power has been demonstrated [11.830]. In a distributed-Bragg-reflector cavity, mode-hop-free single-frequency operation has been demonstrated [11.831]. Finally, also Raman conversion of Tm^{3+}-fiber laser power of nearly 10 W at 1940 nm to 580 mW at 2185 nm in a fluoride fiber has been reported [11.832].

Four-Level Lasers at 2.3–2.5 μm. The mid-infrared four-level CW laser at ≈ 2.3 μm on the transition $^3F_4 \rightarrow {}^3H_5$ has been operated in GSGG:Tm^{3+} and $LiYF_4$:Tm^{3+}, with wavelength tunability ranging from 2.2–2.37 μm [11.835] and 2.2–2.46 μm [11.836], respectively. This laser operates best at low Tm^{3+} concentrations of < 2 at. % in order to avoid the aforementioned cross-relaxation, which in this case would depopulate the upper laser level (Fig. 11.70). The lifetime of the lower laser level of the $^3F_4 \rightarrow {}^3H_5$ transition is quite short and leads to a low pump threshold.

Doping Tm^{3+} ions into a ZBLAN fiber offers an increased quantum efficiency of the $^3F_4$ level [11.837–839]. Deliberately designing the fiber to have a relatively low Tm^{3+}-ion concentration reduces cross-relaxation and hence severe lifetime quenching of the $^3F_4$ level. The tunability extends from 2.25 μm to 2.5 μm [11.751]. Simultaneous lasing on the $^3H_4 \rightarrow {}^3H_6$ transition at 1.9 μm produces a two-color fiber laser [11.840]. Applications requiring highly efficient output or multi-mid-infrared-wavelength output will benefit from the use of Tm^{3+}-doped ZBLAN fibers.

Holmium-Doped Solid-State Lasers at 2.1 μm and 2.9 μm

The use of the Ho^{3+} ion as the active dopant for solid-state lasers opens up a number of very useful mid-infrared transitions. In this section, we will concentrate on the $^5I_7 \rightarrow {}^5I_8$ ground-state transition at ≈ 2.1 μm and the $^5I_6 \rightarrow {}^5I_7$ transition at ≈ 2.9 μm; see the energy-level scheme in Fig. 11.72. One of the significant shortcomings of Ho^{3+}, however, is the lack of ground-state-absorption (GSA) transitions [11.841] that

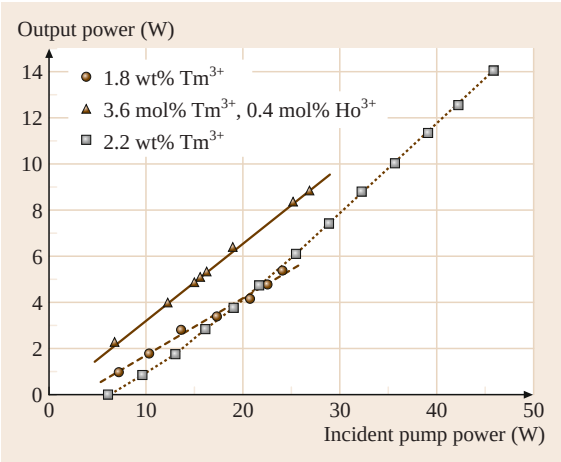

Fig. 11.71 Measured output powers from diode-cladding-pumped fiber lasers using 1.8 wt % Tm^{3+}-doped silica [11.812], 2.2 wt % Tm^{3+}-doped silica [11.833], and 3.6 mol % Tm^{3+}, 0.4 mol % Ho^{3+}-doped fluoride glass [11.834]

overlap with convenient high-power pump sources. As a result, many of the early demonstrations of Ho^{3+}-doped room-temperature crystalline CW lasers [11.699] involved sensitizing with Tm^{3+} in order to access the convenient absorption bands and the practical cross-relaxation process Tm^{3+} provides, as we have discussed in Sect. 11.3.1. Energy migration amongst the Tm^{3+} ions and a suitable Tm^{3+}:Ho^{3+} concentration ratio ensures that efficient energy transfer to Ho^{3+} takes place [11.842, 843] (Fig. 11.72).

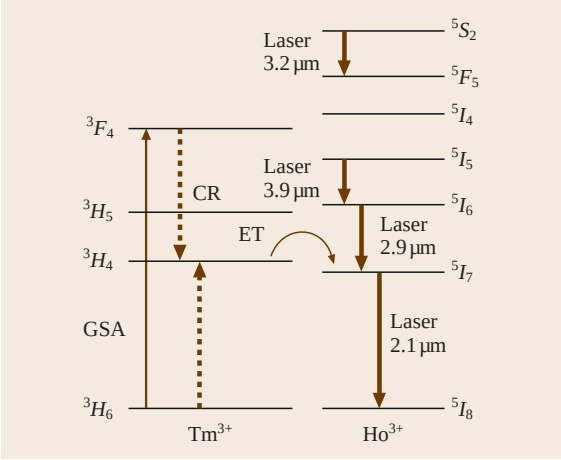

Fig. 11.72 Partial energy-level scheme of Ho^{3+} with a Tm^{3+} sensitizer. ET represents energy transfer

Three-Level Lasers at 2.1 μm. The 2 μm transition $^5I_7 \rightarrow {}^5I_8$ in Ho^{3+} ions was first demonstrated as a laser in $CaWO_4$:Ho^{3+} in 1962 [11.695] and in Tm^{3+}-codoped $CaWO_4$:Ho^{3+} in 1963 [11.844]. In 1971, pulsed operation at room temperature on this three-level laser transition was demonstrated in $LiYF_4$ [11.845]. CW laser emission was achieved under Kr^+-laser pumping in Cr^{3+},Tm^{3+}-codoped YSAG:Ho^{3+} and YSGG:Ho^{3+} in 1986 [11.846]. Like in 2 μm Tm^{3+} lasers (Sect. 11.3.1), the Cr^{3+} codopant served as a sensitizer for the absorption of pump light in the visible spectral range and excitation of Tm^{3+} ions by energy transfer. The subsequent excitation of Ho^{3+} ions by energy transfer from Tm^{3+} [11.847, 848] profits from the same Tm^{3+}-Tm^{3+} cross-relaxation as described for 2 μm Tm^{3+} lasers in Sect. 11.3.1 (Fig. 11.72). In the 1980s, laser emission at 2.1 μm in Ho^{3+} under diode pumping of the Tm^{3+} $^3F_4$ level at 780–790 nm with pump thresholds as low as 5 mW was achieved in YAG [11.849–851]. Compact, monolithic, low-threshold laser devices can be achieved in this way [11.852]. Besides many different garnet crystal systems, $LiYF_4$ also regained interest as a host material for CW diode-pumped 2 μm Ho^{3+} lasers around 1990 [11.853, 854]. An Yb^{3+}-codoped, diode-pumped Ho^{3+} laser at 2.1 μm has also been demonstrated [11.855]. Noise suppression [11.856, 857], amplitude and frequency stabilization [11.858–860] of 2 μm Ho^{3+} lasers have been investigated.

Attempts to exploit the rather large gain bandwidth of Ho^{3+} near 2.0–2.1 μm by tuning the emission wavelength were reported in the early 1990s [11.861, 862]. Nowadays, tuning ranges of > 80 nm are achieved in host materials such as mixed YSGG:GSAG [11.863], BaY_2F_8:Ho^{3+} [11.864], and KYF_4 [11.865]. Mode-locking experiments have resulted in 800 ps, 370 ps, and 70 ps pulse durations, obtained in YAG:Cr^{3+},Tm^{3+},Ho^{3+} [11.782], $LiYF_4$:Tm^{3+},Ho^{3+} [11.866], and BaY_2F_8:Tm^{3+},Ho^{3+} [11.867], respectively. In mixed crystals of YSGG:GSAG:Cr^{3+},Tm^{3+},Ho^{3+}, which provide an inhomogeneously broadened, and therefore smoother, gain shape, a pulse duration as short as 25 ps could be achieved [11.863]. Q-switched laser operation [11.868–870] has been investigated and applied for microsurgery [11.871].

Besides the cross-relaxation and energy-transfer processes shown in Fig. 11.72, several other energy-transfer processes can occur in Tm^{3+},Ho^{3+}-codoped materials [11.872–876], thereby making the system rather complex and introducing parasitic processes which can deplete the Ho^{3+} $^5I_7$ upper laser level, increase the laser threshold, and diminish the laser efficiency. Rather than codoping the host with Tm^{3+} ions and exciting the Ho^{3+} ions via nonradiative energy transfer from the Tm^{3+} ions, one can directly pump the Ho^{3+} $^5I_7$ upper laser level at 1.9 μm using laser diodes [11.877], the output from a 1.9 μm Tm^{3+} laser [11.878], which provided up to 15 W [11.879] and 19 W [11.760] output power from Ho^{3+}, or a MgF_2:Co laser [11.880]. This approach ensures a low quantum defect and, hence, low heat generation in the laser crystal. This scheme was proven very successful by the use of a high-power Tm^{3+} fiber laser as the pump source, providing 6.4 W of output power and a slope efficiency of 80% versus incident pump power at 1.9 μm [11.881]. Also an efficient 2 μm Ho^{3+} single-frequency ring laser has been demonstrated in this way [11.882]. Recently, intracavity side pumping of a YAG:Ho^{3+} crystal by a Tm^{3+}-doped slab laser has resulted in a compact laser with 14 W of output power [11.883], and 5.1 W of output power with 70% slope efficiency have been obtained from a Tm^{3+} in-band-pumped $LuLiF_4$:Ho^{3+} laser [11.884]. In-band pumping directly by a GaSb-based laser diode resulted in 15 W of output power from a Lu_2O_3:Ho^{3+} crystal [11.885] and 55 W of output power with a slope efficiency of 62% and narrow-linewidth operation with 18 W of output power from a YAG:Ho^{3+} crystal [11.886].

The first fiber laser configuration making use of this transition employed ZBLANP glass (a variant of ZBLAN) and argon-ion pumping [11.887]. A year later, this was followed by the demonstration of an argon-ion-pumped Ho^{3+}-doped silica fiber laser [11.888]. In both cases, the fiber was singly doped with Ho^{3+}, the output power < 1 mW, and each needed a relatively high pump power to reach laser threshold. Improvements in the output power and efficiency have been made recently with Yb^{3+}-doped silica fiber laser pumping of the $^5I_6$ level [11.889]; however, the output power had only increased to 280 mW because the pump fiber laser was operated at the low-efficiency 1150 nm wavelength. Using the pump wavelength of 1100 nm, which is more optimal with respect to the operation of an Yb^{3+}-doped silica fiber laser, the output power has been increased by approximately an order of magnitude to 2.7 W [11.890]. Diode-cladding pumping at 1150 nm of a Ho^{3+}-doped silica fiber delivered an output power of 2.2 W and a slope efficiency of 51% [11.891].

As mentioned above, a practical method of efficiently generating laser emission on the $^5I_7 \rightarrow {}^5I_8$ transition is to codope Ho^{3+} laser ions with Tm^{3+} sensitizer ions. The first demonstration of a fiber laser

operating with the Tm^{3+},Ho^{3+} system occurred in 1991 [11.892] when 250 mW was generated at a slope efficiency of 52% from a Ti:sapphire-pumped fluoride fiber laser. A year later [11.893], this work was followed by an increase in the Tm^{3+} concentration to improve cross-relaxation and resulted in a higher slope efficiency being obtained. Demonstration of a Tm^{3+},Ho^{3+}-doped silica fiber laser soon followed [11.894, 895]; however, owing to lower Tm^{3+} concentrations which forces weaker cross-relaxation, significantly lower slope efficiencies were measured, especially when pumped at 1.064 μm [11.896]. When the concentrations are increased and the double-clad pump arrangement used, a significant augmentation of the output power to 5.4 W has been demonstrated [11.897]. An output power of 8.8 W from a fiber laser operating on the $^5I_7 \rightarrow {}^5I_8$ transition was produced by a diode-cladding-pumped Tm^{3+},Ho^{3+}-doped fluoride fiber laser [11.834] (Fig. 11.71). To date, the highest output power at 2.1 μm of 83 W has been achieved in a Tm^{3+},Ho^{3+} co-doped silica fiber diode-cladding pumped bi-directionally at 793 nm [11.898]. The slope efficiency was 42%. Narrow-band operation with tuning over 280 nm was demonstrated in an aluminosilicate fiber with output power up to 6.8 W [11.899]. Passive Q-switching in a core-pumped silica fiber delivered 20 ns pulses at a repetition rate of 57 kHz and a pulse energy of 15 μJ [11.900]. Active Q-switching of a double-clad diode-pumped silica fiber laser resulted in 12.3 W of average output power at 2072 nm with pulses as short as 45 nm [11.901]. In an analogous way to recent demonstrations in bulk laser systems, tandem-pumping Ho^{3+} with a separate Tm^{3+} laser operating at 1.9 μm also proves effective in fibers, because it similarly exploits the cross-relaxation process between Tm^{3+} ions but avoids any ETU between Ho^{3+} ions in the $^5I_7$ upper laser level and excited Tm^{3+} ions [11.876]. An output power of 6.7 W from an in-band-pumped Ho^{3+}-doped fluoride fiber laser was reported [11.902]. Using a gain-switched Tm^{3+} fiber laser as the pump source generated output pulse energies of 3.2 μJ at 80 kHz repetition rate [11.903]. In a double-core geometry, an outer-Tm^{3+}-core laser that absorbed the diode pump light pumped the inner Ho^{3+} core resonantly, exhibiting pulsed output behavior [11.904]. Alternatively, in-band diode pumping at 1.94 μm of a Ho^{3+}-doped fluoride fiber lased with 78% slope efficiency [11.905]. When sensitizing with Yb^{3+} ions, a Ho^{3+}-doped silica fiber laser at 2.1 μm has been shown [11.906] to operate at moderate efficiency levels despite the fact that the energy transfer from Yb^{3+} to Ho^{3+} is quite nonresonant (Fig. 11.73).

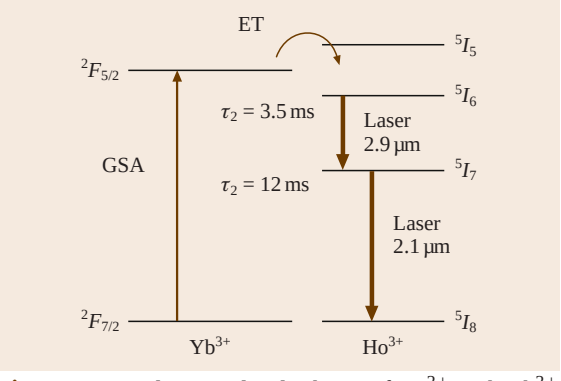

Fig. 11.73 Partial energy-level scheme of Ho^{3+} with Yb^{3+} sensitizer displaying the measured lifetimes of Ho^{3+} when doped into fluoride glass host [11.907]

Four-Level Lasers at 2.9 μm. Laser emission at the transition $^5I_6 \rightarrow {}^5I_7$ near 3 μm in an Ho^{3+}-doped crystal was demonstrated in 1976 [11.908]. Sensitizing Ho^{3+} with Yb^{3+} ions (see the energy-level scheme in Fig. 11.73) in order to exploit the more-favorable absorption features of Yb^{3+} has been used in diode-pumped crystalline lasers for the generation of 2.9 μm output [11.909]. Recent reports on this transition include laser investigations of $YAlO_3$:Ho^{3+} [11.910], diode-pumped Yb^{3+}-codoped YGSS:Ho^{3+} with 10 mJ output energy [11.911], and Cr^{3+},Yb^{3+}-codoped YGSS:Ho^{3+} tunable in the range 2.84–3.05 μm [11.912] and in Q-switched operation [11.913]. Since the $^5I_7$ lower laser level is a metastable excited state with a longer lifetime than the $^5I_6$ upper laser level, it is difficult to achieve CW inversion on this transition. Cascade lasing on the $^5I_6 \rightarrow {}^5I_7$ and $^5I_7 \rightarrow {}^5I_8$ transitions at 3 and 2 μm, respectively [11.914, 915], may help to deplete the $^5I_7$ level radiatively, i. e., without significant heat generation. Passive Q-switching of this transition has also been demonstrated [11.913].

The combined effect of the infrared absorption cut-off wavelength of ≈ 2.5 μm for pure silica glass and the strong multiphonon relaxation quenching of mid-infrared transitions of rare-earth ions in this host means that four-level fiber lasers operating on the $^5I_6 \rightarrow {}^5I_7$ transition at ≈ 2.9 μm have only involved fluoride glass as the host material. The first demonstration of a fiber laser using this transition [11.916] produced only ≈ 13 mW when pumped at a wavelength of 640 nm. High-power cascade lasing at 2.9 μm and

2.1 μm has been employed to extend the output power to 1.3 W [11.917] by removing bottlenecking at the $^5I_7$ level [11.907] via the second laser transition at 2.1 μm. Also diode-cladding pumping of this laser cascade was achieved [11.918].

In an analogous manner to the Er^{3+}-doped fluoride glass system discussed below, the most successful arrangement to date for extracting high power from this transition has involved the use of Pr^{3+} as a desensitizer for the $^5I_7$ energy level: a maximum output power of 2.5 W was produced when the pump wavelength of 1100 nm from a Yb^{3+}-doped silica fiber laser was used [11.920]. Similar output power was obtained by diode-cladding pumping at 1150 nm [11.921]. Also narrow-linewidth operation and tuning between 2825 and 2900 nm was demonstrated [11.922].

An Yb^{3+}-sensitized Ho^{3+}-doped ZBLAN fiber could be directly pumped with diode lasers and may efficiently provide high-power 2.9 μm output without the costly requirement of an intermediate laser system. Initial spectroscopic results look encouraging [11.923], however, the many excited ion interactions that a fluoride host provides may be problematic. A recent demonstration has shown that ion–ion interactions (specifically ETU) in Ho^{3+}-doped fluoride glass are critical to the production of 2.9 μm output from singly Ho^{3+}-doped fluoride glass fiber lasers [11.924].

(After [11.919])

Erbium-Doped Solid-State Lasers at 2.7–2.9 μm

For a long time, the development of erbium lasers operating on the $^4I_{11/2} \rightarrow {}^4I_{13/2}$ transition near 3 μm was dominated by crystalline systems. The early success of the erbium 3 μm crystal laser has given rise to a significant amount of spectroscopic investigations. This has led to a deep understanding of the rather complex population mechanisms of this laser system and to the development of a large number of suitable host materials.

Crystalline Lasers. The first observation of coherent emission near 3 μm from erbium ions was reported in 1967 [11.696]. Yttrium aluminum garnet (YAG) was demonstrated as a host for the erbium 3 μm laser [11.925] in 1975. In 1983, the first CW lasing near 3 μm was obtained in this material [11.926]. At about the same time, it was established [11.927–930] that energy transfer processes [11.931] between neighboring erbium ions in the host lattice play an important role in this laser system. Energy transfer processes can become very efficient at high excitation density [11.932] and govern the population mechanisms of the 3 μm laser at high erbium concentration. In the energy-level scheme of Fig. 11.74a, the important ETU and cross-relaxation processes are introduced. The ETU process $(^4I_{13/2}, {}^4I_{13/2}) \rightarrow (^4I_{15/2}, {}^4I_{9/2})$ leads to a fast depletion of the lower laser level and enables CW operation of a laser transition which, otherwise, could be self-terminating owing to the unfavorable lifetime ratio of the upper compared to the lower laser level. The ETU process from $^4I_{13/2}$ can be so dominant that even under direct pumping of the $^4I_{13/2}$ lower laser level and subsequent excitation of the $^4I_{11/2}$ upper laser level by ETU, 3 μm laser operation was demonstrated in several host materials [11.933].

This ETU process offers another great advantage. Half of the ions that undergo this process are upconverted to the $^4I_{9/2}$ level and, by subsequent multiphonon relaxation, are recycled to the $^4I_{11/2}$ upper laser level from where they can each emit a second laser photon, for a single pump-photon absorption. For a large number of ions participating in this process, a slope efficiency η_{sl} of twice the Stokes efficiency $\eta_{St} = \lambda_{pump}/\lambda_{laser}$ is obtained [11.934], because the quantum efficiency $\eta_{QE} = n_{laser}/n_{pump}$ of pump photons converted to laser photons increases from 1 to 2 (λ

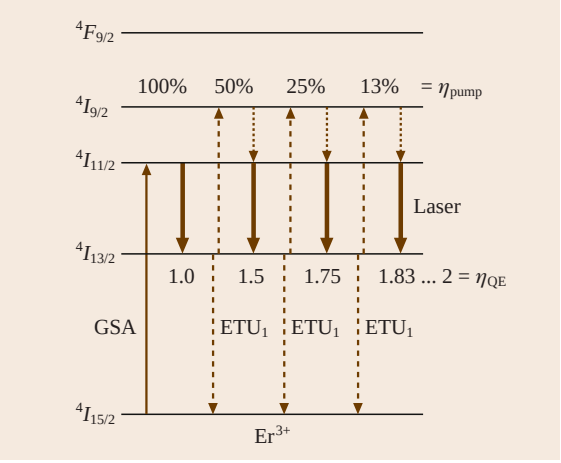

Fig. 11.75 Partial energy-level scheme of erbium illustrating the process of energy recycling from the lower to the upper laser level by ETU. Indicated are the relative pump rate η_p of the upper laser level and the quantum efficiency η_{QE} which increases from 1 to 2 if a large number of ions participate in the process. (After [11.935])

and n are the wavelengths and photon numbers of laser and pump transitions, respectively)

$$\eta_{sl} = \eta_{QE}\eta_{St} = 2\eta_{St} \,. \tag{11.89}$$

This is illustrated in Fig. 11.75.

In a simple rate-equation system which includes the processes shown in Fig. 11.74a the slope efficiency is given by [11.934]

$$\eta_{sl} = \eta_{St}\frac{\ln(1-T)}{\ln[(1-T)(1-L)]}\left(2 - \frac{b_1^2}{b_2^2}\frac{W_{22}}{W_{11}}\right) , \tag{11.90}$$

with T the transmission of the out-coupling mirror, L the internal resonator losses, and b_i and W_{ii}, the Boltzmann factors and ETU parameters of the upper ($i = 2$) and lower ($i = 1$) laser levels, respectively. If ETU occurs only from the lower laser level, i. e., $W_{22} = 0$, we obtain the predicted factor of two increase in slope efficiency from (11.90). The slope efficiency is reduced, however, by the resonator losses, the imperfect mode overlap, and the ETU process from the upper laser level in the case of $W_{22} > 0$. In the investigated host materials, the parameters W_{ii} of both ETU processes increase with increasing erbium concentration because of the influence of energy migration within the erbium $^4I_{11/2}$ and $^4I_{13/2}$ levels on ETU. The slope efficiency of (11.90) is optimum for a maximum ratio W_1/W_2. Spectroscopy of these processes in crystal hosts and laser experiments revealed that the maximum ratio is obtained at dopant concentrations of $\approx 12-15\%$ in BaY_2F_8 [11.936, 937], $\approx 15\%$ in $LiYF_4$ [11.726], $\approx 30\%$ in YSGG [11.938], and $\approx 50\%$ in $Y_3Al_5O_{12}$ [11.939]. A trend in this series is the increase of the optimum erbium concentration with phonon energy of the host material.

Energy recycling by ETU is the most efficient way to operate a CW erbium laser near 3 µm. The highest slope efficiency obtained experimentally is currently 50% in $LiYF_4$:15% Er^{3+} [11.940]. The pump wavelength that provides the highest Stokes efficiency of $\eta_{St} = \lambda_{pump}/\lambda_{laser} = 35\%$ is 980 nm, which corresponds to pumping directly into the upper laser level [11.941] (Fig. 11.74a). The highest slope efficiency obtained experimentally [11.940] is currently $\eta_{sl} = 50\%$ in $LiYF_4$:15% Er^{3+}. This result shows that energy recycling is indeed efficient and that slope efficiencies far above the Stokes efficiency can be obtained under CW pumping. Under quasi-CW excitation, the slope efficiency is strongly reduced [11.942], because the lower laser level is much less populated than in the steady-state regime and ETU is less efficient [11.943, 944]. Other operational regimes which deplete the lower laser level without recycling the energy to the upper laser level are less efficient. Consequently, neither colasing at the 1.6 µm transition from the lower laser level to the ground state [11.945] nor energy transfer from the erbium lower laser level to a rare-earth codopant [11.725] have reached the efficiency of the recycling regime.

Lifetime quenching of the $^4I_{11/2}$ upper laser level by multiphonon relaxation is stronger in oxide compared to fluoride host materials because of the larger maximum phonon energies in oxides. With an energy gap between the $^4I_{11/2}$ upper and $^4I_{13/2}$ lower laser levels of $\approx 3400-3500\,cm^{-1}$, the radiative decay becomes dominant for phonon energies below $\approx 550\,cm^{-1}$. Since a long lifetime of the $^4I_{11/2}$ upper laser level provides a small pump threshold, fluorides are preferable host materials [11.946] for this laser transition if the pump power is not many times above threshold.

In the 1980s and 1990s, numerous host materials were investigated for CW and pulsed laser operation of Er^{3+} in the 2.7–2.9 µm region. A major role was played by the family of garnet crystals YAG, YSGG, YSAG, YGG, and GGG [11.698, 947, 948]. In the early years, Cr^{3+} codoping was used in order to improve the absorption of broadband flashlamp pump light in the visible spectral range and transfer the absorbed energy from Cr^{3+} to Er^{3+}. Typical output characteristics obtained

were 2.7 W average power at a pump energy of 5 J with a repetition rate of 10 Hz [11.948]. Doping levels up to 100% substitution of Y^{3+} by Er^{3+} were tested [11.949]. A new class of host materials, fluoride crystals such as $LiYF_4$, BaY_2F_8, and others, became of importance in the late 1980s [11.950–953]. Laser thresholds as low as 5 mW were obtained under CW excitation by diode lasers [11.952].

In recent years, researchers have obtained CW and quasi-CW diode-pumped output power levels exceeding 1 W at 3 μm from fluoride [11.726] and oxide [11.954–956] crystalline host materials. A significant problem in the energy-recycling regime is increased heat generation due to the multiphonon relaxation $^4I_{9/2} \rightarrow {}^4I_{11/2}$ that follows each ETU process from the lower laser level [11.741]. Glass bulk materials [11.957] suffer from the same thermal and thermo-optical drawbacks as the crystalline bulk materials, with even decreased thermal conductivity in the glass. A possible solution is diode side pumping, which leads to lower excitation densities and correspondingly weaker ETU processes, as well as better heat removal in the slab geometry. High output powers of 1.8 W and later 4 W from an erbium 3 μm crystal laser [11.958, 959] have been obtained in this way. A reduced erbium concentration with correspondingly smaller parameters of the ETU processes may aid this approach. The highest output power reported to date for a crystalline Er^{3+} laser operating in the 3-μm wavelength range is 14 W in a Y_2O_3 ceramic sample, with 26% slope efficiency [11.960].

Other special configurations include the operation of Er^{3+}-doped YAG, GGG, and YSGG lasers in monolithic cavities with output powers up to 0.5 W and tunable single-frequency output [11.961] as well as microlasers in YSGG [11.962]. Pulsed output at 3 μm has been generated from erbium-doped crystalline materials in many configurations and regimes, e.g., under quasi-CW pumping [11.942, 944], active [11.963–972] and passive [11.973–976] Q-switching, and mode-locking [11.702, 973, 977].

Fiber Lasers. The erbium-doped fluoride fiber represents a promising alternative for the construction of a compact and efficient all-solid-state laser emitting at the transition at 3 μm. Due to its geometry, the fiber provides large flexibility and potentially high pump and signal beam intensities without the drawbacks of thermal and thermo-optical effects. The first erbium 3 μm fiber laser was demonstrated in 1988 [11.978]. Single-mode [11.979] and diode-pumped [11.980] operation were demonstrated shortly afterwards. Although the lifetime of the $^4I_{13/2}$ lower laser level exceeds that of the $^4I_{11/2}$ upper laser level, CW lasing can be obtained on this four-level-laser transition in ZBLAN (but also in fluoride crystals, see the paragraph on crystalline lasers) without employing special techniques to depopulate the $^4I_{13/2}$ lower laser level, because the lower laser level is not fed significantly by luminescent decay or multiphonon relaxation from the upper laser level [11.981]. In addition, the Stark splitting of the laser levels contributes to population inversion, because the laser transition occurs between a low-lying Stark component of the upper and a high-lying Stark component of the lower laser level [11.935]. During the relaxation oscillations at the onset of lasing, a red-shift of the lasing wavelength is often observed in erbium 3 μm laser systems [11.982–985], because the excitation energy is accumulated in the long-lived $^4I_{13/2}$ lower laser level and the character of the lasing process changes from four-level to three-level lasing [11.935]. For the same reason, the tunability range of a 3 μm CW laser [11.986] is narrowed and red-shifted with increasing pump power.

Pump excited-state absorption (ESA), which is present in Er^{3+} at almost all available GSA wavelengths [11.987], has a major influence on the performance of low-doped, core-pumped erbium 2.7 μm ZBLAN fiber lasers because of the significant amount of ground-state bleaching and excitation of the laser levels under these conditions [11.988]. Pumping at 980 nm directly into the upper laser level provides the highest Stokes efficiency of $\eta_{St} = \lambda_{pump}/\lambda_{laser} = 35\%$ [11.941]. However, ESA at 980 nm from the $^4I_{11/2}$ upper laser level [11.989] is detrimental to lasing. Experimentally, the best pump wavelength [11.988] is near 792 nm, at the peak of ESA from the $^4I_{13/2}$ lower laser level [11.990]; see the measured GSA and ESA cross sections in Fig. 11.76a. Depletion of the lower laser level by ESA favorably results in a redistribution of its population density and overcomes the bottleneck that results from the long lower-level lifetime. However, slope efficiencies obtained in this way were $< 15\%$. Moreover, saturation of the output power at 2.7 μm was observed and the highest reported output powers were in the 20 mW region [11.991, 992]. The excitation of the metastable $^4S_{3/2}$ level (lifetime ≈ 580 μs [11.919]) led to inversion with respect to the $^4I_{13/2}$ level. A second laser transition at 850 nm repopulated the $^4I_{13/2}$ lower laser level of the 2.7 μm transition (Fig. 11.76b), causing the 2.7 μm laser to saturate at low output powers [11.988]. Significant improvement in the performance of this laser system was obtained by delib-

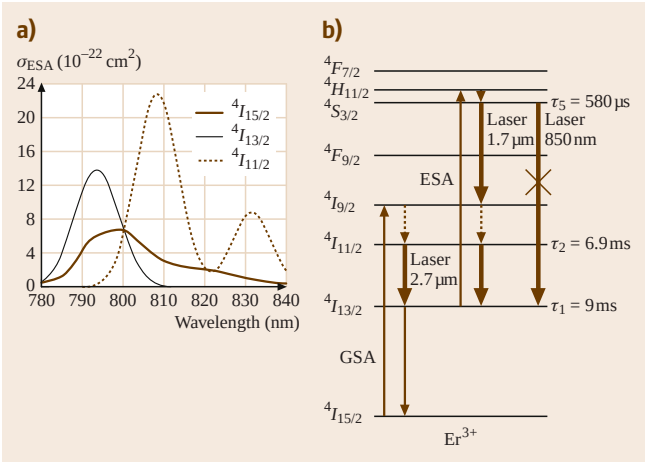

Fig. 11.76 **(a)** Absorption cross sections in ZBLAN:Er^{3+} near 800 nm: GSA $^4I_{15/2} \rightarrow {}^4I_{9/2}$ and ESA $^4I_{13/2} \rightarrow {}^2H_{11/2}$, $^4I_{11/2} \rightarrow {}^4F_{3/2}$, and $^4I_{11/2} \rightarrow {}^4F_{5/2}$ (After [11.990]). **(b)** Partial energy-level scheme of erbium indicating the processes relevant to the ZBLAN:Er^{3+} cascade laser: *lower loop* with GSA to $^4I_{9/2}$, multiphonon relaxation, laser transition at 2.7 μm, luminescent decay, and *upper loop* with ESA to $^2H_{11/2}$, thermal relaxation, laser transition at 1.7 μm, multiphonon relaxation, laser transition at 2.7 μm. Competitive lasing at 850 nm is suppressed in the cascade regime ▶

erately operating a third laser transition $^4S_{3/2} \rightarrow {}^4I_{9/2}$ at 1.7 μm, thereby suppressing the competitive laser at 850 nm and recycling the excitation energy accumulated in the $^4S_{3/2}$ level into the upper laser level; see the energy-level scheme in Fig. 11.76b. The slope efficiency of the 2.7 μm transition increased significantly to 23% [11.993], close to the Stokes efficiency limit of 29% under 800 nm pumping. An output power of 150 mW was demonstrated experimentally [11.993]. Also a three-transition-cascade lasing regime with additional lasing at the transition $^4I_{13/2} \rightarrow {}^4I_{15/2}$ near 1.6 μm was demonstrated [11.994].

In ZBLAN fibers with higher dopant concentrations of typically 1–5 mol % ($\approx 1.6–8 \times 10^{20}$ cm^{-3}) and with the double-clad geometry, ESA is much less important, because the reduced pump intensity with low-brightness diode lasers leads to smaller excitation densities. A successful approach towards a high-power erbium 2.7 μm fiber laser is codoping of the fiber with Pr^{3+} [11.995, 996]. This idea was reported already in [11.991, 997, 998] and was proposed for the double-clad fiber laser in [11.999]. In this approach, the Er^{3+} 2.7 μm transition is operated as a simple four-level laser; see the energy-level scheme in Fig. 11.77a. The $^4I_{13/2}$ lower laser level is depopulated by the energy transfer process ET_1 to the Pr^{3+} codopant and fast decay to the ground state by multiphonon relaxation within Pr^{3+}. The energy-transfer process ET_2 from the $^4I_{11/2}$ upper laser level to the Pr^{3+} codopant is weak [11.919]. The strong lifetime quenching of the $^4I_{13/2}$ lower laser level significantly reduces ground-state bleaching and excitation of the laser levels, thus making the influence of ESA negligible, but similarly preventing energy recycling by ETU [11.1000]. Each pump photon can at best produce one laser photon in the Er^{3+},Pr^{3+}-codoped system. The theoretical limit of the slope efficiency is given by the Stokes efficiency, which is 29% under 800 nm pumping. Experimentally, a slope efficiency of 17% and an output power of 1.7 W were obtained [11.995] (Fig. 11.77b). Other researchers [11.1001] reported output powers of 660 mW. Since ESA from both laser levels is negligible, the system can alternatively be pumped near 980 nm, which provides a Stokes efficiency of 35%. In this way,

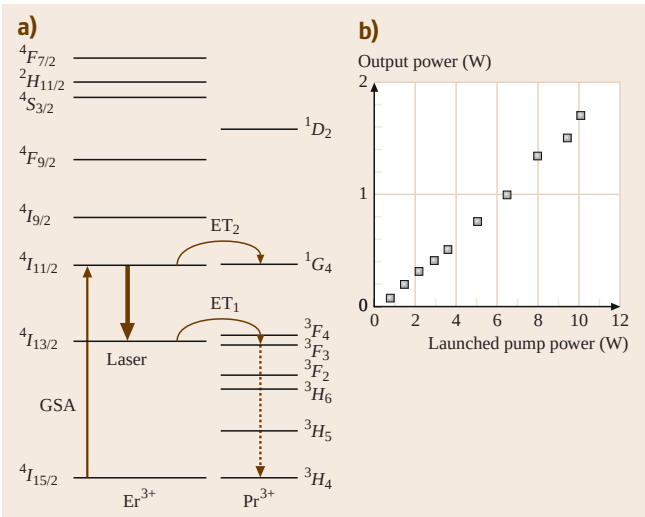

Fig. 11.77 **(a)** Partial energy-level scheme of erbium indicating the processes relevant to the ZBLAN:Er^{3+} lifetime-quenching laser: GSA at 980 nm to the $^4I_{11/2}$ upper laser level (or at 790 nm to the $^4I_{9/2}$ pump level and subsequent multiphonon relaxation to $^4I_{11/2}$), laser transition to the $^4I_{13/2}$ lower laser level, and relaxation to the ground state via energy transfer ET_1 to the Pr^{3+} codopant. The energy transfer ET_2 from the $^4I_{11/2}$ upper laser level to the Pr^{3+} codopant is weak. **(b)** Output power at 2.7 μm under 792 nm pumping. (After [11.995]) ▶

the experimental slope efficiency could be increased to 25% [11.1002]. With improvements in diode-laser technology and an optimized fiber design, an output power of 5.4 W at 2.7 μm with a slope efficiency of 21% could recently be demonstrated from an Er^{3+},Pr^{3+}-codoped ZBLAN fiber laser [11.996, 1003, 1004].

There have also been attempts to operate the ZBLAN fiber laser in the energy-recycling regime. The parameters W_{ii} of both ETU processes in ZBLAN bulk glasses [11.919] versus Er^{3+} concentration are shown in Fig. 11.74b. The criterion for optimization of the slope efficiency in (11.89) is maximizing the ratio W_{11}/W_{22}. For Er^{3+} concentrations of $>$ 2–3 mol % at which ETU processes become important, this ratio is ≈ 3, see the *dashed line* in Fig. 11.74b, a more favorable value than reported for $LiYF_4$:Er^{3+} [11.954]. Energy recycling by ETU at high Er^{3+} concentrations [11.1005] can lead to slope efficiencies exceeding the Stokes limit, which is 35% under 975 nm pumping. In early attempts, two research groups tried to exploit energy recycling [11.1006, 1007], however the slope efficiencies in these experiments did not exceed the slope efficiencies obtained in Er^{3+},Pr^{3+}-codoped fibers pumped at corresponding pump wavelengths [11.995, 996, 1002]. 9 W of output power with a slope efficiency of 21.3% were demonstrated from a highly Er-doped (60 000 ppm) ZBLAN fiber when end-pumping the fiber with 24.8 W of launched pump power at 975 nm [11.1008]. Again, the achieved slope efficiency is very similar to that of 25% obtained with the same pump wavelength in an Er^{3+},Pr^{3+}-codoped fiber [11.1002]. Recent approaches using highly Er^{3+}-doped ZBLAN fiber have shown further improvement in output power. In a liquid-cooled fiber with dual-end diode pumping, 24 W of output power and a slope efficiency of 13–16% were demonstrated [11.1009]. In a highly Er^{3+}-doped, passively cooled fiber with a fiber Bragg grating [11.1010] written in an undoped, fusion-spliced ZBLAN fiber as incoupling mirror, a single-mode output power of 20.6 W was obtained with a slope efficiency of 34.5%, which decreased to 28.2% at higher power [11.1011], thereby for the first time demonstrating that the predicted energy-recycling regime [11.1005] can be obtained also in Er^{3+}-doped ZBLAN fiber lasers. However, highly efficient energy recycling with correspondingly improved slope efficiency similar to the result of 50% in a crystalline host material [11.940] is still lacking, potential reasons for which have been proposed in [11.1012].

Disadvantages of the attempt to exploit the energy-recycling regime are the high absorbed pump-power density and increased heat generation due to the multiphonon relaxation $^4I_{9/2} \rightarrow {}^4I_{11/2}$ that follows each ETU process from the lower laser level [11.413]. As a result, passive or active fiber cooling is required when operating highly Er^{3+}-doped ZBLAN 3 μm fiber lasers at output powers above $\approx$ 10 W. A potential solution, albeit again being restricted to slope efficiencies not exceeding the Stokes limit, is extracting the pump power almost completely radiatively by cascade lasing on the $^4I_{11/2} \rightarrow {}^4I_{13/2} \rightarrow {}^4I_{15/2}$ transitions at 2.8 and 1.6 μm [11.981]. Recently, it has been shown that this approach diminishes the heat generation significantly, and by now an output power of 8.2 W at 2.8 μm, with a slope efficiency of 16% was obtained in a 5000 ppm Er^{3+}-doped ZBLAN fiber [11.750]. Simultaneously, the fiber emitted an output power of 6.5 W at 1.6 μm, which would otherwise have largely been converted to heat. This may turn out to be the most practical approach toward truly high-power Er^{3+}-doped ZBLAN fiber lasers in the 3 μm wavelength range.

Investigation of the temporal dynamics in erbium 3 μm ZBLAN lasers has revealed spectral and power fluctuations [11.1013]. The first steps toward pulsed output from erbium 3 μm ZBLAN lasers [11.975, 993, 994] were unsatisfactory in terms of output energies and average powers. An order-of-magnitude improvement to average output power of 19 mW and pulse durations of 250 ns was obtained by active Q-switching [11.1014]. In fibers with relatively large core diameters and therefore transverse multimode operation, singly Er-doped with concentrations smaller than those required for efficient energy recycling, 3 W of output power was obtained [11.999]. With further increase of the core diameter to 90 μm, a pulsed output of $>$ 0.5 mJ could be demonstrated by the same researchers. Recently a gain-switched fiber laser with pulse duration of 300 ns and 68 W peak power at 100 kHz repetition rate, yielding 2 W average power, has been demonstrated [11.1015], and active Q-switching has delivered an average output power of $>$ 12 W, with pulse energies of 100 μJ and a pulse duration of 90 ns, resulting in a peak power of 900 W [11.1016]. After the demonstration of wavelength tuning over 120 nm from 2.71–2.83 μm, albeit with only $\approx$ 1 mW of output power [11.976], high-power wavelength tuning over $\approx$ 100 nm around 2.7–2.8 μm with output powers of 1–2 W has been demonstrated in Er^{3+}-doped and Er^{3+}, Pr^{3+} co-doped fibers [11.1017, 1018]. Recently, stable $\approx$ 10 W operation with tuning over 110 nm from 2.77–2.88 μm and a total tuning range of 170 nm from 2.71–2.88 μm

has been demonstrated [11.1019]. Towards the long wavelength end, lasing at 2.94 μm with an output power of 5.2 W and a slope efficiency 26.6% was achieved [11.1020].

Dysprosium-Doped Solid-State Lasers at 2.3–2.4 μm and 2.9–3.4 μm

The search for new mid-infrared laser transitions depends entirely on the structure of the energy-level diagram of the rare-earth ions. The Dy^{3+} ion offers a rather dense energy-level scheme in the infrared spectral region, resulting in a range of absorption peaks, as well as a four-level laser transition at 2.3–2.4 μm and a phonon-terminated 3 μm laser transition. The transition at 2.3–2.4 μm was among the first laser transitions reported and the first to be demonstrated in continuous-wave operation [11.692, 693]. Because of the dense energy-level scheme of Dy^{3+}, multiphonon relaxation is an issue of concern in this ion, hence low-phonon host materials may improve its laser performance. Recently, room-temperature laser emission at 2.43 μm was reported in the low-phonon host materials $CaGa_2S_4$:Dy^{3+} and KPb_2Cl_5:Dy^{3+}. At the 3.4 μm transition, room-temperature laser oscillation from Dy^{3+} in $BaYb_2F_8$ has been reported [11.1021]. The 1100 nm output from a Yb^{3+}-doped silica fiber laser has been successfully used to pump a Dy^{3+}-doped fluoride fiber laser [11.1022]. In this case, a maximum output power of 275 mW was generated with a slope efficiency of only ≈ 5%, however, when the pump wavelength was increased to ≈ 1.3 μm using a YAG:Nd^{3+} laser, the slope efficiency is approximately quadrupled to ≈ 20% [11.1023]. Reduced levels of pump ESA are believed to cause this augmentation in the slope efficiency. Recently, a slope efficiency of 23% has been demonstrated under pumping at 1088 nm [11.1024]. Future Dy^{3+}-doped fluoride fiber lasers may benefit from further increases in the pump wavelength to 1.7 μm or 2.8 μm.

Before turning our attention to rare-earth-ion-doped solid-state lasers in the wavelength range beyond 3 μm, it should be noted that solid-state lasers based on the actinide ion U^{3+} have also attracted attention in the recent past [11.1025, 1026].

Solid-State Lasers at Wavelengths Beyond 3 μm

Laser wavelengths longer than typically 3 μm are generally difficult to achieve in solid-state host materials by direct generation from rare-earth or transition-metal ions, because the energy gap between the upper and lower laser level is necessarily small and all the common oxide and fluoride host materials possess maximum phonon energies, which lead to fast multiphonon relaxation of the excitation of the upper laser level. Therefore, many of the laser transitions reported in the literature require cooling of the active device. On the other hand, the attractiveness of this wavelength range for a number of applications has inspired the search for host materials with maximum phonon energies below ≈ 300 cm^{-1}.

In crystalline hosts, a flashlamp-pumped, cooled Er^{3+} laser at 4.75 μm [11.697], a CW diode-pumped, cooled Er^{3+} laser at 3.41 μm [11.1027], and a pulsed diode-pumped room-temperature Er^{3+} laser at 4.6 μm [11.1028] have been operated. A room-temperature BaY_2F_8:Ho^{3+} laser was operated at 3.9 μm [11.1029]. Due to its dense energy-level scheme, Dy^{3+} offers a large range of possible mid-infrared transitions. Recently, room-temperature lasing of Dy^{3+} transitions in the low-phonon host materials $CaGaS_2$ and KPb_2Cl_5 was demonstrated [11.1030], in the former material even at 4.31 μm. As a recent example, in a $PbGa_2S_4$ host pulsed lasing at 4.29 μm with an output energy of 90 μJ and average power of 1.8 mW was obtained [11.1031]. The longest-wavelength lasers shown to operate in a solid-state material are room-temperature 5 μm and 7 μm lasers in $LaCl_3$:Pr^{3+} [11.1032, 1033].

The operation of lasers at wavelengths of 3.22 μm [11.1034] and 3.95 μm [11.1035] has been obtained from Ho^{3+}-doped ZBLAN fiber and at 3.45 μm [11.1036, 1037] from Er^{3+}-doped ZBLAN fiber. It was, however, necessary to cool the ZBLAN fiber for the 3.45 and 3.95 μm transitions. These two laser transitions span five or six maximum phonon energies in ZBLAN, therefore the lifetime of the upper laser level for each of these transitions is short and engenders an increase in the pump threshold compared to other ZBLAN fiber lasers operating at the shorter mid-infrared wavelengths. In addition, the lower laser levels of these transitions possess quite long lifetimes and some saturation of the output power has been observed [11.1038]. This problem (while it can be mitigated with cascaded lasing), combined with the use of inconvenient pump sources has impeded the full utilization of these laser transitions. The 3.95 μm wavelength emitted from the cooled ZBLAN fiber laser is currently the longest laser wavelength that has been generated from a fiber laser. Supercontinuum generation does not suffer from the limitations imposed by lifetime quenching, hence it was possible to convert the output from a pulsed-pumped Tm-doped fiber amplifier at 1.9 m to a supercontinuum in ZBLAN fiber extending to 4.5 μm [11.1039].

Generating wavelengths longer than 3 μm from fiber lasers is a task that tests the limits of current glass technology. The need for lower phonon energies has to be balanced with acceptable mechanical, chemical, and thermal properties. Since the highly developed ZBLAN glass is only useful for laser transitions up to 3–3.5 μm, glasses such as the chalcogenides [11.1040, 1041] will need to fill the gap. It is because these fragile glasses have to be drawn into low-loss fiber that has prevented long-wavelength emission to the extent that is possible in crystalline-based solid-state lasers. Creating efficient, high-power mid-infrared fiber lasers with output wavelengths $> 3\,\mu m$ is at the forefront of current fiber-laser research efforts.

As mentioned above, fiber lasers operating on laser transitions that have wavelengths $> 3\,\mu m$ will need to use glasses, which have very low phonon energies. While rare-earth-ion-doped heavy-metal oxides [11.1045] have been studied for 2–3 μm mid-infrared emission; to date, there has been no report of laser action for a fiber laser comprised of such a glass. Heavy-metal oxides do not seem to be suitable for lasers at wavelengths beyond 3 μm, because their maximum phonon energies are comparable to fluoride glasses and are too high for laser transitions beyond 3 μm.

Although providing only low solubility of ≈ 0.1 mol. % for rare-earth dopants, the chalcogenide glasses have been activated with a number of rare-earth ions including Ho^{3+} [11.1044], Tm^{3+} [11.1043], Tb^{3+} [11.1043], Dy^{3+} [11.1042], Pr^{3+} [11.1046], and Er^{3+} [11.1047, 1048] for studies into $> 3\,\mu m$ mid-infrared luminescence (Table 11.21). Fiber-laser action has been reported, however, only for an Nd^{3+}-doped GLS glass operating at a wavelength of $\approx 1\,\mu m$ [11.1049]. Recent demonstrations of fabricating Bragg gratings [11.1050], single-mode fibers [11.1051] and holey fibers [11.1052] with chalcogenide glass highlight the utility of this glass for fiber-based applications; however, the purity and toxicity of the starting materials and the difficulty of making ultralow-loss fiber currently impede the widespread use of chalcogenide glass for mid-infrared fiber-laser applications. Once these obstacles have been overcome, future $> 3\,\mu m$ fiber lasers will most likely involve the rare-earth ions Pr^{3+}, Nd^{3+}, Dy^{3+}, and Ho^{3+} doped into chalcogenide glass, because most of the important mid-infrared transitions relevant to these ions can be accessed with pump-photon wavenumbers $< 10\,000\,cm^{-1}$. Judicious choice of the overall dopant-ion concentration and the use of particular sensitizer and quenching ions will enable the production of efficient $> 3\,\mu m$ output some time in the future.

Table 11.21 Examples of luminescent transitions investigated as candidates for mid-infrared lasers in sulfide glasses

Ion	λ_{laser} (μm)	Transition	References

Ho^{3+}	4.9	$^5I_4 \rightarrow {}^5I_5$	[11.1044]

Conclusions

In the roughly five decades since the demonstration of the first mid-infrared solid-state lasers, thousands of scientific papers have been published which have reported on lasing in novel host materials, replacement of flashlamps by ion-laser and later diode-laser pump sources, ever-growing output powers, higher efficiencies, larger tunability ranges, shorter pulse durations and the like. A general tendency is that, the shorter the wavelength, the better the laser performance. When we approach longer wavelengths in the mid-infrared spectrum, we find that the quality and durability of the required low-phonon-energy host materials decline, Stokes and slope efficiencies decrease, whereas the thermal problems increase. While many crystalline host materials and the corresponding laser techniques have matured during the 1990s, the fast development of high-power, fundamental-mode fiber lasers, which could be witnessed in the 1 μm spectral range, has now also reached the mid-infrared spectral region. However, the assumption that, due to its large surface-to-volume ratio, the fiber geometry might avoid all thermal problems has been questioned by several recent high-power fiber-laser experiments in the near- and mid-infrared spectral region. These phenomena are, in principle, not much different from the situation found in crystalline lasers. Nevertheless, there remain distinct differences between these two host categories. When flexibility of the resonator design, short pulses, and high peak powers are required, crystalline lasers have advantages. On the other hand, fiber lasers are preferred when high beam quality or low pump threshold combined with medium-to-high CW output power are desired. The low pump threshold of fiber lasers is an invaluable advantage when cascade-laser operation is required to depopulate the long-lived terminating level of one laser transition by

a second laser transition. The comparatively low dopant concentrations that are useful in fiber lasers due to the long interaction lengths can minimize energy dissipation by interionic processes but, equally, limit the exploitation of these processes as a tool to optimize the population mechanisms of a certain laser system, as has been done successfully in several of the mid-infrared crystalline laser systems discussed above. Although still a great challenge with respect to fabrication process and durability, low-phonon crystalline and fiber host materials have the potential to revolutionize CW mid-infrared lasers in the wavelength range between 3–5 μm.

11.2.5 Transition-Metal-Ion Lasers

Basics

In this chapter an overview of transition-metal-ion lasers will be given. The main focus lies on the laser characteristics and results, a more spectroscopically oriented overview is given in [11.1053]. Transition metals are elements of the third, fourth and fifth row of elements in the periodic table. Laser oscillation has so far only been obtained with ions of the transition metals of the third row (the Fe row; Ti to Cu). Due to the strong coupling between the electronic levels of the transition-metal ion with the surrounding field established by the crystalline environment, transition-metal-ion lasers are usually tunable over a wide spectral range up to several hundred nanometers. These lasers are of interest for a wide field of applications, e.g., in scientific research, in medicine, for measurement and testing techniques, ultrashort-pulse generation, and communication. They can also be used as coherent light sources for second-harmonic generation, for optical parametric oscillators, and for sum- and difference-frequency generation.

The energy-level scheme and thus also the spectroscopic and laser characteristics of a transition-metal ion in a crystalline field is strongly dependent on the valence state of the ion, the number of ligands (i. e., the coordination number) and the strength and symmetry of the surrounding crystalline field. Therefore it is not possible to draw some kind of Dieke diagram for the transition-metal ions, as it is possible for the trivalent rare-earth ions (see the section on 4f–4f transitions in Sect. 11.2.1). The energy-level schemes of the transition-metal ions in crystalline hosts are in principle described by the so-called Tanabe–Sugano diagrams [11.1054–1056]. These diagrams are distinguished by the number of electron within the 3d electron shell. In these diagrams the energy of a specific level of the transition-metal ion is depicted as a function of the

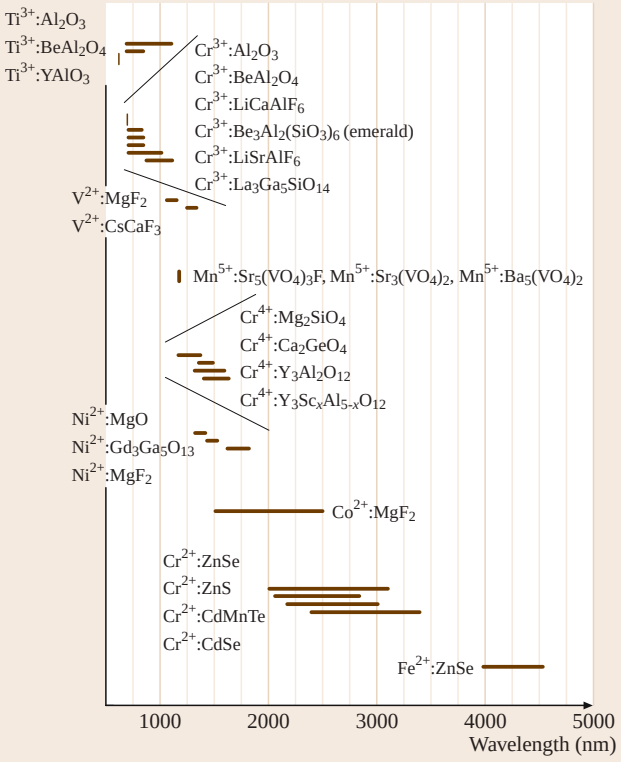

Fig. 11.78 Overview of tunable solid-state lasers based on transition-metal-ion-doped crystals

crystal field strength. We will not describe the quantum-mechanical background to obtain these diagrams, which would be beyond the frame of this handbook. The reader is referred to the appropriate literature [11.1057–1062].

In comparison to laser systems based on the 4f↔4f transitions of trivalent rare-earth ions, lasers based on 3d↔3d transitions are in general more affected by a higher probability of excited-state absorption, a higher probability of nonradiative decay, and a higher saturation intensity, leading to higher laser thresholds. Often laser oscillation cannot be obtained at all. In the following section, the focus is on specific transition-metal-ion lasers, ordered according to their laser wavelength from visible over the near-infrared to the mid-infrared. This overview includes Ti^{3+} lasers, especially Ti^{3+}:Al_2O_3, Cr^{3+} lasers, Cr^{4+} lasers and finally Cr^{2+} lasers. At the end of this section, other transition-metal-ion lasers are presented, including Co^{2+} and Ni^{2+} lasers. Finally, some general comments about transition-metal-ion lasers will be given in the last section. In Fig. 11.78 an overview of lasers based on 3d↔3d transitions of

transition-metal ions is given. It can be seen that almost the whole spectral range between 650 nm and 4500 nm is covered.

Overview of Transition-Metal-Ion Lasers

Ti^{3+} Lasers. Ti^{3+}-doped Al_2O_3 (Ti:sapphire) has been intensively investigated as a tunable laser material since the first laser operation was reported [11.1063, 1064]. Efficient laser oscillation was obtained in Al_2O_3 in pulsed [11.1063, 1065, 1066] and continuous-wave [11.1065, 1067, 1068] operation, for further references see [11.229]. The tuning range covers more than 400 nm and spans approximately 670–1100 nm [11.1069]. It has a relatively high emission cross section of approximately 4.1×10^{-19} cm^2 [11.1070] at the maximum of the emission spectrum. A slope efficiency of 62% has been reported [11.1071], which is close to the quantum limit in that experiment of 78% (pump wavelength 589 nm, emission wavelength 750 nm). This indicates the low intrinsic losses of the system.

The Ti^{3+} ion belongs to the $3d^1$ configuration, which is very favorable with respect to laser application because of its simple energy-level scheme (see Figs. 11.79, 11.80). There are only two $3d^1$ energy levels, which diminishes the possibility of excited-state absorption of the laser radiation, a process that limits the tuning range and efficiency of other transition-metal-ion-doped lasers. The orbital degeneracy of the d levels is removed due to the Jahn–Teller effect, which yields the large absorption and emission bandwidths. The room-temperature absorption and emission spectra are shown in Fig. 11.81. Excited-state absorption transitions occurs to energy levels correlated to charge transfer and conduction-band levels and between the two Jahn–Teller-split components of the upper (^2E) d level. In Ti:sapphire, excited-state absorption was not observed in the spectral range of emission [11.1072]. In Table 11.22 the laser-relevant parameters of Ti:sapphire are listed. Besides the favorable spectroscopic and laser characteristic, the Al_2O_3 host material offers a variety of advantageous properties: a high thermal conductivity, as well as mechanical and chemical hardness.

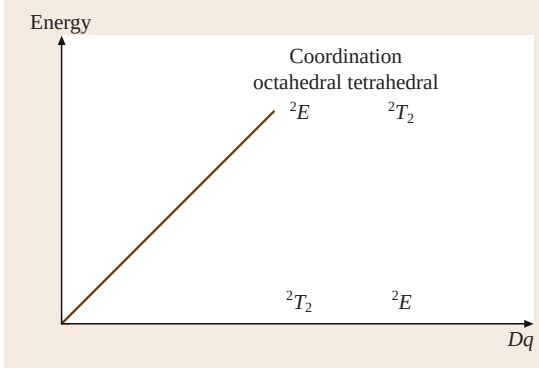

Fig. 11.79 Basic energy-level schemes of $3d^1$ ions in octahedral and tetrahedral coordination

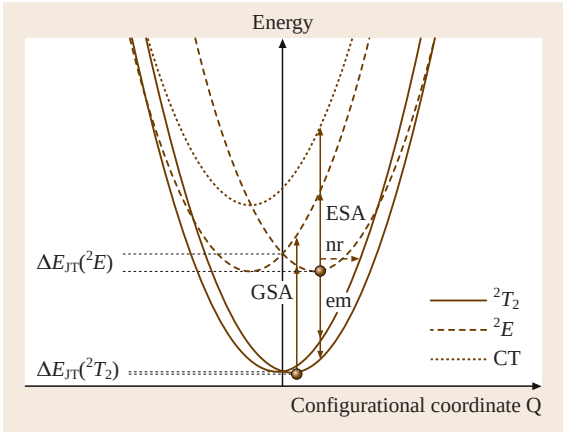

Fig. 11.80 Schematic diagram of the Jahn–Teller effect for octahedrally coordinated d^1-systems. ^2E, $^2T_2$ and CT (charge transfer) are the energy levels, GSA, ESA, and em are ground-state absorption, excited-state absorption, and emission, respectively. nr represents the nonradiative decay via tunneling between the excited state and the ground state. ΔE_{JT} is the Jahn–Teller stabilization energy

To date, Ti^{3+}:Al_2O_3 is the most common and commercially available tunable solid-state laser. Nowadays, it can be pumped with frequency-doubled Nd lasers at wavelengths around 532 nm, thus efficient all-solid-state laser operation is possible. Formerly, Ar^+-ion laser pumping was applied. In commercial systems, overall efficiencies as high as 30% are obtained.

Besides the broad tuning capability of the Ti:sapphire laser, its ability for ultrashort-pulse generation and amplification is especially exploited. In mode-locked operation, pulses as short as 5 fs [11.1073–1077] and octave-spanning spectra (e.g., 600 nm to 1200 nm [11.1077]) have been obtained.

Laser oscillation with reasonable efficiency has also been reported for Ti^{3+}:$BeAl_2O_4$ [11.1078–1081] (Table 11.23). However, the efficiency as well as the tuning range is smaller than Ti^{3+}:Al_2O_3, thus this laser has no commercial application. In $Y_3Al_5O_{12}$ [11.1082] and $YAlO_3$ [11.1083, 1084] crystals doped with Ti^{3+} the

Fluorescence bandwidth (FWHM)	≈ 200 nm
Peak emission wavelength	790 nm
Peak stimulated emission cross section	4.1×10^{-19} cm^2 ($E \parallel c$)
	2.0×10^{-19} cm^2 ($E \perp c$)
Quantum efficiency	≈ 0.9–1
Saturation fluence	0.9 J/cm^2
Dopant concentration	0.1% (weight)
Growth	Czochralski, heat exchange
T_m	2050 °C
Thermal conductivity	28 W/(m K)
Thermal lens (dn/dT)	12×10^{-19} K^{-1}

observed efficiencies are very low (Table 11.23). The main reason for this is excited-state absorption in the spectral region of emission and absorption [11.1072, 1085]. In Ti^{3+}-doped systems nonradiative decay processes due to phonon-assisted tunneling between the Jahn–Teller-split excited and ground states also occur, which prevent efficient laser oscillation, e.g., in Ti^{3+}:$Y_3Al_5O_{12}$ [11.1086, 1087].

Cr^{3+} *Lasers.*

Basics. The Cr^{3+} ion is almost always found in octahedral coordination and its energy-level scheme is described by the Tanabe–Sugano diagram shown in Fig. 11.82. In low crystal fields, the first excited state is the $^4T_2$ level, whereas in strong crystal fields the ^2E level is the first excited state. This means, that either broadband emission ($^4T_2 \rightarrow {}^4A_2$) or narrow-line emission ($^2E \rightarrow {}^4A_2$) occurs. The absorption spectra are dominated by quartet–quartet transitions, whereas the excited-state absorption spectra are dominated either by quartet–quartet or doublet–doublet transitions depending on the total spin of the lowest excited state.

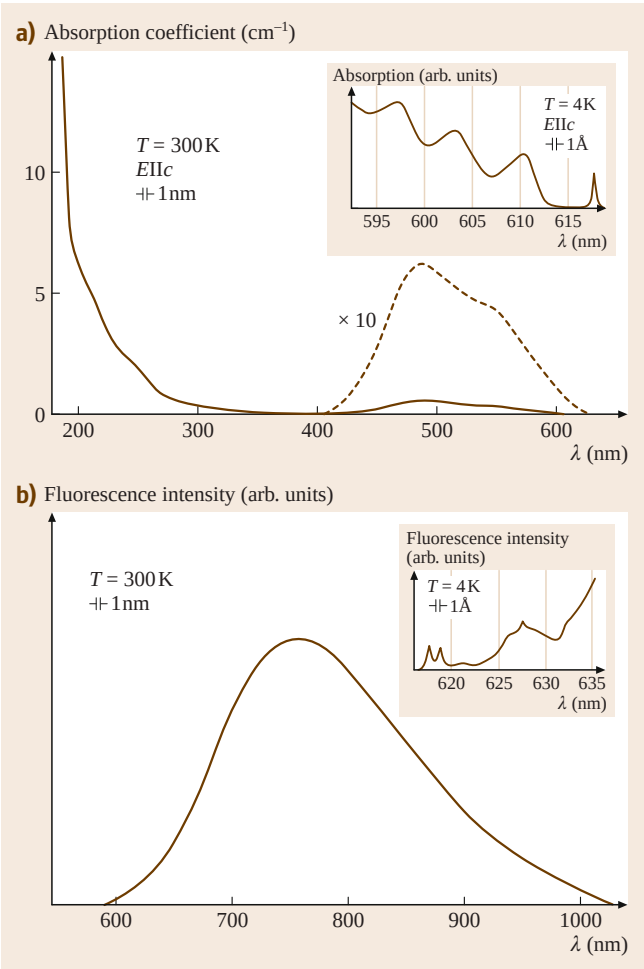

Fig. 11.81a,b Absorption (**a**) and emission (**b**) spectra at room temperature and at 4 K of Ti:sapphire. (After [11.1068])

Laser Characteristics. The first laser was realized in 1960 with ruby, i. e., Cr^{3+}-doped Al_2O_3 [11.1088]. In ruby – due to the strong crystal field experienced by the Cr^{3+} ion – the laser oscillation occurs on the $^2E \rightarrow {}^4A_2$ transition. Thus, ruby is a three-level

Table 11.23 Overview of other Ti^{3+}-laser materials

Crystal	λ_{laser} (nm)	Tuning range (nm)	Slope efficiency (%)	Mode of operation	Pump source	References
$BeAl_2O_4$	810	730–950	15	Pulsed	SHG Q-switched Nd:YAG (532 nm)	[11.1079]
	–	753–949	0.013	Pulsed	Flashlamp (10 µs)	[11.1081]
$Y_3Al_5O_{12}$	No details given in the reference					[11.1082]
$YAlO_3$	615	–	0.3	Pulsed	SHG Q-switched Nd:$YAlO_3$ (540 nm)	[11.1083, 1084]

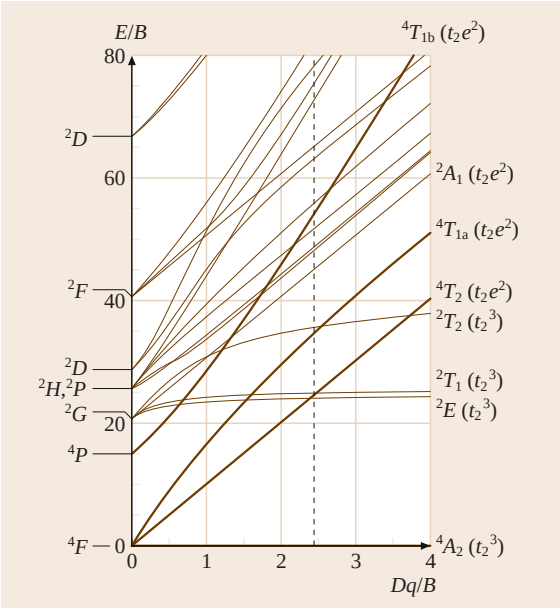

Fig. 11.82 Tanabe–Sugano diagram for octahedrally coordinated $3d^3$ ions, e.g., Cr^{3+} with $C/B = 5.5$. The *dashed vertical line* marks the border between low and high crystal field strength

laser and not tunable over a wide range. Ruby is still a commercially available pulsed laser system with peak output powers in the MW range used for applications in measurement and pulsed holography. Ruby has remarkable thermo-mechanical properties which allows high peak power operation, especially in the Q-switched regime. In 1976, *Morris* et al. [11.1089] realized with Cr^{3+}-doped $BeAl_2O_4$ (alexandrite) the first tunable laser based on the Cr^{3+} ion. The laser transition is $^4T_2 \rightarrow {}^4A_2$ and terminates in the higher vibronics of the ground state. Therefore, a four-level laser system is realized. To date, the alexandrite laser has found significant commercial applications in industry (e.g., marking, writing and printing), scientific research (e.g., fluorescence dynamics, fluorescence imaging, LIDAR), and medicine (e.g., hair and tattoo removal). Its advantages are its tunability between 700 and 820 nm, the high heat conductivity of 23 W/(m K), which allows high-power pulsed operation, and its high slope efficiency of up to 51% [11.1090, 1091]. Even broader laser tuning ranges with similar efficiencies were achieved with the Cr^{3+}-doped colquirite crystals $LiCaAlF_6$, $LiSrAlF_6$, and $LiSrGaF_6$ [11.1092] (Table 11.24). However, these crystals suffer from poor thermo-mechanical properties (Table 11.25), which allow only relatively low pump and laser powers. The broad tuning range is exploited for mode-locked operation with pulse lengths down to 9 fs for Cr^{3+}:LiCAF [11.1093]. The crystals also offer the possibility of efficient laser-diode pumping with laser diodes at wavelengths around 670–690 nm. Thus compact, mode-locked laser systems in the low-power range are possible [11.1094–1096]. It is interesting to note that the highest slope efficiency ever obtained with a Cr^{3+}-based laser was achieved with Cr^{3+}:$Be_3Al_2(SiO_3)_6$ (emerald). Also here, however, the thermo-mechanical properties are poor and, furthermore, the emerald crystal is very difficult to grow in laser quality. For the most efficient Cr^{3+} laser materials the relevant laser and materials parameters are listed in Table 11.25. Laser oscillation with Cr^{3+}-doped systems has been realized in more than 30 materials. In Table 11.24 an overview of reported laser systems is given [11.103, 1097]. In general the tuning ranges for Cr^{3+} lasers are not as broad as for Ti^{3+}:Al_2O_3 lasers, however, they exhibit the advantage of direct diode-laser pumping around 670 nm, i. e., in the spectral region of the $^4A_2 \rightarrow {}^4T_2$ absorption.

For Cr^{3+} laser systems excited-state absorption (ESA) plays a very important role and is the main reason for the observed large differences in the laser efficiencies. Due to its energy-level scheme (Fig. 11.82), spin-allowed ESA transitions are expected either between the quartet states (for low-crystal-field hosts) or between the doublet states (in strong-field hosts). These transitions cover a wide spectral range, due to the strong electron–phonon coupling. Thus, in general, these ESA transitions overlap with the absorption and emission bands. The influence of the ESA is strongly dependent on the host lattice, i. e., on the crystal field experienced by the Cr^{3+} ion. In general, it is observed that crystals with a medium crystal field for the Cr^{3+} ion are favorable. Furthermore, in some crystals (e.g., the colquirites, alexandrite, emerald etc.) the polarization-dependent selection rules can be exploited. Cubic hosts are generally more strongly affected.

Summary and Perspectives for Cr^{3+} Lasers. Cr^{3+} lasers are generally interesting for laser applications. High-efficiency diode-pumped and broadly tunable continuous-wave and mode-locked laser oscillation have been obtained in a variety of crystals. Some laser systems are commercially available. However, all of these crystals have specific drawbacks: they have poor thermal mechanical properties, the growing process is difficult or the tuning range is small. Therefore Cr^{3+} lasers are at this time in general not competitive with the

Ti^{3+}:Al_2O_3 laser, which offers a broader tuning range, allows shorter pulses in the mode-locked regime and has better thermo-mechanical properties. Ti^{3+}:Al_2O_3 cannot be pumped directly with diode lasers; however, advances in the frequency-doubling technique of neodymium lasers has led to efficient all-solid-state pump lasers which replaced the argon-ion laser as pump. Additionally, pump laser diodes in the spectral region between 630 and 700 nm with high beam quality and output power are currently not available in a satisfactory manner. Concerning the research for new Cr^{3+} laser systems one has to take into account that the Cr^{3+} ion has already been investigated in a large number of systems. In principle, new host materials with the perspective of efficient laser operation should have a medium crystal field for the Cr^{3+} ion and polarization-dependent optical properties that could help to avoid or at least significantly reduce excited-state absorption in the spectral region of the emission. Furthermore, good thermo-mechanical properties are required.

Cr^{4+} *Lasers.*

Basics. Cr^{4+}-doped crystals have been of interest as tunable, room-temperature laser materials since the late 1980s. In a variety of materials laser oscillation in different operation schemes has been achieved, see Tables 11.26 and 11.27, where an overview of the obtained laser results is given. The energy-level scheme of the Cr^{4+} ion in crystals can be described with the Tanabe–Sugano diagram shown in Fig. 11.83. The absorption spectra are dominated by the three spin-allowed transitions between the $^3A_2$ ground state and the $^3T_2(^3F)$, $^3T_1(^3F)$, and $^3T_1(^3P)$ excited states. Usually, the energy levels are strongly crystal field dependent and split, thus the absorption spectra of different materials differ significantly. In all materials

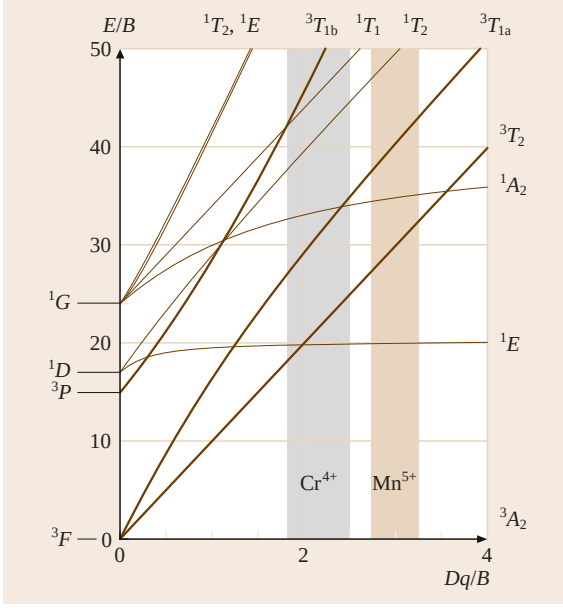

Fig. 11.83 Tanabe–Sugano diagram for tetrahedrally coordinated $3d^2$ ions. The *marked area* correspond roughly to the regions of Dq/B values of Cr^{4+} and Mn^{5+}. For simplicity, C/B was set to 5.6, although it differs for different systems ▶

investigated thus far, broadband emission due to the transition between the $^3T_2$ excited state and the $^3A_2$ ground state is observed. Referring to the Tanabe–Sugano diagram and the indicated area of crystal field values for the Cr^{4+} ion, one would expect – at least in some materials – narrow-line emission. However, due to lattice relaxation and crystal field splitting of the excited state, the $^3T_2$ or one of its crystal field components becomes lower than the ^1E level.

The most efficient laser oscillation of Cr^{4+}-doped materials was realized in Mg_2SiO_4 and $Y_3Al_5O_{12}$ (YAG). The laser data and main spectroscopic data of these materials are listed in Tables 11.26 and 11.28. A variety of further host materials for the Cr^{4+} ion were also investigated, but with either low efficiency (Table 11.27) or without realization of laser oscillation. A detailed overview of Cr^{4+}-doped systems is given in [11.1053].

In all Cr^{4+}-doped materials investigated thus far, there are two main drawbacks for efficient laser oscillation or laser oscillation at all: excited-state absorption and nonradiative decay. Investigation of excited-state absorption has been performed on garnets [11.1235–1237], forsterite [11.1238–1241], cunyite [11.1242], silicates [11.1239] and Wurtzite-type crystals [11.1241, 1243, 1244]. The nonradiative decay via multiphonon relaxation leads to quantum efficiencies far below 100% at room temperature; see the overview given in [11.1053]. The preparation of Cr^{4+}-doped crystals requires for most materials special conditions before, during or after the growth process. The Cr^{4+} ion is

not as stable in its valence state as Cr^{3+}. Therefore, there is the tendency for incorporation of chromium ions in different valencies in the crystals, especially for materials that do not exhibit an appropriate tetravalent tetrahedrally coordinated lattice site. This is, e.g., the case for $Y_3Al_5O_{12}$, therefore here additional codoping with divalent cations (Mg, Ca) is necessary. But also in Mg_2SiO_4, Cr^{3+} is incorporated into the Mg lattice. No

traces of Cr^{3+} were observed in these materials, which do not exhibit an appropriate lattice site for the Cr^{3+} ion, e.g., Ca_2GeO_4 and Y_2SiO_5. However, the laser results obtained with $Y_3Al_5O_{12}$ and Mg_2SiO_4 indicate that the laser efficiency is not necessarily affected by the presence of Cr^{3+}.

Laser Characteristics. In Table 11.26 an overview of the laser results obtained with Cr^{4+}:YAG and Cr^{4+}:Mg_2SiO_4, the materials in which the most efficient laser operation has been obtained, is given. In YAG, the highest slope efficiency obtained thus far in the continuous-wave regime is 42% [11.1195]. The corresponding input–output curve is shown in Fig. 11.84a. Attempts to improve the laser efficiency by changing the crystals composition, i. e., by substituting Lu for Y on the dodecahedral site or Sc for Al on the octahedral site were not successful [11.1196, 1197]. The efficiency decreased significantly. The reason is mainly excited-state absorption, but the lower crystal quality and increased nonradiative rate also contribute [11.1259]. A remarkable characteristic – on first sight – is that the Cr^{4+}:YAG laser oscillates polarized parallel to one of its main crystallographic axes. The laser output was highest when the pump beam of a Nd:YAG laser operating at 1064 nm and propagating along the [001]-axis of the Cr^{4+}:YAG crystal is polarized parallel to one of the crystallographic ⟨100⟩-axes of the Cr^{4+}:YAG crystal, and was lowest when its polarization was parallel to one of the ⟨110⟩-axes (Fig. 11.84b). The Cr^{4+}:YAG laser output is polarized and maintains its polarization while rotating the pump beam polarization. When the pump beam polarization is parallel to one of the ⟨110⟩-axes, the Cr^{4+}:YAG laser polarization switches [11.1194]. This characteristic can be explained by the crystal structure, the location of the Cr^{4+} ions and the local symmetry they experience. For details, see [11.1260, 1261].

With the Cr^{4+}:Mg_2SiO_4 laser, slope efficiencies of up to 38% [11.1212] and output powers around 1.1 W [11.1213] in continuous-wave operation at room temperature have been realized (Fig. 11.84c). For crystals from the forsterite group the attempts to obtain better laser results by substituting the constituent ions of the host lattice were also not successful. A variety of crystals were investigated [11.1262–1264] (see the overview given in [11.1053]) but only for Ca_2GeO_4 was laser oscillation obtained. For Ca_2GeO_4 excited-state absorption on the laser wavelength is detrimental [11.1242].

Laser oscillation was also obtained for Cr^{4+}-doped Y_2SiO_5, $LiGeNbO_5$, $CaGd_4(SiO_4)_3O$, and $SrGd_4(SiO_4)_3O$. The low efficiencies are probably due

to excited-state absorption and the high nonradiative decay rate.

Summary and Outlook for Cr^{4+} Lasers. Cr^{4+}:YAG and Cr^{4+}:Mg_2SiO_4 are efficient and broadly tunable laser systems for the infrared spectral range including the very interesting region for telecommunication applications around 1.3 and 1.55 μm. Mode-locked operation with pulse lengths as short as 20 fs for Cr^{4+}:YAG [11.1206] and 14 fs for Cr^{4+}:Mg_2SiO_4 [11.1233] were obtained. Also direct diode-pumped laser operation was realized, however, with lower efficiencies [11.1204, 1207]. For both systems, power handling is a problem and the ion concentration in both materials is rather low, yielding a low absorption efficiency of the pump light.

The main obstacle for Cr^{4+} laser materials is excited-state absorption at the emission wavelength, which is present in practically all crystals. Its influence is small in systems with an advantageous energy-level scheme and/or a crystal structure that supports strong polarization-dependent selection rules. A second but less important point concerning Cr^{4+} laser materials is the nonradiative decay rate. To decrease this rate, crystals with low-energy phonons and/or small electron–phonon coupling should be used as host materials, e.g., those in which silicon is substituted by germanium or aluminum is substituted by gallium. However, attempts in this direction have not been successful thus far.

Cr^{2+} *Lasers.*

Basics. The energy-level scheme of tetrahedrally coordinated Cr^{2+} is shown in Fig. 11.85. The Cr^{2+} ion experiences a low crystal field, e.g., in ZnSe the value of Dq/B is about 0.9. Thus, the $^5T_2$ level is the ground state and the ^5E level is the first excited state, whilst all higher-lying levels are triplet and singlet states. In consequence, the $^5E \rightarrow {}^5T_2$ emission is a spin-allowed transition, while all interionic excited-state transitions are spin-forbidden. Such systems are in general very promising for the realization of efficient tunable laser oscillation, because even in the case of a spectral overlap between stimulated emission and excited-state absorption, the transition probabilities for the latter are expected to be about a factor of 10 smaller.

Cr^{2+}-doped chalcogenide crystals have been shown to be efficient and broadband tunable solid-state lasers for the infrared spectral range between 2 and 3 μm. Pulsed, continuous-wave, mode-locked and diode-pumped laser operation have been demonstrated in recent years. Possible applications of these mid-infrared lasers include scientific research, remote sensing, trace-gas analysis, medicine, biology, materials processing, and ultrashort-pulse generation.

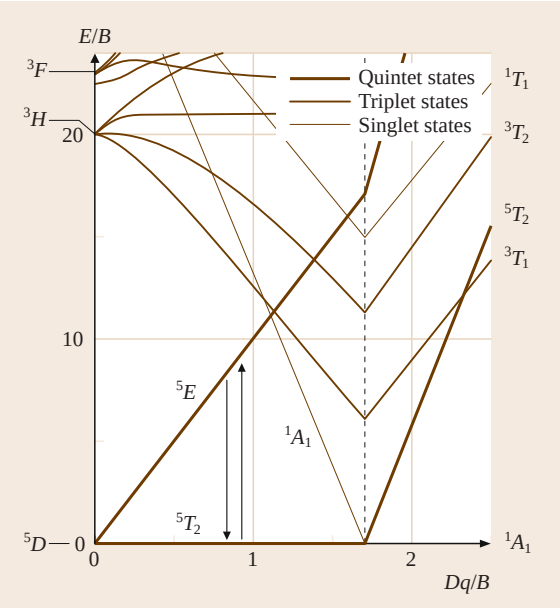

Fig. 11.85 Tanabe–Sugano diagram for tetrahedrally coordinated ions with $3d^4$ configuration, $C/B = 4$

Materials. The choice of host materials for the Cr^{2+} laser ion is limited due to special conditions. First, the materials have to exhibit a tetrahedrally coordinated lattice site. A divalent lattice site is also preferably, because otherwise a charge-compensation mechanism would have to be established in the lattice. Furthermore, host crystals with low phonon frequencies have to be chosen in order to decrease the possibility of nonradiative decay via multiphonon relaxation. Chalcogenide crystals, with their tetrahedrally coordinated divalent cation lattice sites and with phonon energies lower than 400 cm^{-1}, are thus very suitable with respect to the realization of efficient broadband emission in this mid-infrared spectral range. In Table 11.29 some material parameters of the investigated chalcogenide crystals are given in comparison to the data for Al_2O_3. The thermal conductivities of the chalcogenides are rather high and comparable to the values for Al_2O_3. However, the main disadvantages of the chalcogenide crystals are the growth techniques, which are Bridgman or vapor transport, which usually lead to a lower crystal quality than in the case of growth by the Czochralski method, and

Table 11.29 Materials parameter of some chalcogenide crystals suitable for Cr^{2+}. The data for $Y_3Al_5O_{12}$ are given for comparison. (*: for CdTe). (After [11.1266–1268]) w: Wurtzite, z: Zincblende

the high values for dn/dt, which lead to strong thermal lensing during laser operation, especially in the case of high-power operation.

Spectroscopy. The spectroscopy of Cr^{2+} ions in chalcogenide crystals has been thoroughly investigated in the past [11.1269–1277]. Tetrahedrally coordinated Cr^{2+} ions exhibit a broad band in the absorption spectrum due to the ${}^5T_2 \rightarrow {}^5E$ transition in the infrared spectral range with a maximum around 1.7–1.9 μm. The emission spectrum due to the ${}^5E \rightarrow {}^5T_2$ transition is also broad and occurs between 2 and 3 μm. The absorption and emission cross sections for the Cr^{2+}-doped chalcogenides are on the order of $\approx 10^{-18}$ cm^2; these are values expected for tetrahedrally coordinated transition-metal ions and are larger than those for Ti^{3+}:Al_2O_3 [11.1068]. The room-temperature absorption and emission spectra are shown in Fig. 11.86. The emission lifetimes at room temperature are on the order of several μs and the emission quantum efficiencies are close to unity. The $\sigma_{em}\tau$ product gives an indication of the expected laser threshold, because $P_{thr} \propto (\sigma_{em}\tau)^{-1}$. The values for the Cr^{2+}-doped chalcogenides are higher than in the case of Ti^{3+}:Al_2O_3, so that generally lower laser thresholds for the Cr^{2+}-doped materials are expected. The ratio between the emission bandwidth and the central emission wavelength, $\Delta\lambda/\lambda_{peak,em}$, is a measure for the principle ability to generate ultrashort pulses in the mode-locked regime; the higher this value, the shorter the pulses. The values for Cr^{2+}-doped crystals are comparable to those of Ti^{3+}:Al_2O_3, for which laser pulses shorter than 5 fs have been realized. However, one has to keep in mind that bandwidth is not the only important parameter for ultrashort-pulse generation. Other important parameters are the nonlinearities of the material and the thermal lensing introduced by the high peak power, which occurs in the mode-locked

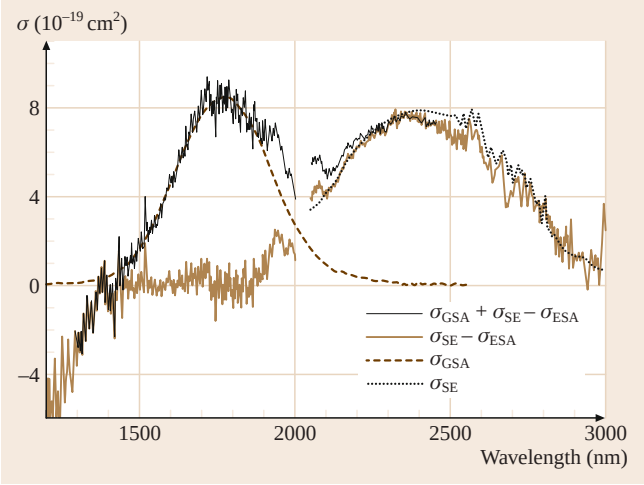

Fig. 11.86 σ_{GSA} (*dashed line*), σ_{SE} (*dotted line*), ($\sigma_{GSA} + \sigma_{SE} - \sigma_{ESA}$) (*thin solid line*), and ($\sigma_{SE} - \sigma_{ESA}$) spectrum (*thick solid line*) of Cr^{2+}:ZnSe at room temperature. The sharp structure beyond 2500 nm is attributed to the water absorption in air and the following normalization process. (After [11.1265])

regime. Only recently *Sorokina* et al. [11.1278] obtained mode-locking in the fs regime, after a lot of work was spent in order to understand the mechanisms behind the pulse-forming processes and how they can be controlled. In Table 11.30 the main spectroscopic data for the Cr^{2+}-doped chalcogenides are summarized in comparison to the data for Ti^{3+}:Al_2O_3.

For the tetrahedrally coordinated Cr^{2+} ion strong ESA transitions due to inner-shell 3d transitions are not expected, because all possible transitions are supposed to be spin-forbidden. This assumption was proven by ESA measurements [11.1265, 1285] (Fig. 11.86). Neither in the spectral region of the ground-state absorption nor in the emission region is ESA observed. Tunability up to and beyond 3 μm was predicted for Cr^{2+}:ZnSe [11.1265]. This prediction was later proven with laser experiments, where laser oscillation was observed up to 3100 nm [11.1286].

As far as electrically pumped emission and stimulated emission in the mid-infrared spectral range are concerned, Cr^{2+}:ZnSe is one of the most interesting materials. In recent investigations, room temperature electroluminescence of single crystalline and polycrystalline bulk Cr^{2+}:ZnSe was observed [11.1287, 1288]. Further work on Cr^{2+}:ZnSe is the production of thin films as active material in order to obtain wave guiding. *Vivet* et al. [11.1289] deposited thin Cr^{2+}:ZnSe films on glass, Si, or GaAs substrates at room temperature by radio-frequency magnetron sputtering. Excitation into the $^5T_2 \rightarrow {}^5E$ Cr^{2+} absorption band and also into the Cr^{2+}/Cr^{+} charge transfer band at 458 nm yields a typical broad band Cr^{2+} emission centered at around 2200 nm.

Laser Results. Laser materials based on the Cr^{2+} ion as the active ion have been investigated since the mid 1990s. Nowadays, Cr^{2+} lasers are operating in a variety of different operation schemes and under different excitation sources. In Table 11.31 an overview of the obtained laser results is given.

The best laser results were thus far obtained for Cr^{2+}:ZnSe. In different setups using different pump sources (Tm^{3+} lasers, Co^{2+}:MgF_2 lasers, diode lasers between 1.54 and 2.0 μm, erbium-doped fiber amplifiers) slope efficiencies up to 73%, output powers up to 7 W, thresholds lower than 100 mW, a tuning range of 2000–3100 nm and mode locking with pulse durations as short as ≈ 100 fs were obtained (Table 11.31). *McKay* and coworkers [11.1290] reported results of a thin-disc laser setup for a Cr^{2+}:ZnSe laser, a setup that was successfully applied to Yb-doped laser materials [11.1291]. This setup appears to be favorable also for Cr^{2+}:ZnSe, because *Wagner* and *Carrig* [11.1292] reported on thermal rollover in the case of high-power pumping. In McKay's experiment, a Q-switched Tm,Ho:YLF laser operating at 2.05 μm with a repetition rate of 10 kHz was used as the pump source. An output power of 4.27 W with a slope efficiency of 47% with respect to the absorbed pump power was obtained. The other possibility is to use a rather large pump beam radius of 260 μm ($1/e^2$ radius), as was done by *Alford* et al. [11.1293]. Using a 35 W Tm^{3+}:$YAlO_3$ as the pump laser, a continuous-wave output power of 7 W at 2.51 μm was achieved.

Besides ZnSe, other chalcogenide and mixed chalcogenide host materials for the Cr^{2+} ion are also suitable for efficient laser oscillation. For Cr^{2+}-doped ZnS, the spectroscopic characteristics are very similar to those of Cr^{2+}:ZnSe. From the material point of view, ZnS even seems to have some advantages over ZnSe as ZnS has a higher bandgap energy (3.84 eV for ZnS, 2.83 eV

for ZnSe), a higher hardness, a higher thermal conductivity [27 W/(m K) for ZnS (cubic phase), 19 W/(m K) for ZnSe] and a lower dn/dT (46×10^{-6} 1/K for ZnS, 70×10^{-6} 1/K for ZnSe) (Table 11.29). However, ZnS is much more difficult to grow and many different structure types exist. Thus far, the obtained laser results for Cr^{2+}:ZnS are not as good as the results for Cr^{2+}:ZnSe (Table 11.31). The highest output power obtained was about 700 mW at an absorbed pump power of 2.65 W from an Er-doped fiber laser [11.1294, 1295]. The thresholds are around 100 mW and are thus comparable to those observed for Cr^{2+}:ZnSe. The widest tuning range obtained so far is 2110–2840 nm. The highest slope efficiency in CW regime is about 40%. Direct diode pumping has also been realized, with an output power of 25 mW at an absorbed pump power of 570 mW [11.1294]. However, in the same setup a Cr^{2+}:ZnSe laser showed better results. Investigations revealed that the passive losses of the Cr^{2+}:ZnS crystal (14%/cm) were much higher than the losses from the Cr^{2+}:ZnSe crystal (4%/cm), indicating the larger problems with crystal growth and crystal quality in the case of Cr^{2+}:ZnS compared to Cr^{2+}:ZnSe.

Compared to ZnSe and ZnS, the thermal properties and material parameters of $Cd_{0.55}Mn_{0.45}Te$ are much worse, i. e., the dn/dT is higher and the thermal conductivity is lower (Table 11.29). Therefore, efficient laser operation was only achieved under pulsed pumping [11.1284]. An output power of 170 mW with a slope efficiency of 64% was realized for a repetition rate of 2 Hz; the tuning range was 2.17–3.01 µm [11.1284]. *Mond* et al. [11.1315] reported diode-pumped CW operation with an output power of 6 mW and a slope efficiency of 4%. A thermal rollover at higher pump powers was observed, indicating the strong thermal lensing problems. The threshold pump power was only

120 mW. This low value is expected from the spectroscopic parameters. Under diode pumping at a duty cycle of 1 : 4, the thermal rollover is not observed at the pump powers available. Then the highest output power is 15 mW with a slope efficiency of 5% and a threshold of ≈ 100 mW.

Cr^{2+}:CdSe exhibits a similar behavior to Cr^{2+}:$Cd_{0.55}Mn_{0.45}Te$, as expected from the material parameters and spectroscopic characteristics. Thus also strong thermal lensing and power-handling problems are encountered in the laser experiments. CW laser operation has not yet been reported, however, the laser results under pulsed pumping are very promising. Using a Q-switched Tm,Ho:YAG laser operating at 2.05 μm with a repetition rate of 1 kHz, a maximum output energy of 0.5 mJ per pulse and a slope efficiency of 50% was obtained [11.1300]. The highest average output power was 815 mW [11.1307] while the largest tuning range achieved thus far is 2.4–3.4 μm [11.1302].

In order to overcome the difficulties in the crystal growth of single crystalline Cr^{2+}-doped chalcogenides, the use and the investigation of polycrystalline material is interesting. For polycrystalline Cr^{2+}:ZnS an output power of more than 7 W at 2410 nm and tunability between 1940 and 2780 nm at room temperature was obtained [11.1330]. It should also be noted that Cr^{2+}-doped chalcogenides are also of interest for random lasing in the mid-infrared spectral range. Room temperature laser oscillation between 2240 and 2630 nm was obtained with different semiconductor mixtures based on Cr^{2+}-doped ZnSe, ZnS, and CdSe powders, and powders imbedded in polymer liquid solutions and polymer films [11.1331].

Outlook for Cr^{2+} Systems. Cr^{2+}-doped materials are highly efficient lasers in a very interesting wavelength range for application; see the overview in Table 11.31. In all materials investigated, the material parameters are still a large problem, i. e., the quality of the crystals, the strong thermal lensing, the high nonlinearity, yielding a strong tendency for self-focusing, and the relatively low damage threshold. All these problems are most severe for CdMnTe and CdSe. Therefore, the thin-disc setup may be a way to overcome some of these problems. Another alternative is the use of larger pump and laser modes. As far as ultrashort-pulse generation is concerned, *Sorokina* et al. recently realized mode locking in the fs regime [11.1332]. Thus far, only a few materials have been investigated for laser applications. Therefore, there is a possibility to look for different host materials for the tetrahedral Cr^{2+} ion, e.g., $ZnGa_2S_4$, $ZnGa_2Se_4$, $CaGa_2S_4$, and $CaGa_2Se_4$. Also, the recent work on thin films and electroluminescence may pave the way towards an electrically pumped laser oscillation, which will provide an enhancement in quantum efficiency.

Other Transition-Metal-Ion Lasers.

V^{2+} Lasers. The V^{2+} ion is isoelectronic to the Cr^{3+} ion. Therefore, its energy-level scheme can also be described with the Tanabe–Sugano diagram shown in Fig. 11.82. The absorption spectra of octahedrally coordinated V^{2+} is similar to that of Cr^{3+}, but red-shifted due to the lower valence of the V^{2+} ion. The spectra are dominated by the three broad spin-allowed bands

due to transitions between the $^4A_2(^4F)$ ground state and the $^4T_2(^4F)$, $^4T_1(^4F)$, and $^4T_1(^4P)$ excited states. The emission spectra consist of a broad band due to the $^4T_2(^4F) \rightarrow {}^4A_2(^4F)$ transition, also shifted to longer wavelengths compared to the emission spectra of Cr^{3+}. Laser oscillation with V^{2+} on the $^4T_2(^4F) \rightarrow {}^4A_2(^4F)$ transition was realized only in MgF_2 [11.1325–1327] and $CsCaF_3$ [11.1328, 1329]. An overview of the obtained laser results is given in Table 11.32. The laser efficiencies are very low. *Payne* et al. [11.44, 1333] and *Moncorgé* et al. [11.1334] found that ESA is the dominant loss mechanism for laser oscillation. In some materials nonradiative decay also competes with the emission, leading to small emission quantum efficiencies.

Ni^{2+} Lasers. The energy-level scheme of octahedrally coordinated Ni^{2+} in crystals can be described with the Tanabe–Sugano diagram shown in Fig. 11.87. In the absorption spectra, three bands according to the spin-allowed transitions from the $^3A_2(^3F)$ ground state to the $^3T_2(^3F)$, $^3T_{1a}(^3F)$, and $^3T_{1b}(^3P)$ excited states are observed. The laser transition of Ni^{2+} lies in the infrared spectral range due to the $^3T_2(^3F) \rightarrow {}^3A_2(^3F)$ transition. Its spectral position is strongly wavelength dependent (Table 11.33). The emission lifetime is typically on the order of ms and the emission quantum efficiency is near unity at room temperature in most materials.

Despite these advantageous spectroscopic data, laser oscillation with Ni^{2+} was obtained only at temperatures below 240 K and only in a few materials (Table 11.33). The absence of laser oscillation at room temperature can be explained by excited-state absorption (ESA), which overlaps with the spectral range of emission. Detailed measurements of the ESA for several Ni^{2+}-doped crystals were performed by *Koetke* et al. [11.1344, 1346]. With increasing temperature the excited-state absorption and ground-state absorption bands become broader and thus overlap to a larger extent with the stimulated emission. As a result, the spectral region where $\sigma_{eff} = \sigma_{se} - \sigma_{ESA} > 0$ becomes narrower. Furthermore, the losses due to ground-state

absorption increase. However, at low temperatures output powers up to 10 W and slope efficiencies up to 57% were obtained [11.1327].

Mn^{5+} Lasers. The Mn^{5+} ion incorporates into crystals mainly at tetrahedrally coordinated lattice sites. Its energy-level scheme can be described with the Tanabe–Sugano diagram shown in Fig. 11.83. Compared to Cr^{4+}, the crystal field is higher due to the higher valence state, thus the Mn^{5+} ion exhibits narrow-line emission due to the $^1E(^1D) \rightarrow {}^3A_2(^3F)$ transition. Optical properties of Mn^{5+} ions in solids have been under investigation for more than 30 years [11.1347, 1349–1356]. Mn^{5+} laser operation at room temperature was demonstrated by *Merkle* et al. in $Ba_3(VO_4)_2$, $Sr_3(VO_4)_2$, and in $Sr_5(VO_4)_3F$ [11.1357–1359], see Table 11.34. The laser transition is realized between the $^1E(^1D)$ excited state and the $^3A_2(^3F)$ ground state, thus these lasers are three-level systems. The efficiency is rather low (laser output energy ≈ μJ, $\eta_{sl} \leq 1.6\%$) and laser oscillation from other Mn^{5+} systems has not been reported. The major drawback for these lasers is the excited-state absorption at the stimulated-emission wavelength. Investigations of the excited-state absorption and gain were performed in detail by *Verdún* [11.1356], *Merkle* et al. [11.1357], *Manaa* et al. [11.1360] and *Kück* et al. [11.1053, 1348].

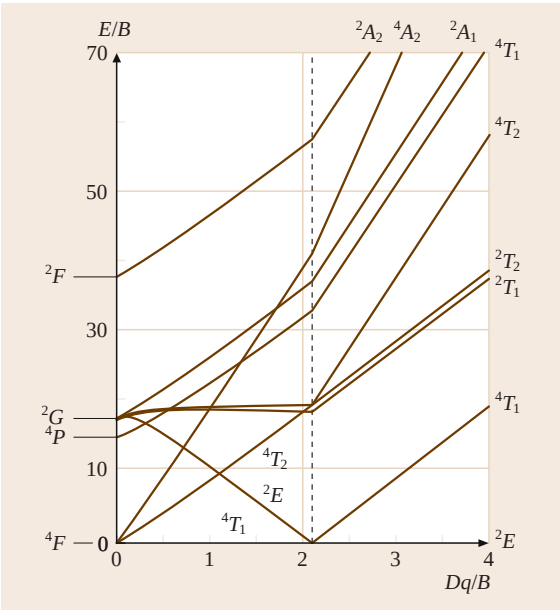

Fig. 11.88 Tanabe–Sugano diagram for the d^7 configuration (after [11.36])

To obtain a four-level system, one should search for crystals with low crystal field strengths or with large energy-level splittings. Then the $^3T_2(^3F)$ or one of its crystal field components would be the lowest-energy level. However, thus far Mn^{5+} systems exhibiting broadband emission are not known.

Co^{2+} Lasers. The Co^{2+} ion in octahedral coordination exhibits laser oscillation in the mid-infrared spectral region between 1.5 and 2.5 μm. Its energy-level scheme can be described with the Tanabe–Sugano diagram for the $3d^7$ electron configuration shown in Fig. 11.88. Three broad and spin-allowed transitions between the $^4T_{1a}$ ground state and the $^4T_2$, $^4A_2$ and $^4T_{1b}$ excited states exist. In MgF_2, these transitions are located around 7000, 15 000, and 20 000 cm^{-1}, respectively [11.1361]. The emission occurs between 1.5 and 2.5 μm, according to the $^4T_2 \rightarrow {}^4T_{1a}$ transition. At low temperatures, the lifetimes are on the order

Table 11.35 Room temperature laser results for the Fe^{2+}:ZnSe laser. λ_p: pump wavelength, λ_c: center laser wavelength, E_{out}: output energy, η_s: slope efficiency, E_{in}: input energy, E_{abs}: absorbed input energy

Pump source	λ_p (μm)	λ_c (μm)	Tuning range (μm)	E_{out}	η_s (%)	References
Nd:YAG, 2nd Stokes	2.92		3.9–4.8	1 μJ	–	[11.1363]

of several ms, while at room temperature the emission is strongly quenched due to nonradiative decay via multiphonon relaxation, yielding very low quantum efficiencies [11.1362]. Excited-state absorption overlaps with the $^4T_{1a} \rightarrow {}^4T_2$ absorption band, which is the main pump band for laser operation. In the region of stimulated emission, the excited-state absorption is negligible [11.1361].

Laser oscillation was obtained in the continuous-wave regime only at cryogenic temperatures, while pulsed laser operation was also realized at room temperature for Co^{2+}-doped MgF_2 and $KZnF_3$. An overview of the laser results for Co^{2+} laser systems is given in Table 11.35. The best laser results were obtained for Co^{2+}:MgF_2, which is also a commercial laser system. With Co^{2+}:MgF_2 an overall tuning range of 1.5–2.5 μm was realized with output powers up to 4.2 W, output energies up to 1.6 J and slope efficiencies as high as 65%. As the pump source, Nd:YAG or Nd:glass lasers around 1.3 μm are usually used, however, laser oscillation has also been realized under flashlamp pumping, argon-ion laser excitation and oxygen–iodine laser excitation. Operation regimes are CW, pulsed, Q-switched and mode-locked.

Fe^{2+} Lasers. The Fe^{2+} ion has a $3d^6$ electron configuration that is complementary to that of Cr^{2+}. The ^5D free-ion state also splits into a $^5T_2$ and a ^5E state, however, for the Fe^{2+} ion ^5E is the ground state and $^5T_2$ is the first excited state. Consequently, there is just one spin-allowed absorption ($^5E \rightarrow {}^5T_2$) and emission ($^5T_2 \rightarrow {}^5E$) transition. As for the Cr^{2+} ion, all excited-state transitions are spin-forbidden. Thus, one might expect similar laser characteristics for Fe^{2+}-doped lasers as for Cr^{2+} lasers. However, the energy gap between the $^5T_2$ excited state and the ^5E ground state is smaller, thus the emission is at longer wavelengths and the nonradiative decay rate is higher, leading to lifetime shortening and low quantum efficiencies at elevated temperatures. For Fe^{2+}:ZnSe, the emission lifetime first increases from 12 to 120 K from 33 to 105 μs and then decreases to about 5 μs at 250 K due to thermally activated multiphonon decay [11.1366, 1367]. At 14 K, the $^5E \rightarrow {}^5T_2$ absorption band is between 2.5 and 3.75 μm, and the $^5T_2 \rightarrow {}^5E$ emission band is between 3.7 and 4.8 μm.

Room-temperature tunable laser oscillation in a pulsed regime pumped around 2.9 μm by an Er:YAG laser or the 2nd Stokes component of a Nd:YAG laser was reported for Fe^{2+}:ZnSe [11.1363–1365], see Table 11.35. Output energies up to 1.4 mJ and slope efficiencies up to 11% were obtained. The maximum laser tuning range was from 3.9 to 5.1 μm. Laser oscillation of Fe^{2+}:ZnSe at lower temperatures was reported in [11.1366–1369]. In *n*-InP, Fe^{2+} laser oscillation was obtained at 2 K at 3.53 μm, i. e., at the zero-phonon transition [11.1370].

Lasers Based on the Bismuth Ion. Recently laser oscillation in glass fibers was obtained with the bismuth ion as an active ion [11.1371, 1372]. Tunability between 1150–1215 nm, output powers in the Watt-range and slope efficiencies of ≥ 20% were achieved. Furthermore, laser oscillation was also obtained in the wavelength region around 1450 nm. Mode-locked operation was obtained with Bi-doped fibre lasers, the minimum pulse length was 0.9 ps. Although detailed spectroscopic studies have been performed [11.1373, 1374], the valence state of the bismuth ion has not been identified and is still under discussion. The laser results obtained are summarized in Table 11.36.

Summary

In this chapter an overview of transition-metal-ion-doped crystals as solid-state laser materials is given. It was shown that they are efficient (usually tunable) laser sources covering a wide spectral range (Fig. 11.78). However, compared to lasers based on $4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions, they play only a small role as far as commercialization is concerned. In principle only the Ti^{3+}:Al_2O_3 and – with limitations – the Cr^{3+}:$BeAl_2O_4$ laser can be mentioned. These lasers are mainly used in the field of scientific research. The main reason for this is that their advantages, i. e., their tunability and their capability to generate ultrashort pulses, are not relevant for most industrial applications. They exhibit lower output power than lasers based on

$4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions (e.g., Nd^{3+}:YAG, Yb^{3+}:YAG) and are more expensive and less efficient than diode lasers. Direct diode-laser pumping is either inefficient or – in the case of Cr^{3+} and Cr^{2+} lasers – requires laser diodes that are not yet available at a satisfactory price and quality on the market.

Transition-metal-ion and especially tunable laser systems exhibit a stronger coupling of the electronic levels to the vibrating lattice of the crystal. This leads to higher possibilities for ESA and nonradiative decay processes compared to the $4f^n \rightarrow 4f^n$ transitions of trivalent rare-earth ions in crystals.

The main problem in realizing efficient laser oscillation is the excited-state absorption from the metastable upper laser level. From (11.86) and (11.87) its effect on laser threshold and slope efficiency becomes clear. It occurs in principle for every electron configuration, either as intra- or interconfigurational transitions or as a transition to charge transfer or conduction-band-related levels. The electron configurations are in general favorable, when intraconfigurational excited-state absorption transitions are not possible, e.g., in the d^1 and d^9 configuration, or are less strong due to selection rules, e.g., in the d^4 and d^6 configurations. Other configurations exhibit more-complex energy-level schemes, therefore intraconfigurational ESA transitions occur with high probability in the spectral regions of emission and excitation. The influence of ESA, however, can even in this case be reduced, e.g., by taking advantage of polarization-dependent transition rules, which result in higher stimulated-emission cross sections than ESA cross sections, as it is the case, e.g., for Cr^{3+}:$LiSrAlF_6$ and Cr^{4+}:$Y_3Al_5O_{12}$.

The role of nonradiative decay for the realization of efficient laser operation is less important, although not negligible. It affects to a first approximation only the laser threshold, which is increased (11.83). However, a nonradiative rate leads to a temperature increase in the pump channel, which also affects the overall laser characteristics. Thus, its general influence depends strongly on the material parameters of the laser system, i. e., mainly of the host material. Materials with a high thermal conductivity and mechanical strength are favored. As an example, Cr^{4+}:$Y_3Al_5O_{12}$ can be given. Here, the quantum efficiency is less than 20%, whereas laser operation with a slope efficiency close to 40% was realized.

Table 11.37 gives an overview of the transition-metal ions in octahedral and tetrahedral coordination

investigated to date. They are listed according to their corresponding energy-level diagram (i. e., Tanabe–Sugano diagram). The laser-active transition-metal ions are indicated. Almost all transition-metal ions with different valence states and ligand coordinations have been investigated thus far. Efficient room-temperature laser oscillation was only obtained for Ti^{3+} and Cr^{3+} in octahedral and for Cr^{2+} and Cr^{4+} in tetrahedral coordination. Whether efficient laser operation will also be obtained for other ions depends very much on the host material chosen. For example, the Ti^{3+} ion exhibits efficient laser operation only in Al_2O_3. Therefore, other ions cannot a priori be excluded as efficient laser ions.

11.2.6 Overview of the Most Important Laser Ions in Solid-State Lasers

Research on laser materials has created a number of compact, efficient solid-state laser sources for a large variety of applications. Laser materials have been developed for various wavelengths (near-infrared, visible, UV) and power regimes (mW to multi-kW). Special geometries of the active material (microchip, rod, disc, fiber) strongly correlate with the active ion concentrations and cross sections of absorption and gain transitions.

The values of the cross sections depend on the quantum numbers of the final and initial states as well as on the local environment of the active-ion site in the material. The lifetimes of the states are influenced by radiative and nonradiative transitions. So, the microscopic crystal properties play an important role for static and dynamic processes in the laser crystal.

In the near-infrared spectral region high efficiencies have been achieved with diode-pumped oxide- and fluoride-based laser materials doped with the rare-earth ions Nd^{3+}, Tm^{3+}, Ho^{3+}, Er^{3+}, and Yb^{3+}. For high-average-power operation Nd^{3+}- and Yb^{3+}-doped crystals are of greatest interest. Especially the Yb^{3+} ion exhibits very small Stokes losses and minimum heat generation, which reduces thermal lensing and improves beam quality. Transition-metal-doped crystals based on the ions Ti^{3+}, Cr^{2+}, Cr^{3+}, and Cr^{4+} offer broadly tunable radiation within the spectral region 680–3000 nm. In the visible region Er^{3+}-, Tm^{3+}-, and Pr^{3+}-doped laser materials operate at several red, green, and blue transitions with laser diode upconversion and/or direct pumping. So far Ce^{3+} is the only ion with reasonable direct laser performance in the UV.

The following wavelength data provide a rough guide to the spectral range of the various laser ions.

Near-IR Rare-Earth Lasers.

Nd^{3+}	0.9, 1.06, 1.3 μm
Yb^{3+}	1–1.1 μm
Tm^{3+}	2, 1.5 μm (upconversion)
Ho^{3+}	2 μm
Er^{3+}	1.6, 3, 0.85 μm (upconversion)

Visible Rare-Earth Lasers.

Pr^{3+}	0.64 μm (diode-pumped)
Pr^{3+},Yb^{3+}	0.52, 0.63 μm (upconversion)
Er^{3+}	0.55 μm (upconversion)
Tm^{3+}	0.45, 0.48, 0.51, 0.65, 0.79 μm (upconversion)

Frequency doubling of near IR rare-earth lasers (Nd, Yb).

UV Rare-Earth Lasers.

Ce^{3+}	0.3 μm

Frequency doubling of visible rare-earth lasers.
Frequency tripling/quadrupling of near-IR lasers.

Transition-Metal Lasers.

Ti^{3+}	0.68–1.1 μm
Cr^{3+}	0.7–1.1 μm
Cr^{4+}	1.2–1.6 μm
Cr^{2+}	2–3 μm.

11.3 Semiconductor Lasers

11.3.1 Overview

In crystalline solids the interaction between *atomic energy levels* generates energy bands. A quantum-mechanical treatment provides, in the single-electron approximation, energy bands which overlap which each other or are separated by bandgaps from each other. In semiconductors, we find between the energetically highest band, which is fully occupied by electrons at $T = 0\,\mathrm{K}$, the valence band (VB), and the energetically lowest band, which is completely empty at $T = 0\,\mathrm{K}$ the conduction band (CB) an energy range, in which we

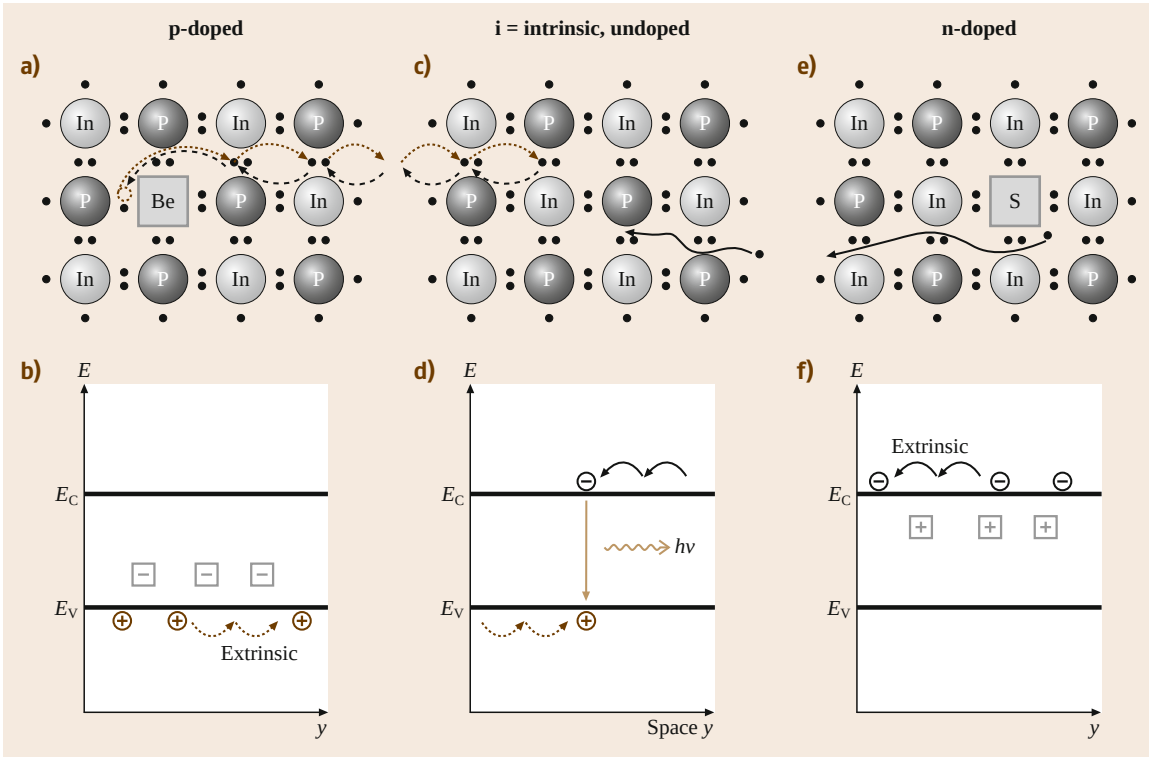

Fig. 11.89a–f Schematic of a planarized lattice structure of p-doped, undoped and n-doped InP **(a,c,e)**. *Below* are the corresponding band structures in space **(b,d,f)**. The dopants are indicated by *squares*, the *full lines* indicate the movement of electrons, the *broken line* the movement of defect electrons (= holes) in space and the *dotted line* the movement of holes on the VB

find no allowed energy states, disregarding energy states originating from dopants. This bandgap E_g is the energy difference between the lower conduction-band edge E_C and the upper valence-band edge E_V. For laser operation an extreme deviation from thermal equilibrium (nonthermal carrier distribution) is required: carrier inversion. In the CB close to E_C carrier inversion means a much higher density of electrons than holes and in the VB close to E_V a much higher density of holes than electrons. This extremely nonthermal condition is generated by strong electrical or optical pumping of the laser-active material. The electrical carrier injection in most cases is obtained by a p-i-n heterojunction made of III/V semiconductor materials. Choosing InP as a typical example, Fig. 11.89 displays a planarization (projection into 2-D space for simplification) of the real 3-D zinkblende crystal structure with the corresponding band structures below. From the left to the right p-InP, intrinsic i-InP and n-InP are shown (Fig. 11.89a,c,e).

In the highly p-doped InP bulk regions, at room temperature nearly all acceptors have released their holes into the valence band. Well away from the pn junction the hole field current (drift current) dominates the carrier transport. At the left edge of the device, holes are generated under the p contact. At the right edge of the device, electrons are injected through the n contact. Well away from the pn junction the electron field current dominates the carrier transport there. The bandgap E_g nearly equals the energy of the photons generated in the central intrinsic region. However, such a homojunction p-i-n structure (Fig. 11.89) suffers from enormous carrier leakage and the lack of a medium guiding the generated light. To enable operation at room temperature and considerably reduce the threshold currents at least a double heterostructure (heterojunction p-i-n structure) is required (Fig. 11.90). This Nobel-prize-winning idea by *Kroemer* and *Alferov* [11.1379, 1380] enables carrier confinement and optical confinement by a single important modification: using higher-bandgap

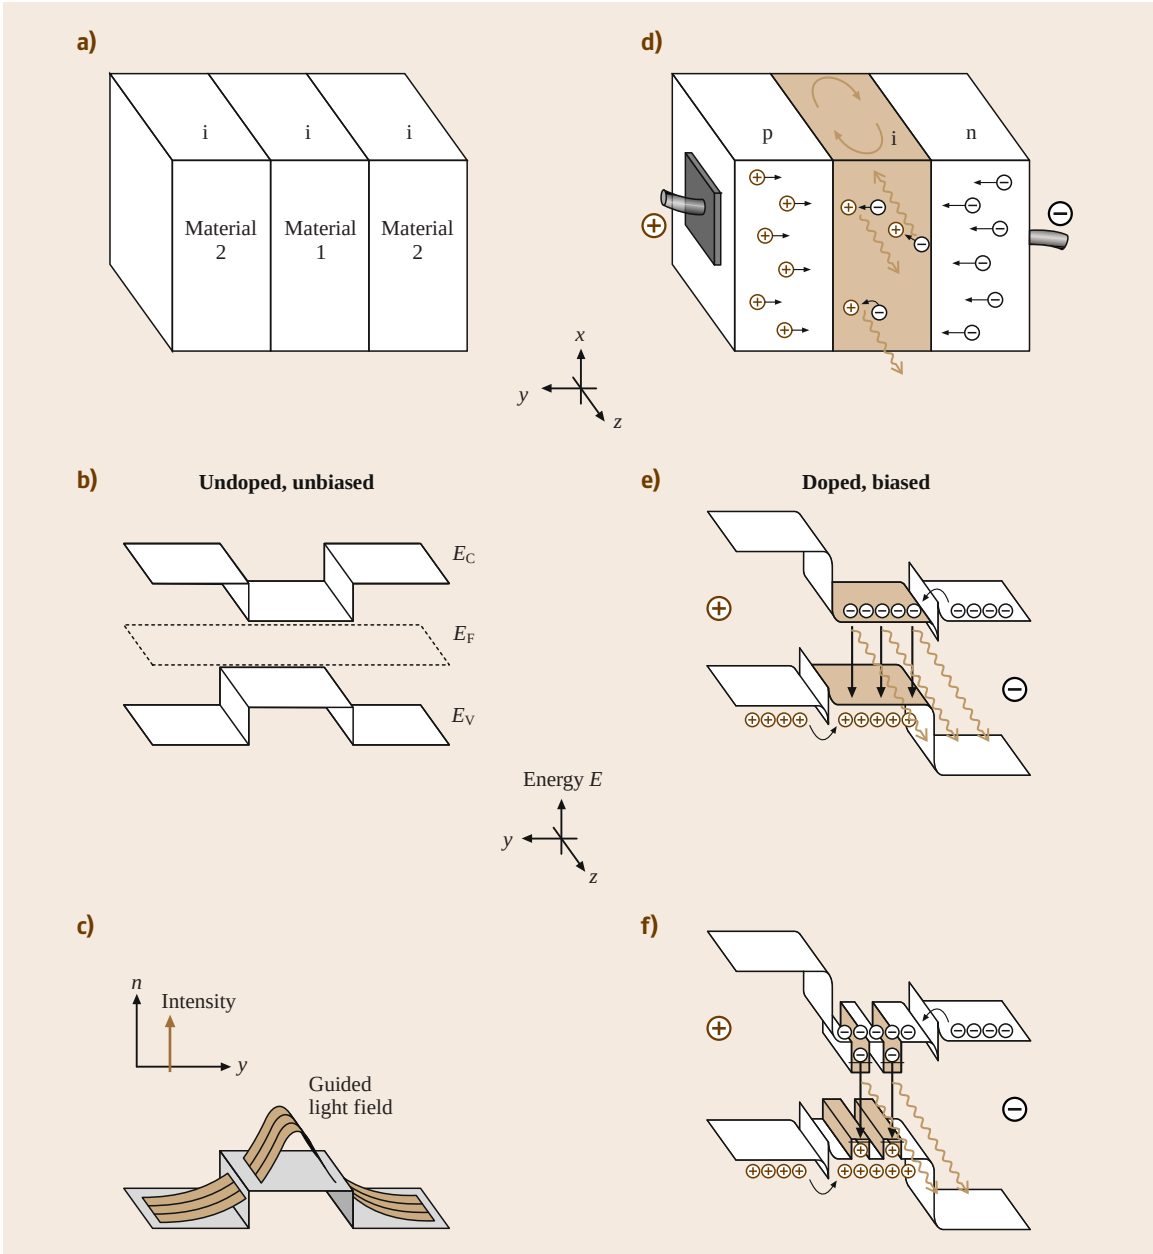

Fig. 11.90a–f Undoped and unbiased **(a,b)** and doped and biased **(d,e,f)** separate confinement heterostructures, **(a,d)** schematic layer structure in space, **(b,e,f)** the corresponding band structures in space. E_g materials for the p and n regions compared to the central intrinsic active layer. Thus, for semiconductor lasers at least two different materials are required, as shown in space $z(x, y)$ (Fig. 11.90a) and in the band structure $E(y, z)$ in space (Fig. 11.90b) for an undoped and unbiased structure. The central layer (material 1) has a lower E_g than the embedding bulk layers (materials 2) and therefore electrically confines electrons

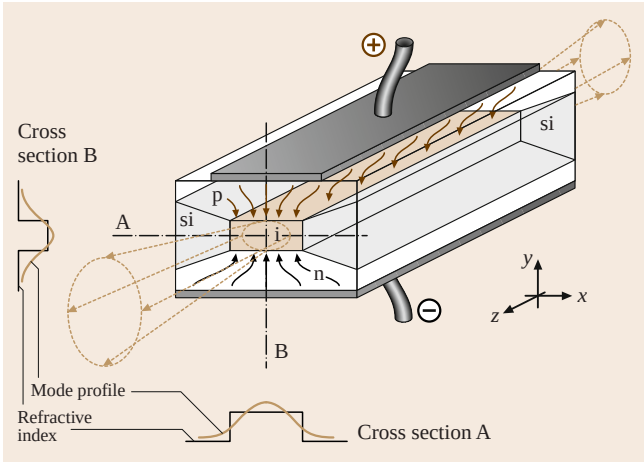

Fig. 11.91 Schematic of a semiconductor laser with 3-D laser-active layer and buried waveguide. *Insets*: refractive index profiles and mode profiles in the *x*- and *y*-directions intersecting the active layer at A and B, respectively

in the CB and holes in the VB, which is visualized by the band edge. Since for semiconductors decreasing E_g in nearly all cases increases the refractive index n we fortunately obtain an optical waveguide: a central higher-n material embedded in a lower-index material (Fig. 11.90c). Thus, the laser-active layer is the core layer of the waveguide at the same time. By a proper design, essentially of the refractive index differences and dimensions, we can efficiently guide the generated light in a fundamental mode (see the profile in Fig. 11.90c) similar to a single-mode optical fiber. Considering an edge-emitting laser, the structure is now p-i-n doped and forward-biased (Fig. 11.90d), enabling the carrier transport described above: hole injection from the left and electron injection from right. The band structure (Fig. 11.90e) of the doped and biased laser structure visualizes the operation of the p-i heterointerface acting as a border (electrical confinement) for the electrons. The small potential barrier at the i-n heterointerface is no real obstacle. The electrons can tunnel through or thermally jump across. In analogy, the p-i heterointerface is no real obstacle for the holes, whereas the n-i heterointerface provides the required border (electrical confinement). Modern semiconductor lasers, however, include quantum wells (QWs, a 2-D carrier system) [11.1381] or quantum dots (QDs, a 0-D carrier system) [11.1382] as the laser-active medium, instead of a 3-D laser-active region in bulk lasers (Fig. 11.90e). In Fig. 11.90f two QWs are depicted as an example, providing the emission energy as the difference between the energetically lowest bound states in the wells (note that the ordinate indicates the electron energy).

Finally, electrical and optical confinement in the *y*-direction (Fig. 11.90c) has to be completed by electrical and optical confinement in the *x*-direction (Fig. 11.91). Note that this figure is rotated by 90° with respect to Fig. 11.90. In Fig. 11.91 the active material is embedded in the *x*-direction by semi-insulating (si) material to force the current to move mainly in the active layers (lateral electrical confinement). The si material is chosen to have a higher bandgap, and thus a lower refractive index, than the active material (lateral optical confinement). Also in this case, wave guiding is applied in the *x*- and *z*-directions. This is shown in the two insets by the two cross sections A and B, showing the refractive-index profiles and light-intensity profiles. Here, waveguiding in fundamental mode is shown for the case of bulk 3-D active layers.

11.3.2 Resonator Types and Modern Active Layer Materials: Quantum Effects and Strain

Modern optoelectronic semiconductor devices are based on a sequence of materials of different composition. Embedding a film of lower E_g between a material of larger E_g, we obtain quantization effects if the film thickness L_y is on the order of the electron wavelength or below (QW) [11.1381]. Using the Schrödinger equation, we obtain at least one bound state in the CB and VB potential wells, respectively. The electrons and holes are still fully mobile in the *x*- and *z*-directions. This means that a wavevector $\boldsymbol{k}_{||}$ parallel to the heterointerfaces exists. The motion in the *y*-direction is considerably restricted and statistically described by quantum mechanics. Figure 11.92 displays the VB structure in *k*-space ($\boldsymbol{E}(\boldsymbol{k}_{||})$) obtained by a theoretical model calculation [11.1383] based on the Schrödinger equation for four different Ga(In)As/(Al)GaAs QWs ($\boldsymbol{k}_{||}$ is oriented parallel to the heterointerfaces).

In most cases in addition the QWs and the barriers in the active layer are additionally strained [11.1384]. Usually, the wells are compressively strained, which means that the lattice constant of that layer is compressively reduced in the *x*- and *z*-directions to match that of the substrate a_0. In many cases, the barriers are in tension, which indicates that the lattice constant of the barriers is increased in the *x*- and *z*-directions by tensile strain to be identical to the substrate lattice constant a_0.

Strain and quantization effects in the active layers of semiconductor lasers are used to improve the de-

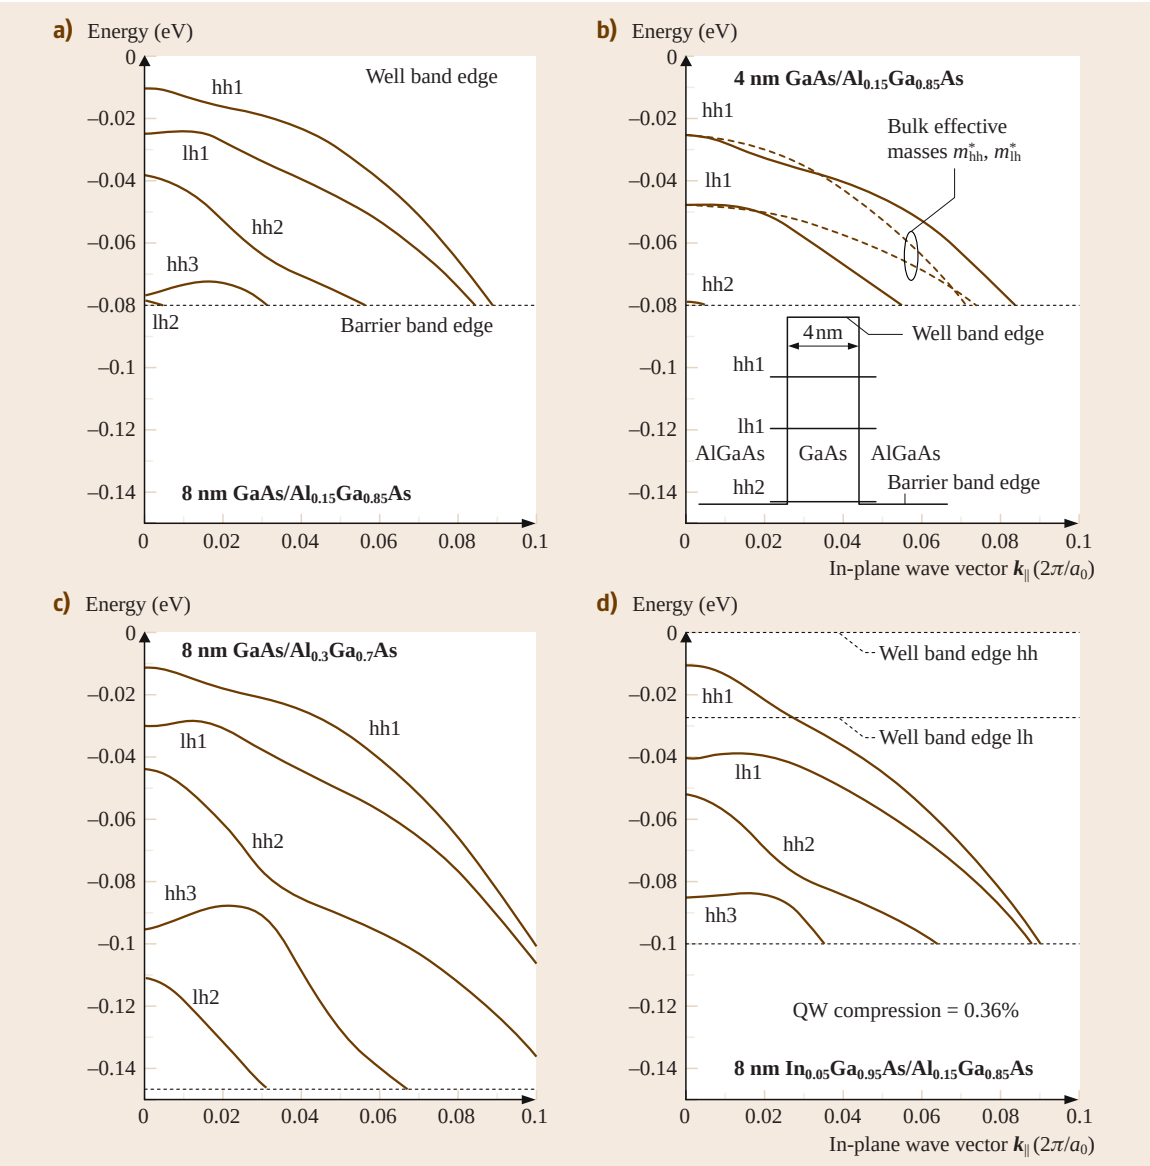

Fig. 11.92 Valence-band structure $\boldsymbol{E}(\boldsymbol{k}_{\|})$ of various Ga(In)As/AlGaAs QWs (after [11.1383])

vice properties. For the laser it is beneficial to make the effective masses of electrons and holes as similar as possible, to increase material gain, to reduce threshold, to tailor the density of states and to increase differential gain. This can be obtained by applying strain and/or quantization. In Fig. 11.93, the energy dependence of the density of states is shown for 3-D material to be root-like, and to be constant for 2-D material.

Figure 11.94 depicts examples of InAs [11.1385] and CdSe [11.1386] QDs. Schematically, Fig. 11.94a shows the QD formation in a cross section of the crystal structure. We see the three upper monolayers of the GaAs substrate. During the self-organized QD formation the intentionally integrated strain (a detailed explanation is given below) of the InAs versus GaAs plays an important role. For thermodynamical and elas-

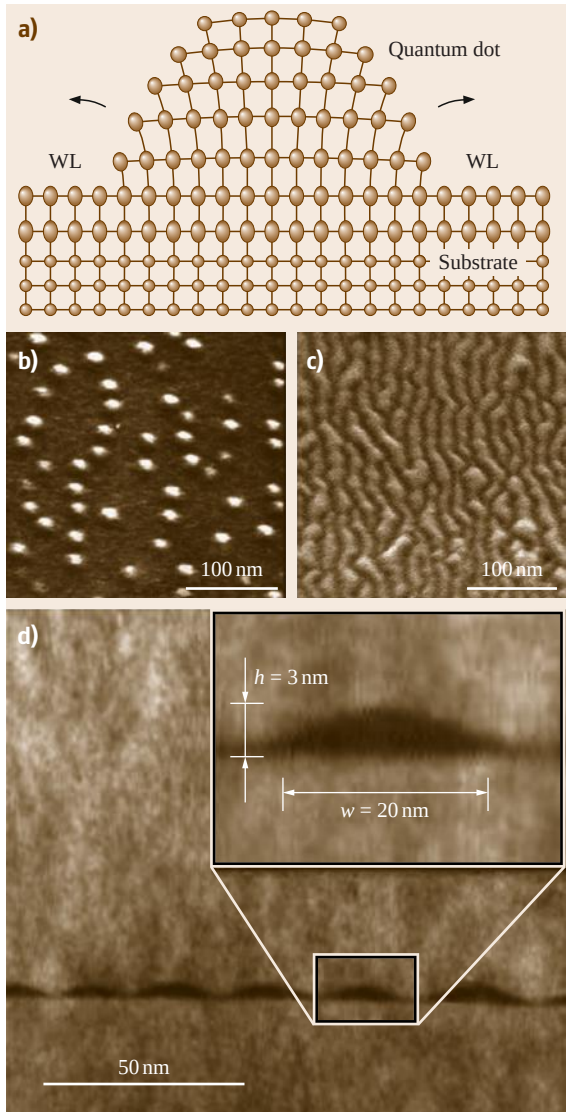

Fig. 11.94 **(a)** *From the bottom to the top* we see in sequence: the three top monolayers of the GaAs substrate, above two compressively strained monolayers InAs (wetting layer, WL) and above the main part of the QD. **(b)** SEM surface images of an InAs QDs on GaAs (after [11.1387]). **(c)** InAs quantum dashes on a GaInAlAs lattice matched to InP. **(d)** XTEM image of a quantum dash layer perpendicular to the elongated direction. The *inset* shows a magnification of a single dash (after [11.1388])

tomechanical reasons, two monolayers of strained InAs are first formed. For the growth to continue, for total-energy reasons, it is of considerable advantage for the semiconductor surface to continue by a localized island-like growth. In this case a possible geometric shape is a pyramid with a base plane directly joined to the top of the InAs monolayers. Experimentally, this phase can be directly studied using an atomic force microscope (AFM) [11.1382, 1387, 1388]. Figure 11.94b,c displays

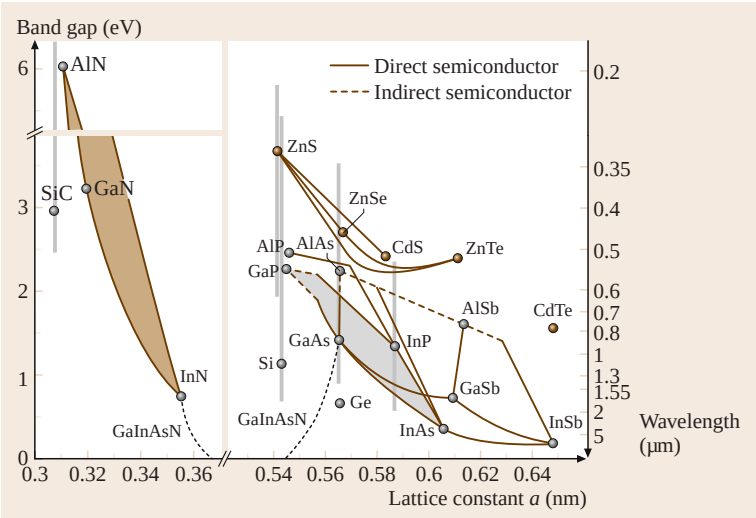

Fig. 11.95 Bandgap energy E_g (*left*) and bandgap wavelength (*right*) as a function of the lattice constant *a*

in a top view a typical AFM surface profile. In the next process step (Fig. 11.94d) the QDs are overgrown by AlGaInAs and thereby embedded. Experimentally, the final layer sequence can be studied by transmission electron microscopy (TEM) after cleaving. In order to increase the number of QDs in the direction perpendicular to the substrate interface, the whole InAs process can be repeated as often as desired after a defined spacer layer thickness [11.1389]. This provides layered QD arrangements.

However, quantization is not limited to a single direction. If we limit the carrier movement in another direction (e.g., in the *z*- and *y*-direction as in Fig. 11.93), we obtain a 1-D carrier system and, thus, a quantum wire [11.1390] with hyperbolically shaped density of states branches. Limitation of carrier movement in all three space directions results in quantum dots [11.1382, 1383, 1385, 1386, 1390–1397], i. e., a zero-dimensional (0-D) carrier system with a δ-like density of states (Fig. 11.93d). For many physical properties of the semiconductor (e.g., carrier mobilities, carrier capture in quantized states and spontaneous or stimulated emission of light), the density of states plays an important role. Using dimensionality and strain efficiently during the design of lasers enables one to enhance desired and suppress undesired properties. Here, modern epitaxy (e.g., metal organic chemical vapour deposition (MOCVD) and molecular beam epitaxy (MBE)) are powerful tools. To date 2-D and 0-D structures have been used successfully for laser devices. 1-D structures have not yet had a breakthrough due to their disadvantageous dynamic properties. QDs are grown today using self-organization in the Stranski–Krastanow growth mode [11.1385, 1390, 1392, 1396]. By growing a large number of QDs with identical quantized energy levels in the laser-active layer, we would benefit from a strongly reduced temperature sensitivity and a very high differential gain and, thus, extremely high bit rates in optical communication. Although many QD lasers have been implemented, the pyramid-like QDs suffer from strong fluctuations in size and thus in their energy levels.

On the basis of these QDs, however, the aforementioned improvements in device properties have not yet be demonstrated. On the other hand, the strong fluctuation causes a strongly spectrally broadened gain profile, which is beneficial for other applications, e.g., short-pulse generation by mode locking or wide spectral tuning of the laser device. Of course, we should also remember that 10 years were necessary after implementing the first QW lasers to demonstrate that QW lasers were superior to bulk lasers. Similarly, QD lasers will require time before their final breakthrough. However, we believe that QW and QD lasers will share the application area in the future, depending on the specific requirements.

Figure 11.95 shows the dependence of the bandgap on the lattice constant for various III/V and II/VI semiconductors. The brown area corresponds to the quaternary $Al_zGa_{1-x-z}In_xN$. The grey area describes the quaternary $Ga_{1-x}In_xAs_{1-y}P_y$. For high laser efficiencies in interband lasers, active materials with a direct bandgap are required, disregarding for the moment some intraband lasers. Note that simple bulk Si

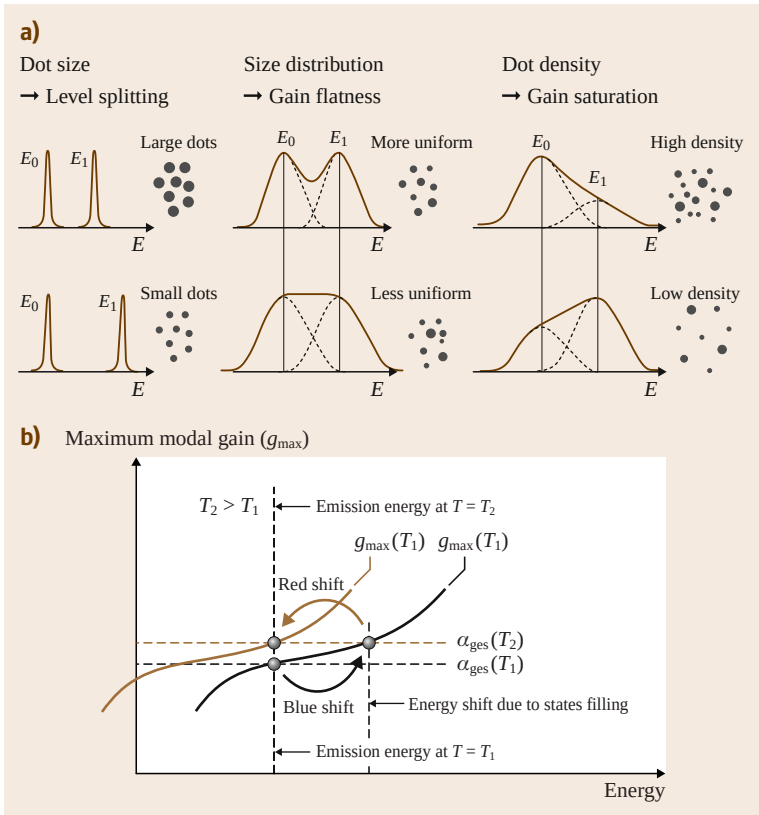

Fig. 11.97 (**a**) Impact of three major geometrical parameters of QDs on optical material properties (after [11.1399]). (**b**) Methodology of internal compensation of laser emission energy shift in QD gain materials (after [11.1400])

has an indirect band structure and does not provide efficient radiative recombination. Modified Si structures have demonstrated strong luminescence, LED operation or laser oscillation, e.g., from Si/Ge superlattices, QDs in Si and Si-based Raman laser structures [11.1398]. All compound semiconductors, located on one of the grey vertical lines (Fig. 11.95) that indicate the lattice constant of important semiconductor substrate materials, can be lattice-matched to the respective substrate. According to Fig. 11.95 the ternary compounds $Al_{0.48}In_{0.52}As$ ($E_g = 1.43\,eV$) and $Ga_{0.47}In_{0.53}As$ ($E_g = 0.75\,eV$) have the same lattice constant as InP ($E_g = 1.34\,eV$), which is available in wafers today up to a diameter of 150 mm.

QW widths (or QD dimensions), effective masses (more precisely the $E(k)$ functions), and bandgaps of well and barrier materials energetically determine the quantized states and, thus, the spectral gain profile of the laser, i. e., the possible range of laser emission. Figure 11.95 shows that a very large wavelength range can be covered for different applications. Some examples are red and blue lasers which are used for data storage in digital versatile and blue-ray discs, respectively. Emission at about 850 nm is used for short-range optical fiber communication and CD devices, 980 nm lasers for pumping Er-doped fiber amplifiers, while between 1.25 and 1.65 μm the lasers are applied in ultrahigh-bit-rate long-haul optical fiber communication. Visible and infrared wavelengths are very attractive for optical sensing. The range between 0.8 and 1 μm is used for direct laser applications (welding, drilling, cutting and soldering) since it includes lasers with extremely high output power, highest wall-plug efficiencies and lowest price per watt of optical power.

Stimulated emission and optical gain (Fig. 11.96) are essentially determined by the product of the reduced electronic density of states and the Fermi factor ($f_c - f_v$). This Fermi factor originates from $f_c(1 - f_v) - f_v(1 - f_c)$, namely the *probability of processes photon-generating photons (emission)*, i. e., the probability that the CB states are occupied by electrons and VB states are not occupied by electrons $f_c(1 - f_v)$ *minus* the *probability of processes destroying photons (reabsorption)*, i. e., the probability of VB states occupied by electrons and CB states not occupied by electrons $f_v(1 - f_c)$. The full lines in Fig. 11.96a,b schematically show the spectral material gain profile of 3-D and 2-D semiconductors, respectively. Gain ranges spectrally from the bandgap E_g to the difference between the two quasi-Fermi levels ΔE_F. In reality there are additional effects such as Fermi-level filling, profile broadening [11.1383] (bold broken line) or many-body effects. Material gain minus loss provides net gain (Fig. 11.96c,d). If these laser-active materials are placed in a Fabry–Pérot (FP) laser the net gain can support the modes (vertical lines) as indicated. In Fig. 11.96 the spontaneous emission is shown by the thin broken lines, revealing a different spectral profile, which is important, e.g., for LEDs.

With QD material a higher degree of freedom can be obtained to tailor spectral gain as illustrated in Fig. 11.97a. By generating an appropriately flat gain profile (Fig. 11.97b) the state filling effect (blue curve) can be used to compensate internally the temperature dependent band gap shrinkage (red curve) to stabilize the emission wavelength of lasers (after [11.1400]).

Figure 11.98 depicts a classification summary of the most important semiconductor laser geometries. Most of them will be treated in detail below. Generally, the heterointerfaces are located horizontally. We distinguish between horizontal (left) and vertical (right) resonator structures, which is indicated by the orientation of the broad brown double arrow. Thus, we have horizontal cavity lasers (in-plane lasers) and vertical cavity (VC) lasers.

First Case: Fabry–Pérot (FP) Structures. Here the optical reflection (feedback) is provided by the borders of the resonator (facets). In many cases, the high refractive index difference between the semiconductor and the air is already sufficient, providing an optical reflection coefficient of about 30%. By additional facet coatings this coefficient can be tailored continuously between 0% (antireflection) and 100% (perfect reflection). The resonator modes are given by

$$m_{FP}\left(\frac{\lambda_B}{2n_{eff}}\right) = L\,. \tag{11.91}$$

Intuitively, the resonator length L has to be a positive integer multiple of half of the wavelength of light in the medium, where n_{eff} is the effective refractive index (eigenvalue of the Helmholtz equation, see below) of the waveguide. In the second case, in so-called structures with distributed feedback (DFB), the optical reflection is extended over the whole resonator. Here a very important design parameter is the Bragg wavelength λ_B, which is correlated with the DFB grating period Λ via the Bragg condition

$$m_{DFB}(\lambda_B/n_{eff}) = 2\Lambda\,. \tag{11.92}$$

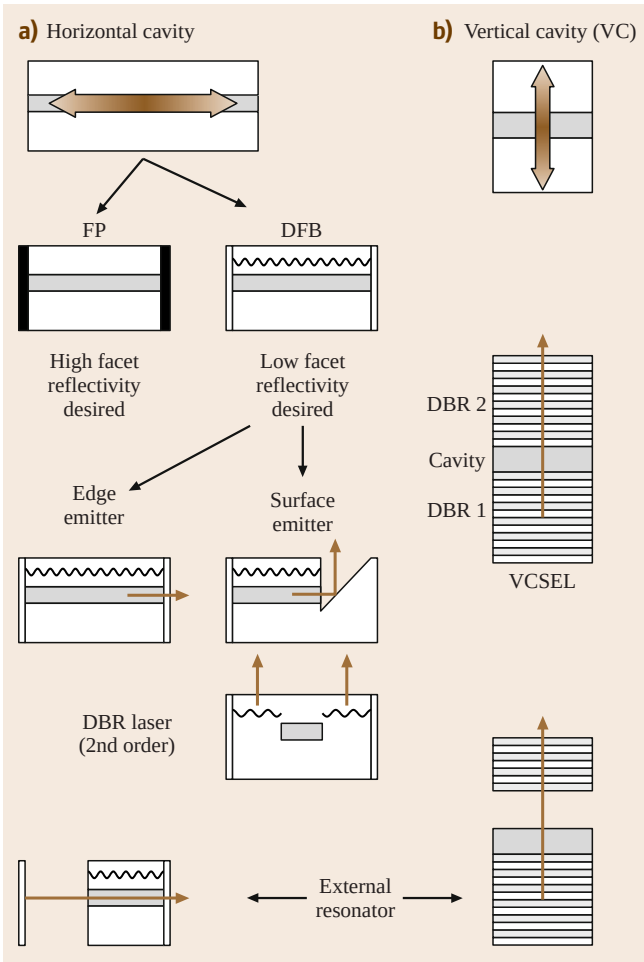

Fig. 11.98a,b Different geometries of lasers with horizontal (**a**) and vertical resonators (**b**)

m_{DFB} is a positive integer and describes the grating order. An example for a single mode DFB laser (Fig. 11.103c) emitting at $\lambda_B = 1.55\,\mu m$ having a first-order grating ($m_{DFB} = 1$) and an effective refractive index $n_{eff} = 3.27$, a grating period of $\Lambda = 237$ nm is required. Intuitively, an integer multiple of the wavelength in the medium has to correspond, according to (11.92), to the double grating period. Note that the mathematical structure of (11.91) and (11.92) is identical. In lasers with a typical length of 200 μm we obatin for FP laser modes within the gain profile a very large m_{FP} (on the order of 1000) while for DFB lasers in most cases m_{DFB} is 1 (for a first-order grating).

As expected, light is emitted in horizontal directions for edge-emitting lasers (Fig. 11.98). Surface emitters can be implemented by etching an out-coupling mirror inclined at 45° or by a second-order DFB grating (note the doubled grating period in the figure). In a second-order grating the light field is reflected back horizontally (180°) and coupled out vertically. If the Bragg condition is exactly fulfilled, the emission occurs exactly perpendicular to the surface (90°). However, the larger the deviation in (11.92) in the (>)-direction or (<)-direction, the larger or smaller the angle, respectively. If the grating is interrupted we have a distributed Bragg reflector (DBR) structure. Typically, a central grating-free section is embedded between two DBR sections. In the DFB and DBR structures the horizontally propagating light field alternatively passes two virtual *quasi-layers* of slightly different refractive index. For DBR resonators with *real layers* (Sect. 11.3.4 or the next section) these operation principles become more evident.

Second Case: VCSELs. They are also based on DBR structures, which in contrast to the first case consist of real multiple layers having a very high refractive-index difference. The central cavity has no grating and is embedded between two DBR mirrors, thus also forming a FP-like structure. However, feedback is distributed over the two DBR structures. In most cases the thickness of a single period (equivalent to a pair of neighboring layers) is chosen to equal half the wavelength of light in the medium for the design wavelength. This corresponds to a first-order grating according to (11.92). Since the resonator is oriented perpendicularly and the emission occurs perpendicular to the main chip surface (oriented parallel to the substrate area), this laser is called a vertical-cavity surface-emitting laser (VCSEL). The two mirrors must have a very high reflectivity to reach the laser threshold, since the laser-active layer is relatively thin and has a weak overlap with the light field in the resonator.

Edge-emitting lasers as well as VCSELs will be treated in detail in the following sections. On the basis of both cases (A and B), it is possible to implement lasers with external resonators, as indicated in the last row of Fig. 11.98.

11.3.3 Edge-Emitting Laser Diodes with Horizontal Resonators

As already mentioned, the population inversion between the valence and conduction bands, which is necessary for the coherent amplification of radiation [11.1401], can be obtained by an injection of electrons and holes via a forward-biased pn junc-

tion (Figs. 11.90, 91). The electrons injected into the n semiconductor as well as the holes injected into the p semiconductor diffuse to the pn junction and can recombine there radiatively and generate a photon with energy $\hbar\omega$ (Fig. 11.89). If the external voltage is increased and the carrier density exceeds a critical value in the range of $10^{18}\,\mathrm{cm}^{-3}$, the rate of photon emission becomes higher than the absorption rate, so that an incident wave can be amplified coherently due to stimulated emission. The condition for this population inversion is that the separation between the quasi-Fermi levels E_{f_c} and E_{f_v}, which describe the filling of the conduction and valence bands, is larger than the bandgap E_g (Bernard–Durafourg condition)

$$E_{f_c} - E_{f_v} \geq \hbar\omega \geq E_g \,. \tag{11.93}$$

In this case the semiconductor material is transparent for the generated wave with the wavelength defined by the bandgap. The resulting gain values are very high (in the range of $10^3\,\mathrm{cm}^{-1}$) due to the high carrier density. Lasing occurs if the additional losses of the optical resonator providing the feedback are compensated.

Double-Heterostructure Lasers

The active region, where population inversion is achieved, is very thin in homojunction lasers and the threshold current is very high, since only a small portion of the injected carriers is utilized for the lasing process. Lower threshold currents and continuous operation at room temperature can be achieved with double-heterostructure lasers, where the low-bandgap active layer is sandwiched between n- and p-doped cladding layers with a higher bandgap epitaxially grown on a substrate (Fig. 11.90). The technical realization of these structures is possible if the lattice mismatch between the different layers of the material system does not exceed a critical value. Double heterostructures [11.1379] have three main advantages with respect to laser operation:

- The bandgap difference between the layers is distributed between the valence and conduction bands and creates potential barriers for the injected electrons and holes. For an appropriate choice of doping and applied voltage, a nearly rectangular-shaped potential well can be achieved (Fig. 11.90), which efficiently confines the carriers in the low-bandgap active layer if the potential difference is higher than the thermal activation energy $k_B T$. The width of the active layer d_{act} is defined by the heterostructure geometry. The carriers injected via the pn junction are captured in the potential well and confined to a small volume, thus decreasing the injection current, which is necessary to achieve inversion.
- There is no reabsorption of the radiation emitted from the active layer in the surrounding layers due to the difference in bandgap energies.
- In the material systems used for semiconductor lasers, the low-bandgap active layer has a higher refractive index than the surrounding cladding layers. Therefore, the double heterostructure acts as a dielectric planar slab waveguide, confining the generated optical field to the active region due to the refractive-index difference between the layers. The number of modes supported by this optical waveguide for a given wavelength depends on the thicknesses and the refractive indices of the layers. By a proper choice of the design parameters, a single transverse (perpendicular to the pn junction) mode can be selected, which concentrates the photon density for stimulated emission in the gain region.

Thus, a double heterostructure enables the confinement of carriers and generated photons in the active layer. For bulk active layers, the de Broglie wavelength of the carriers is small compared to the thickness of the active layer, leading to a high degree of carrier confinement. The wavelength of the photons, however, is comparable to the dimension of the structure, so that only a portion of the optical intensity is confined to the active region. The transversal distribution of the light intensity in the double heterostructure is given by the solution of the wave equation of a planar slab waveguide supporting TE and TM modes with an effective index n_{eff} as the respective eigenvalue. Figure 11.90c shows the optical intensity of the fundamental TE mode in a double heterostructure as a function of the transversal coordinate y, revealing the incomplete confinement of the optical field in the active region. The fraction of the mode intensity within the active layer is called the optical confinement or the filling factor Γ_{act}, which is an important design parameter for a semiconductor laser

$$\Gamma_{act} = \frac{\int_0^{d_{act}} |E(y)|^2 \,\mathrm{d}y}{\int_{-\infty}^{+\infty} |E(y)|^2 \,\mathrm{d}y} \,, \tag{11.94}$$

where $E(y)$ is the electric field. If the light is also confined in the lateral direction of the laser, the definition has to be modified accordingly.

The dependence of the optical confinement factor of the guided modes on the thickness d for a layer struc-

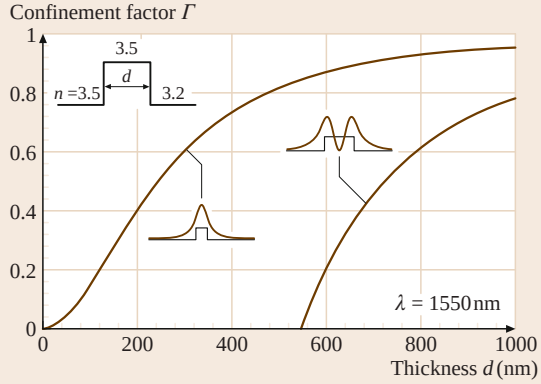

Fig. 11.99 Dependence of the optical confinement factor Γ on the thickness d of an InP/InGaAsP/InP layer structure

ture is shown in Fig. 11.99. For increasing thickness of the waveguide, the confinement factor approaches 1 and additional modes are supported.

An optical mode with an effective refractive index n_{eff} experiences an effective gain g_{eff} in a waveguide with an active layer, which provides the material gain g_{act} and has a refractive index n_{act}

$$g_{\text{eff}} = \frac{n_{\text{act}}}{n_{\text{eff}}} \Gamma_{\text{act}} g_{\text{act}} \,. \tag{11.95}$$

The correction factor $n_{\text{act}}/n_{\text{eff}}$ takes into account the waveguiding effect on the modal gain [11.1402].

Laser Structures

Using modern epitaxial growth methods it is possible to implement semiconductor multilayer structures very precisely so that stable, transverse single-mode operation can be obtained using dielectric waveguiding [11.1403]. For most applications, however, lateral (parallel to the pn junction) patterning of the laser structure is also required to obtain lateral carrier and photon confinement, which is important to obtain stable and efficient laser operation with high spectral purity and good coupling efficiency into a fiber. In addition, lateral confinement of the injection current is necessary to avoid leakage currents bypassing the active region. The confinement of photons, carriers and current has been implemented in many ways, reflecting the specific purpose of the device. Semiconductor lasers can be classified according to the mechanism of lateral waveguiding as gain-guided or index-guided, depending on whether it is the lateral variation of the optical gain or the refractive index that confines the mode. Index-guided lasers can further be subclassified as weakly or strongly index-guided, depending on the magnitude of the lateral refractive-index step. In a gain-guided laser structure (oxide stripe laser, Fig. 11.100, left) the current is injected via a stripe contact (width $w \approx 5\,\mu\text{m}$) in a laterally unpatterned active layer. The optical field is mainly guided by the resulting variation of the gain. The lateral waveguiding is weak, so that even small variations of the refractive index, e.g., due to temperature changes or carrier injection lead to unstable operation. In an index-guided laser structure (buried laser structure, Fig. 11.100, right) the active layer ($w \approx 2\,\mu\text{m}$) is laterally embedded into a material with a lower refractive index ($n < n_{\text{act}}$), higher bandgap and higher electrical resistivity to facilitate stable lateral waveguiding, carrier confinement and current confinement. The typical features of index- and gain-guided laser structures are summarized in Fig. 11.100. The power–current characteristic (P–I curve) of gain-guided lasers is characterized by a high threshold current (typical 50–100 mA) and kinks originating from the unstable lateral waveguiding. The optical spectrum is multimodal due to the enhanced spontaneous emission. The phase-fronts are curved in the resonator and the far field shows the characteristic twin lobes caused by the laterally inhomogeneous gain distribution. The main advantage of gain-guided lasers is the simplicity of their fabrication. For very large stripe widths (50–100 μm) a so-called broad-area laser results, in which the current is injected laterally and homogeneously via a large contact. Since there is no lateral waveguiding in broad-area lasers, the threshold current is very high (typical a few A) and the multimode emission cannot be coupled efficiently into a fiber. Due to the high output power, broad-area lasers are used, e.g., for optical pumping of solid-state lasers.

Index-guided lasers show stable, lateral single-mode emission with a low threshold current (typical 10 mA) and a P–I curve without kinks. The spontaneous emission in each mode is significantly smaller, resulting in a spectrum with a few dominating modes. The phase-fronts are planar and the far field has a smooth shape, enabling a high coupling efficiency into a single-mode fiber.

Weakly Index-Guided Laser Structures. In weakly index-guided lasers the thickness of layers surrounding the active core material is varied, thus resulting in an effective lateral waveguiding structure. Lateral single-mode emission can be obtained by a proper choice of the thickness and width of this variation. The lateral index step has to exceed the carrier-induced reduction of the refractive index ($\Delta n \approx 5 \times 10^{-3}$) so

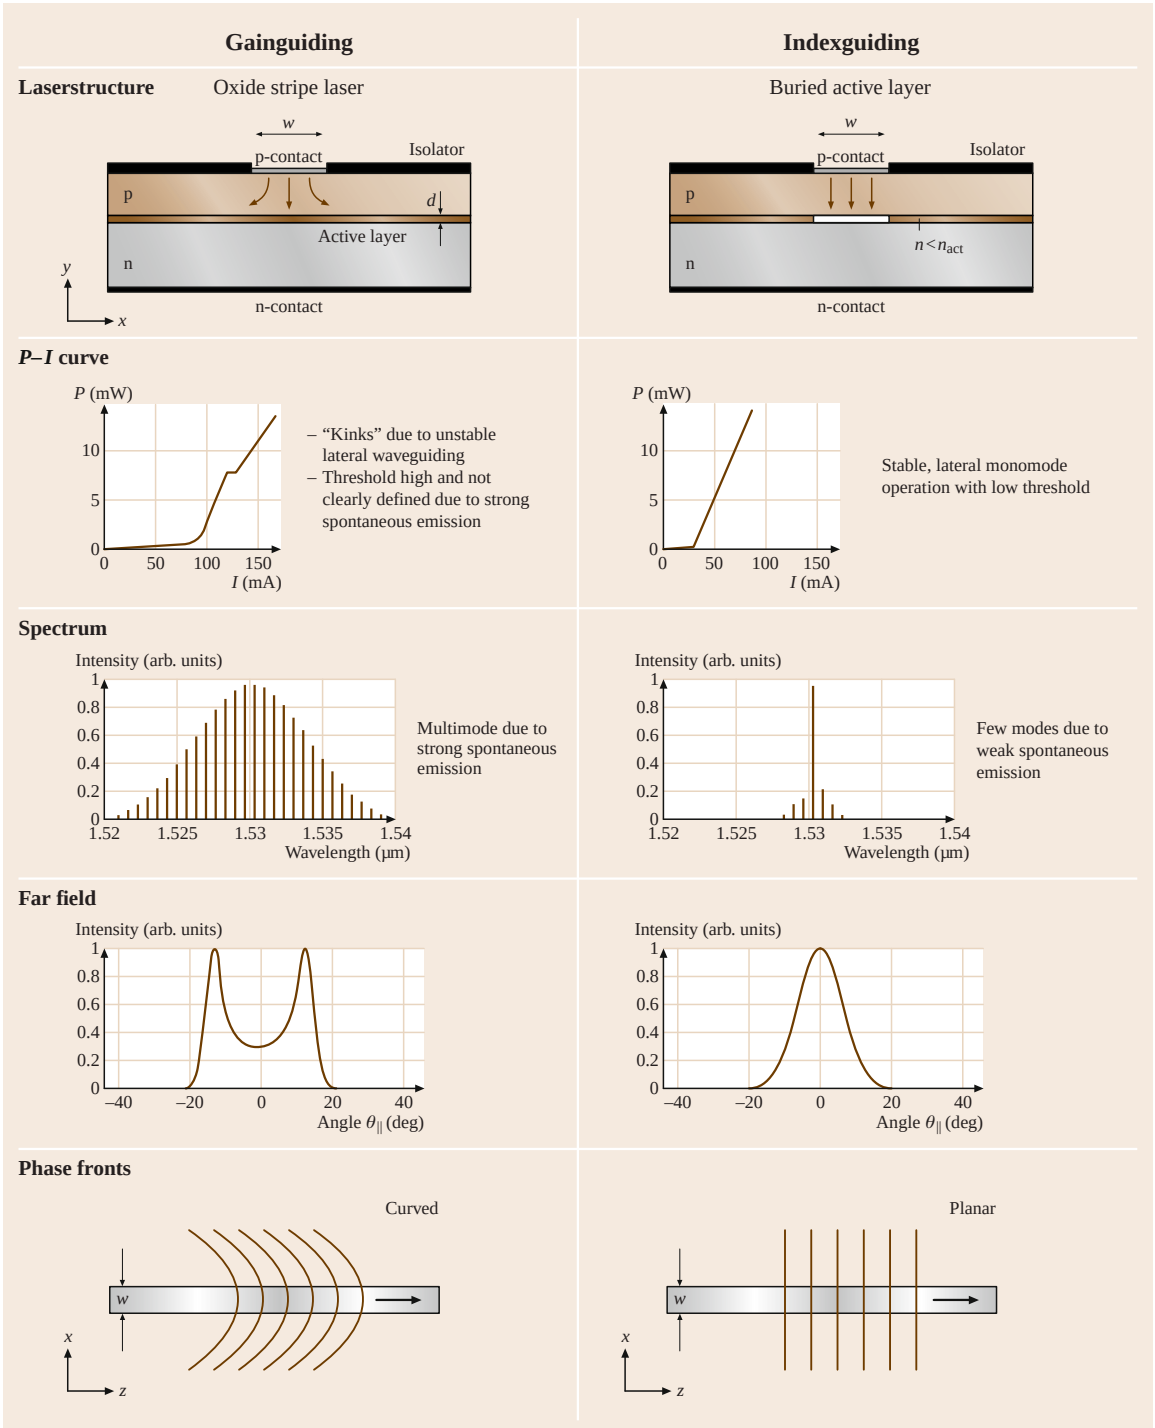

Fig. 11.100 Comparison of gain-guided and index-guided laser structures

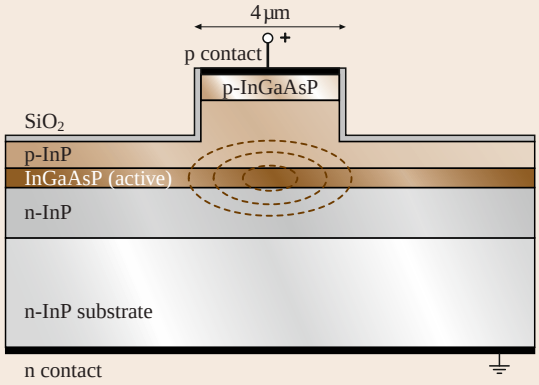

Fig. 11.101 Weakly index-guided laser structure: ridge waveguide laser

that index-guiding is dominating. Weakly index-guided laser structures can be divided into two categories: ridge waveguide lasers and channeled substrate lasers.

In ridge-waveguide lasers, a rib waveguide is defined by etching a narrow stripe ($\approx 3-5\,\mu m$) down near to the active layer (at a typical distance of 200 nm). Thus, the current injection is focused in the region of the active layer below the rib. This current confinement can also be supported by additional isolating layers, e.g., SiO_2 (Fig. 11.101). The lateral waveguiding is accomplished by the higher refractive index of the semiconductor material compared to the surrounding SiO_2 and air. The etch depth has to be carefully controlled (e.g., by using etch-stop layers) in order to select one lateral mode and minimize current bypass.

Weakly index-guided lasers are suitable to obtain low threshold currents of typically 20–40 mA and high output powers with lateral single-mode emission. The weak waveguiding allows for broader active layers compared to buried laser structures, which has a positive effect, e.g., on the series resistance. The low current leakage in ridge waveguide lasers usually results in good linearity of the P–I curve. The emission is more complex than in buried lasers, since index- and gain-guiding are important and even small changes of the refractive index by temperature or current injection can influence the performance. The active layer in weakly index-guided lasers is not affected during processing, so that lateral carrier diffusion in the active layer cannot be avoided, but on the other hand, the unpatterned active layer is advantageous for the reliability of the device. Since only one epitaxial growth step is needed, the fabrication of these lasers is significantly easier than buried semiconductor lasers.

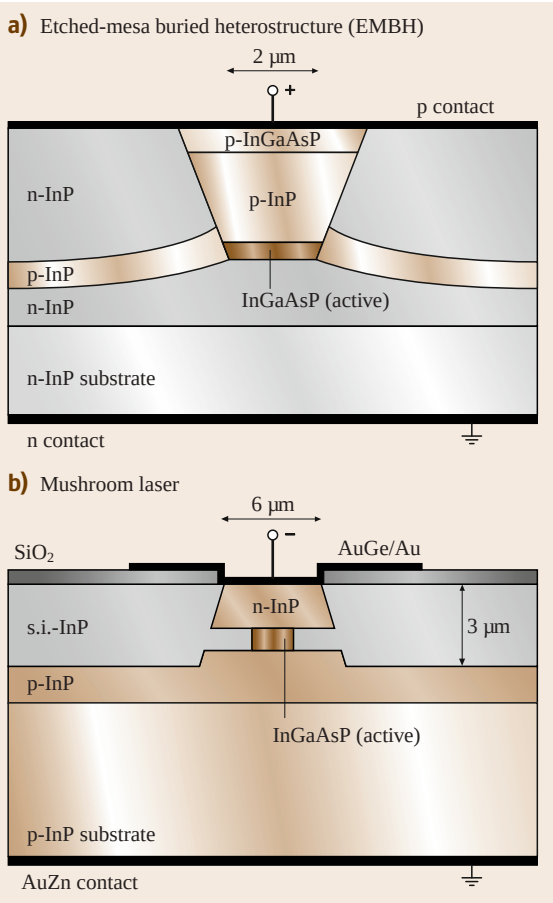

Fig. 11.102 Buried heterostructure lasers

Strongly Index-Guided Laser Structures. Strong index-guiding can be accomplished by buried laser structures, where a small stripe of the active layer material with a high refractive index is embedded into semiconductor material with lower refractive index and larger bandgap. For this purpose, the active layer has to be patterned and epitaxially regrown afterwards. Lateral single-mode operation is possible, if the resulting stripe width of the active layer does not exceed a critical value defined by the cut-off for the higher lateral modes [11.1404].

Figure 11.102 shows some examples for strongly index-guided laser structures. A BH structure is shown for InGaAsP/InP (etched-mesa buried heterostructure laser, Fig. 11.102a). The reduction of leakage current using alternating n- and p-doped layers, however, leads to a significant increase of the parasitic electrical capacity of the laser, which degrades the high-frequency response of the device. Alternatively, electrically iso-

lating regions for the current confinement can be fabricated using semi-insulating material (e.g., Fe-doped InP) or by proton implantation. The processing of the mushroom laser (Fig. 11.102b) begins with the etching of 6 μm-wide mesa in the layer structure, which cuts through the active layer grown in the first epitaxy [11.1405]. Using a selective wet chemical etching process the width of the active region is reduced up to 1–2 μm to obtain lateral single-mode operation. The resulting undercut area is epitaxially refilled afterwards, e.g., using vapor phase epitaxy (VPE) with semi-insulating InP [11.1406].

In addition to this strongly index-guided laser structures with a planar active layer, which are useful for integration with a DFB grating, there also exist buried laser structures utilizing nonplanar active layers based on the regrowth of, e.g., V-grooves or mesas.

Using strongly index-guided structures, a very stable and lateral single-mode laser operation with very low threshold currents (< 10 mA) and excellent high-speed characteristics can be obtained, since stable optical waveguiding, carrier confinement and current confinement are combined. The fabrication of these devices, however, is complicated due to the additional epitaxy step.

Edge-Emitting Fabry–Pérot Laser Diodes

In Fabry–Pérot (FP) lasers, the cleaved facets of the semiconductor crystal form the optical resonator, which enables laser operation by providing the optical feedback of the stimulated amplified radiation. This resonator selects the photons generated by stimulated emission with respect to direction and wavelength. The light wave traveling perpendicularly to the facets is amplified if the wavelength matches a longitudinal mode of the resonator ((11.91), Figs. 11.91, 96, 98, 103a). The lasing process starts if the gain experienced during one round-trip in the cavity equals the losses caused by absorption, scattering and the light output through the facets.

Lasing Condition. The length L of the resonator is typically a few hundred micrometers. The intensity reflection and transmission coefficients of the end facets can be estimated using the Fresnel equations, neglecting the transversal and lateral structure of the waveguide with air ($n = 1$) assumed to be outside the cavity

$$R = \frac{(n_{\mathrm{eff}} - 1)^2}{(n_{\mathrm{eff}} + 1)^2}\,, \quad T = \frac{4n_{\mathrm{eff}}}{(n_{\mathrm{eff}} + 1)^2}\,, \tag{11.96}$$

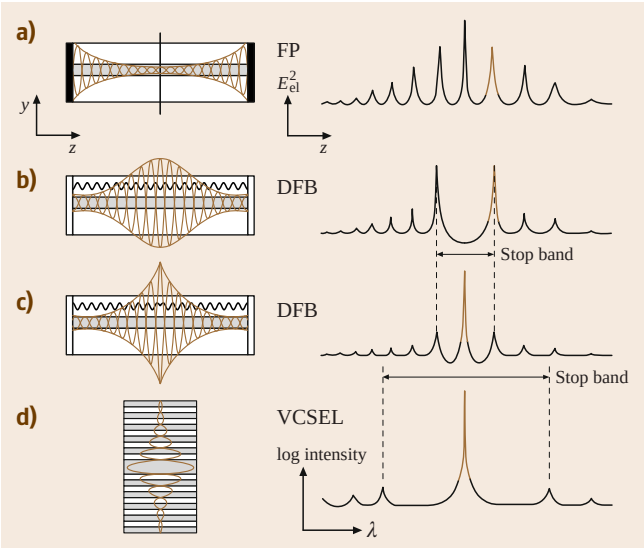

Fig. 11.103 Schematic structural cross sections (*left*) and the corresponding emission spectra (*right*) for various diode lasers

where n_{eff} is the effective refractive index of the waveguide mode considered.

In this one-dimensional model plane waves with electric field amplitude $E(z)$ travel in the longitudinal direction (z) of the FP resonator, experiencing the modal intensity gain g due to stimulated emission. The threshold for laser operation is defined by a round-trip condition requiring that in a stationary state the optical wave remains unchanged after one complete round-trip in the cavity. This round-trip condition gives the mirror losses of the FP resonator

$$g = \alpha_{\mathrm{m}} = \frac{1}{2L} \ln(R_1 R_2)\,, \tag{11.97}$$

where R_1 and R_2 denote the intensity reflection coefficients of the end facets. Since the net gain g in the cavity is composed of the material gain of the semiconductor g_{eff} and the waveguide losses α_{s}, the lasing condition can be written as

$$g_{\mathrm{thr}} = \frac{n_{\mathrm{act}}}{n_{\mathrm{eff}}} \Gamma_{\mathrm{act}} g_{\mathrm{act}}(N_{\mathrm{thr}}) = \alpha_{\mathrm{s}} + \alpha_{\mathrm{m}} \tag{11.98}$$

if the contribution of spontaneous emission is neglected and N_{thr} denotes the carrier density at threshold. The optical losses of the waveguide are caused by optical scattering from imperfections in the bulk media or at interfaces and free-carrier absorption in the active and cladding layers.

The longitudinal distribution of the photon density $s(z)$ in the active FP resonator is given by the sum of the

forward and backward traveling photon densities, which grow exponentially due to the gain g. For a symmetric resonator ($R = R_1 = R_2$) the total photon density $s(z)$ is given by a cosh function (Fig. 11.103a) with a minimum in the middle of the resonator. For a laser diode with as-cleaved facets ($R = 0.28$), the intensity distribution is relatively flat, whereas for antireflection-coated facets a strongly inhomogeneous photon distribution results.

The round-trip condition also gives the optical frequencies of the longitudinal modes of the FP resonator according to $\nu_q = qc/(2Ln_{\text{eff}})$, where $q = 1, 2, 3\cdots$ and c denotes the vacuum speed of light. The frequency separation $\Delta\nu$ of adjacent modes is influenced by the dispersion of the waveguide, which is taken into account by the group refractive index n_g

$$\Delta\nu = \frac{c}{2Ln_g} \tag{11.99}$$

with

$$n_g = n_{\text{eff}} + \nu\frac{dn_{\text{eff}}}{d\nu} . \tag{11.100}$$

For a typical FP laser diode the group index of $n_g \approx 3.5$–5 is higher than the effective index $n_{\text{eff}} \approx 3$–3.5. The separation of the equidistant mode frequencies is about 150 GHz for a 300 μm-long cavity, which is small compared to the width of the gain curve of the semiconductor (≈ 5 THz). Thus, longitudinal multimode operation can be expected above threshold for an FP laser diode.

For many applications the degree of single-mode emission is important; it can be quantified by the side-mode suppression ratio (SMSR)

$$\text{SMSR} = 10\log_{10}(P_1/P_2) , \tag{11.101}$$

where P_1 and $P_2 \le P_1$ denote the output power of the two strongest modes in the optical spectrum. Typical FP laser diodes achieve a maximum SMSR of approximately 20 dB.

Rate Equations. The fundamental static and dynamic properties of semiconductor laser diodes can be modeled using a set of rate equations [11.1407] describing the interaction of electron–hole pairs and photons in the active layer. We consider a strongly index-guiding double heterostructure supporting a single optical mode traveling as a plane wave axially in the cavity. The current I is assumed to be uniformly injected into the active layer with volume V and recombines there, completely neglecting leakage currents. The carrier density within the active layer is treated as homogeneous in the transversal and lateral direction, since the corresponding inhomogeneities of photon density are small and the resulting gradients in carrier density are smoothed out by diffusion. In FP lasers with a sufficiently high mirror reflectivity, the axial variations of the photon density s and the carrier density N can be neglected and the rate equations can be written as

$$\frac{dN}{dt} = \frac{I}{eV} - \frac{N}{\tau_{\text{nr}}} - BN^2 - CN^3 - v_g\frac{n_{\text{act}}}{n_{\text{eff}}}g_{\text{act}}(N,s)s + \frac{F_N(t)}{V} , \tag{11.102}$$

$$\frac{ds}{dt} = v_g\left[\Gamma_{\text{act}}\frac{n_{\text{act}}}{n_{\text{eff}}}g_{\text{act}}(N,s) - g_{\text{thr}}\right]s + \frac{\Gamma_{\text{act}}\left[R_{\text{sp}} + F_s(t)\right]}{V} , \tag{11.103}$$

$$\frac{d\Phi}{dt} = \frac{1}{2}\alpha_H v_g\Gamma_{\text{act}}\frac{n_{\text{act}}}{n_{\text{eff}}}g_{\text{act}}(N,s) + F_\Phi(t) , \tag{11.104}$$

where e is the elementary charge, $1/\tau_{\text{nr}}$, B, and C are the parameters describing nonradiative, bimolecular and Auger recombination, respectively, and $v_g = c/n_g$ is the group velocity of the waveguide. The material gain of the active layer is given by g_{act} and $F_s(t)$, $F_N(t)$ and $F_\Phi(t)$ represent Langevin noise sources taking into account the statistic nature of the spontaneous emission and the shot-noise character of the carrier recombination and generation. The Langevin forces leading to fluctuations of carrier density and photon density are correlated and have zero mean [11.1407]; Γ_{act} is the optical confinement factor of the active layer and Φ is the phase of the complex electric field E, which is connected with the photon number $S = sV/\Gamma_{\text{act}}$ via

$$E(t) = \sqrt{S(t)}\exp[i\Phi(t)] , \tag{11.105}$$

R_{sp} is the time-averaged rate of spontaneous emission into the lasing mode.

The longitudinal excess factor K_z accounts for the enhancement of the spontaneous-emission noise due to the axial dependence of the complex electric field $E(z,t)$

$$K_z(t) = \frac{|\int_0^L |E(z,t)|^2\,dz|^2}{|\int_0^L E^2(z,t)\,dz|^2} . \tag{11.106}$$

In the case of a transversely single-mode index-guided FP laser the factor K_z is given by [11.1408]

$$K_z^{\text{FP}} = \left(\frac{(\sqrt{R_1}+\sqrt{R_2})(1-\sqrt{R_1R_2})}{\sqrt{R_1R_2}\ln(1/R_1R_2)}\right)^2 . \tag{11.107}$$

The first rate equation (11.102) can be formally derived from the quantum-mechanical density-matrix formalism. It can be interpreted as a balance of carriers that are injected as a current I and contribute to stimulated emission or are lost for the lasing process via the different recombination processes. The second and third equations ((11.103),(11.104)) can be derived from the Maxwell equations with the rotating-wave and slowly varying amplitude approximations.

For semiconductor lasers with a bulk active layer, the dependence of the gain on the carrier density $g_{\mathrm{act}}(N)$ can be approximated as linear [11.1409]

$$g_{\mathrm{act}}(N) = \frac{\mathrm{d}g}{\mathrm{d}N}(N - N_{\mathrm{tr}}) \,, \tag{11.108}$$

where $\mathrm{d}g/\mathrm{d}N$ is the differential gain and N_{tr} is the transparency carrier density. In quantum well structures (Figs. 11.92, 93) this dependence is usually described by a logarithmic function [11.1410, 1411]

$$g_{\mathrm{act}}(N) = \frac{\mathrm{d}g}{\mathrm{d}N} N \ln \frac{N}{N_{\mathrm{tr}}} \quad \text{for} \quad g_{\mathrm{act}} \geq 0 \,. \tag{11.109}$$

The influence of the photon density on the gain is taken into account by introducing a nonlinear gain coefficient ε according to

$$g_{\mathrm{act}}(N, s) = \frac{g_{\mathrm{act}}(N)}{1 + \varepsilon s} \,. \tag{11.110}$$

This nonlinear gain compression is caused by spectral hole burning and carrier heating, which is significant if the time constant of stimulated emission becomes comparable to the intraband relaxation time.

Refractive Index Change. In semiconductors the real part of the refractive index depends on the carrier density because of various physical mechanisms. With increasing injection the band-to-band absorption is reduced due to band-filling effects. In addition, the absorption increases due to the reduction of the bandgap (bandgap renormalization resulting from many-body effects) and absorption also increases due to the increasing absorption of free carriers. The resulting total change of the real part of the refractive index, which is related to the gain spectrum via the Kramers–Kronig relation, depends on the wavelength relative to the gain maximum. In the case of 1.5 µm InGaAsP the refractive index decreases with injection. The dependence of the refractive index on the carrier density is theoretically described by the effective line width enhancement or Henry factor α

$$\alpha = \frac{\partial n_{\mathrm{eff}}}{\partial \gamma_{\mathrm{eff}}} \,, \tag{11.111}$$

where the complex effective refractive index is defined by $n_{\mathrm{eff}} - \mathrm{i}\gamma_{\mathrm{eff}}$. The change of the effective index with carrier density can be written as

$$\delta n_{\mathrm{eff}} \cong \Gamma_{\mathrm{act}} \frac{n_{\mathrm{act}}}{n_{\mathrm{eff}}} \delta n_{\mathrm{act}} = -\Gamma_{\mathrm{act}} \frac{n_{\mathrm{act}}}{n_{\mathrm{eff}}} \frac{\alpha\lambda}{4\pi} \frac{\partial g_{\mathrm{act}}(N)}{\partial N} \delta N \,. \tag{11.112}$$

The line width enhancement factor is important for the treatment of line width and frequency chirp under modulation [11.1408]. Typically it ranges from 3 to 5, decreasing from the long-wavelength to the short-wavelength side of the gain curve [11.1409].

Steady-State Characteristics. The single-mode rate equations can be used to analyze the steady-state behavior of a semiconductor laser. Setting the time derivative to zero in (11.103), we obtain an implicit expression for the photon number S in the case of continuous-wave (CW) operation:

$$S = \frac{R_{\mathrm{sp}}}{v_{\mathrm{g}}[g_{\mathrm{thr}} - \Gamma_{\mathrm{act}} g_{\mathrm{act}}(N, s)]} \,. \tag{11.113}$$

The number of photons increases as the gain value asymptotically approaches the losses g_{thr}. The small gain difference is compensated by spontaneous emission, which provides the noise input amplified by stimulated emission. Below threshold the photon density is small and (11.102) gives a linear increase of the carrier density according to $N \propto I/eV$. Above threshold the gain is approximately clamped at $g(N_{\mathrm{thr}}) = g_{\mathrm{thr}}$ and the corresponding threshold current, which is defined in the limiting case of vanishing spontaneous emission ($R_{\mathrm{sp}} = 0$), becomes

$$I_{\mathrm{thr}} = \mathrm{eV} \left(\frac{N_{\mathrm{thr}}}{\tau_{\mathrm{nr}}} + B N_{\mathrm{thr}}^2 + C N_{\mathrm{thr}}^3 \right) \,. \tag{11.114}$$

Using (11.102) the photon number above threshold can then be written as $S = (I - I_{\mathrm{thr}})/e v_{\mathrm{g}} g_{\mathrm{thr}}$. Since the carrier density is clamped at threshold, all injected carriers in excess of the threshold current contribute to stimulated emission and the number of photons increases proportionally to $(I - I_{\mathrm{thr}})$. The total output power $P = v_{\mathrm{g}} \hbar\omega \alpha_{\mathrm{m}} S$ emitted from both facets becomes

$$P = \frac{\hbar\omega}{e} \eta_i \frac{\alpha_{\mathrm{m}}}{g_{\mathrm{thr}}} (I - I_{\mathrm{thr}}) \,, \tag{11.115}$$

where we assume that only a fraction η_i of the external drive current reaches the active region and the remaining fraction $(1 - \eta_i)$ is lost via leakage current or nonradiative recombination. Thus, the P–I

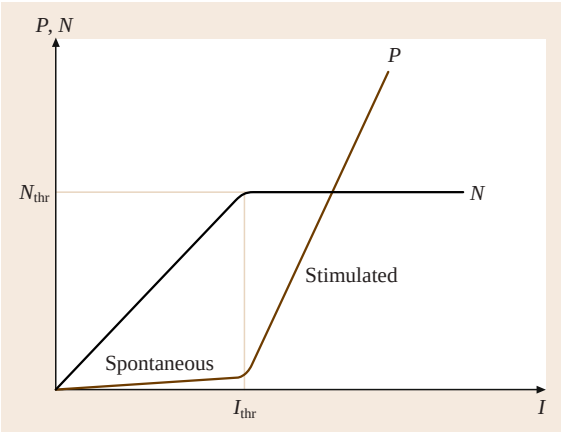

Fig. 11.104 Dependence of the output power (P) and carrier density (N) on the injected current

curve of a semiconductor laser diode is a straight line (Fig. 11.104) above threshold with a slope defined by the external quantum efficiency η_{ext}

$$\eta_{ext} = \frac{dP}{dI}\frac{e}{\hbar\omega} = \eta_i \frac{\alpha_m}{g_{thr}} , \qquad (11.116)$$

which can be interpreted as the ratio of the number of emitted photons to the number of injected electrons per time. The sharpness of the transition from the spontaneous emission below threshold to the stimulated emission above threshold depends on the amount of spontaneous emission into the lasing mode. Leakage currents, thermal effects and spectral hole-burning neglected so far lead to bending of the P–I curve.

Characteristic Temperature. The threshold current of a semiconductor laser depends on the temperature T, which can be described phenomenologically by

$$I_{thr}(T) = I_0 \exp\frac{T}{T_0} , \qquad (11.117)$$

where T_0 is the characteristic temperature, a quality parameter describing the device resistance against temperature changes, which typically ranges between 40 and 90 K for semiconductor lasers emitting around 1550 nm.

Single-Mode Laser Structures

Transmitters used, e.g., in optical-fiber communication systems should emit light predominantly in a single longitudinal mode since the presence of side modes limits the transmission capacity due to pulse broadening caused by the chromatic dispersion of the fiber. Semiconductor lasers with an FP resonator usually exhibit multimode operation since the gain spectrum is wider than the longitudinal mode spacing and the broadening of the gain profile, which due to spectral hole burning is not perfectly homogeneous, offers several modes with sufficient gain to oscillate. The techniques to achieve reliable longitudinal mode control even under high-bit-rate modulation can be categorized into two main groups:

Short Lasers. The discrimination against side modes in FP resonators can be enhanced by reducing the cavity length L. If the mode spacing $\Delta\nu \propto L^{-1}$ becomes comparable to the width of the gain curve, only one mode will oscillate near the gain peak. To obtain stable single-mode operation, however, the lasers must be extremely short. This requires a very good reflectivity of the end facets to overcome the high mirror losses $\alpha_m \propto L^{-1}$, leading to high threshold current densities. The problems of fabricating very short semiconductor devices can be solved using a vertical-cavity surface-emitting laser (VCSEL) structure (Fig. 11.98).

Frequency-Selective Feedback. The second method to obtain single-mode operation is to incorporate a frequency-selective element in the resonator structure. This can be realized by using coupled cavities, an external grating or a Bragg grating:

Coupled Cavities. If one or more additional mirrors are introduced in the FP resonator, the boundary conditions added due to the reflections at each interface severely limit the number of longitudinal modes. To achieve single-mode operation, however, it is often necessary to tune the resonator by changing the drive current or the temperature. Usually the single-mode regime is small so that such structures can only be modulated over a limited current range without mode jumps. In addition, the reproducible fabrication of nearly identical devices turns out to be difficult since the spectral properties strongly depend on the exact lengths of the sections.

External Grating. Frequency selection can also be realized by an external grating outside the resonator. The mechanical stability of such lasers, however, is a critical point since the grating is not integrated on the wafer. Consequently, lasers with external gratings are expensive devices (Fig. 11.113a).

Bragg Grating. The method most frequently used to achieve single-mode emission is to incorporate a Bragg grating, which creates a periodic variation of the

complex refractive index and distributes the feedback throughout the cavity. Dynamic single-mode operation is achieved if the threshold gain for the oscillating mode is significantly smaller than the threshold gain for the other modes. Devices employing Bragg gratings can be classified roughly into three categories: distributed Bragg reflector (DBR), distributed feedback (DFB) (Figs. 11.98, 103, 105, section on Fabry–Pérot structures in Sect. 11.3.2, and Sect. 11.3.6) and gain-coupled (GC) lasers.

In DBR lasers the Bragg grating is etched into passive regions near the cavity ends. The index grating (the variation of the real part of the refractive index) acts as an effective mirror with wavelength-dependent reflectivity and surrounds the central part of the cavity which is active and remains uncorrugated. The longitudinal mode with a wavelength located near the reflectivity maximum of the grating is selected. Since a DBR laser is formed by replacing the mirrors by passive gratings, the properties can be described by an effective mirror model. The transition between the active section and the passive gratings usually complicates the technological realization of in-plane DBR lasers. An important advantage of DBR lasers is that the wavelength can be changed if the grating regions are equipped with separate electrodes that can tune the Bragg frequency via the carrier-induced refractive index change. Thus, DBR gratings are often used in tunable lasers.

In DFB lasers the index grating covers the entire resonator length. At the wavelength corresponding to the corrugation period of the grating, the forward- and backward-traveling waves created by the Bragg scattering are confined in the central part of the cavity so that the mirror losses become a function of the wavelength. The longitudinal mode with the lowest mirror losses corresponding to the most effective concentration of photons in the resonator is selected.

In gain-coupled devices a periodic variation of gain or loss is used to favor a longitudinal mode of the FP resonator. In the ideal case, there is no Bragg scattering at the gain grating, and the longitudinal photon distribution as well as the mirror losses are unchanged compared to the FP cavity. The overlap with the loss or gain grating, however, varies between the different longitudinal modes of the FP resonator. The mode experiencing the largest overlap with the gain grating (or minimum overlap with a loss grating) is selected.

DFB Lasers. The spectral properties of DFB lasers [11.1412] are essentially determined by the integrated Bragg grating. The waveguding in such periodic

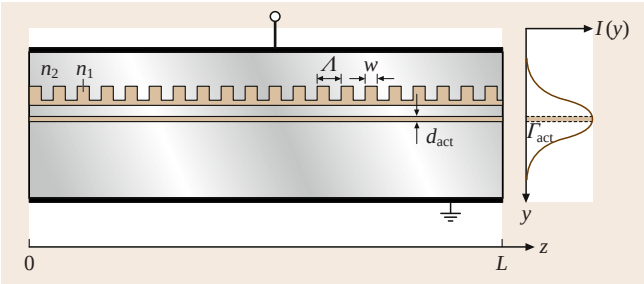

Fig. 11.105 Scheme of a DFB laser structure with an integrated rectangular Bragg grating (duty cycle w/Λ) including the corresponding transversal intensity distribution $I(y)$

structures can be analyzed by the coupled mode theory [11.1413], which yields approximate analytical solutions describing the light propagation in waveguides with a periodic variation of the complex refractive index by counter-propagating modes exchanging energy by scattering. The strength of the interaction and the amount of feedback in the grating structure are determined by the complex coupling coefficient

$$\kappa = \pi \Delta n/\lambda_0 + \mathrm{i}\Delta g/4\,, \tag{11.118}$$

which is proportional to the variation of the refractive index step Δn, the gain variation Δg and the number of corrugations per length in the grating. The Bragg wavelength λ_B is given by the effective index, the corrugation period Λ and the order m_{DFB} of the grating according to (11.92). For an axially homogeneous first-order grating ($m_{DFB} = 1$) with length L and a perfect antireflection coating on the facets ($R_1 = R_2 = 0$) the theory reveals the following solutions.

- In the case of pure index coupling ($\Delta n_{eff} \neq 0$, $\Delta g = 0$) the transmission spectrum turns out to be symmetric with respect to the Bragg wavelength $\lambda_B = 2n_{eff}\Lambda$ where oscillation is forbidden. For a small coupling coefficient, the mode spacing approximately takes the value of an FP resonator $\Delta\lambda = \lambda^2/2n_{eff}L$ but, in contrast to an FP cavity, the threshold gain of the modes is wavelength dependent and increases with growing distance from the Bragg wavelength. A strong coupling produces a transmission stop-band with width $\Delta\lambda \cong \kappa\lambda_B^2/(\pi n_{eff})$ centered at the Bragg wavelength, in which transmission is strongly damped. The two modes with the lowest threshold gain $g \cong 2\pi^2/(\kappa^2 L^3)$ are located at the edges of the stop-band symmetrical to the Bragg wavelength.

- In the case of pure gain coupling ($\Delta g \neq 0$, $\Delta n_{\mathrm{eff}} = 0$) the mode degeneracy is removed, which means that the mode with the lowest threshold gain oscillates at the Bragg wavelength symmetrically surrounded by the other modes with higher threshold gain values. The mode spacing is $\Delta\lambda = \lambda^2/2n_{\mathrm{eff}}L$ and no stop-band occurs since there is no backscattering at index steps in the grating. The mode selection is due to the different overlap of the standing waves in the FP resonator with the gain grating.

In second-order gratings ($m_{\mathrm{DFB}} = 2$) additional scattering occurs in the transversal direction, leading to higher losses. In addition, the coupling coefficient of second-order gratings depends more sensitively on the exact shape of the grating so that it becomes more difficult to control. That is why first-order gratings predominate although the corrugation periods are smaller ($\Lambda \cong 240\,\mathrm{nm}$ for $\lambda = 1.55\,\mu\mathrm{m}$). Due to the scattering perpendicular to the optical axis (Fig. 11.98), second-order gratings can be utilized for the vertical emission of light from edge-emitting laser diodes [11.1414, 1415].

Basic Properties of Index-Coupled DFB Lasers. The spectrum of an index-coupled DFB laser mainly consists of two degenerate lasing modes at the edges of the stop-band (Fig. 11.103b). This mode degeneracy in index-coupled DFB laser structures is usually removed by incorporating a $\lambda/4$ phase shift in the grating. This can technologically be implemented by inserting an additional section of length $\lambda_0/(4n_{\mathrm{eff}}) = \Lambda/2$ in the middle of the grating. The introduction of the $\lambda/4$ phase shift selects the Bragg mode in the middle of the stop-band, revealing the lowest mirror losses so that single-mode operation with an SMSR of $> 40\,\mathrm{dB}$ can be obtained (Fig. 11.103c).

The axial distribution of the light intensity in the cavity is connected to the mirror losses α_{m} via the round-trip condition. Thus, a decrease of the mirror losses for the longitudinal modes in a DFB grating is equivalent to increasing longitudinal optical confinement, which means that the photons are concentrated inside the cavity and only a small fraction of the light intensity leaves the resonator through the end facets. The typical longitudinal photon distribution for a DFB laser with and without a $\lambda/4$ phase shift is shown in Fig. 11.103, revealing the pronounced maximum in the middle of the resonator even for moderate coupling coefficients. This strong inhomogeneity of the photon density distribution in DFB lasers leads to an inhomogeneous carrier density distribution above threshold due to the recombination by stimulated emission. With increasing injection the carrier density is depleted in places with a high photon density. This phenomenon is called longitudinal spatial hole burning (LSHB) and has several important consequences for the static and dynamic behavior of DFB lasers above threshold. First, the mode discrimination is influenced since a variation of the carrier density distribution changes the round-trip gain of the various modes having different photon density distributions. Thus, the side-mode suppression can degrade with increasing output power due to LSHB. Second, the mode wavelengths change, even above threshold, since the inhomogeneity of the carrier density caused by LSHB leads to an inhomogeneous axial distribution of the effective refractive index. This effect is utilized in several types of tunable DFB lasers.

Various DFB lasers with a more complex grating structure have been developed in order to obtain a high yield of single-mode devices and a flat axial photon distribution with reduced LSHB. Some examples are:

- $2 \times \lambda/8$ phase shifts. The distance between the phase shifts, however, must be optimized to achieve a high yield [11.1416].
- Corrugation pitch modulation (CPM). The DFB grating is divided into three sections. The corrugation period in the central section is slightly higher than in the outer sections so that the phase shift is quasi-continuously distributed along the cavity [11.1417].
- Axial variation of duty cycle by using, e.g., a holographic double-exposure technique [11.1418].
- Axial variation of coupling coefficient by variation of the etch depth [11.1419] or sampled gratings [11.1420].
- Bent waveguides superimposed on homogeneous grating fields can be used to obtain quasi-continuously and arbitrarily chirped gratings with high spatial resolution [11.1421].
- Axially inhomogeneous injection using a three-electrode structure. Spatial hole burning can be compensated for if the injected current density is higher in the central section near the peak of the photon density, thus reducing the gain of the side-modes suffering from the lower current in the outer section [11.1422].

The phase relation between the grating and the end facets is difficult to control during the cleaving pro-

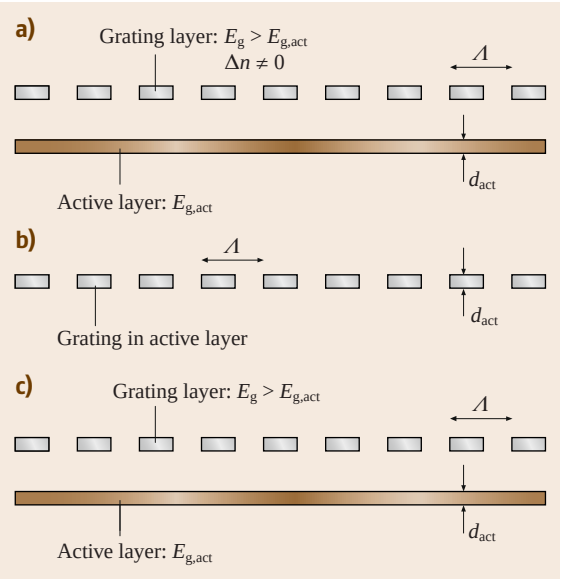

Fig. 11.106a–c Various types of Bragg gratings. **(a)** Index coupling; **(b)** gain coupling; **(c)** loss coupling

cess of DFB lasers, since the corrugation period for a first-order grating ($\lambda = 1.55\,\mu m$) is typically 240 nm. Experimental and theoretical investigations show that all static and dynamic optical properties of as-cleaved DFB lasers are strongly influenced by this phase relation between the grating and facet. The mirror losses of the various longitudinal modes, the mode discrimination, the intensity distribution, the optical spectra and the dynamic and noise characteristics vary considerably as a function of the end facet phases [11.1423]. Since these end facet phases are distributed randomly after the cleaving process, the yield of good DFB devices is limited. The problem of the uncertain end facet phases can be reduced by appropriate antireflection coatings.

Gain-Coupled Lasers. In gain-coupled laser structures, a longitudinal mode of the FP resonator is selected by implementing an axial gain or loss grating. In contrast to index-coupled DFB lasers, there is almost no reflection of the light wave in a gain grating. Therefore, the longitudinal intensity distribution and the spectral positions of the various modes are equal to those of an FP resonator. The mode selection is caused by the different overlap of the longitudinal modes with the gain grating. The mode, whose longitudinal field distribution exhibits the largest overlap with the gain grating or the smallest overlap with the loss grating, is selected.

Gain coupling can be realized in different ways:

- The grating structure can be etched directly into the active layer and regrown afterwards with a semiconductor material [11.1424] that is transparent to the laser emission (Fig. 11.106b). The resulting gain coupling in this grating structure is accompanied by a strong index coupling due to the high refractive-index difference between the active layer and the regrown material. With respect to the phase difference between the index and gain grating one distinguishes between in-phase and anti-phase gratings.
- A current blocking pnp layer structure above the active layer is corrugated and regrown, so that a periodic variation of the current density injected into the active layer is achieved [11.1425]. The parasitic index coupling can be kept very small in this type of gain grating. Due to the Kramers–Kronig relations, however, the gain grating is inevitably accompanied by an index grating.

Loss coupling is obtained if the grating is etched into an additional layer that is separated from the active layer and is absorbing for the emission (Fig. 11.106c). This grating acts as a saturable periodic absorber for the laser emission from the active layer [11.1426]. In contrast to index coupling (Fig. 11.106a) the bandgap E_g of the grating is smaller than the bandgap of the active layer $E_{g,act}$. Usually, the absorbing grating layer has a different refractive index than the material used for the regrowth, so that considerable index coupling occurs. Alternatively, the loss grating can be integrated into a metallization at the surface of the device, so that no epitaxial regrowth is required [11.1427].

There are significant differences between the characteristics of gain- and loss-coupled semiconductor lasers compared to index-coupled DFB lasers:

- In contrast to index-coupled devices, there is almost no reflection of the light wave in an ideal gain grating. Thus, the interference of the reflected wave inside the grating and at the facets is avoided, so that the influence of the end facet phases is strongly reduced compared with index-coupled DFB lasers. Therefore, a high single-mode yield can be obtained without the necessity to use an antireflection coating of the end facets.
- The longitudinal photon distribution is, in the case of a small parasitic index coupling, similar to that of an FP resonator. Thus, the strongly inhomogeneous

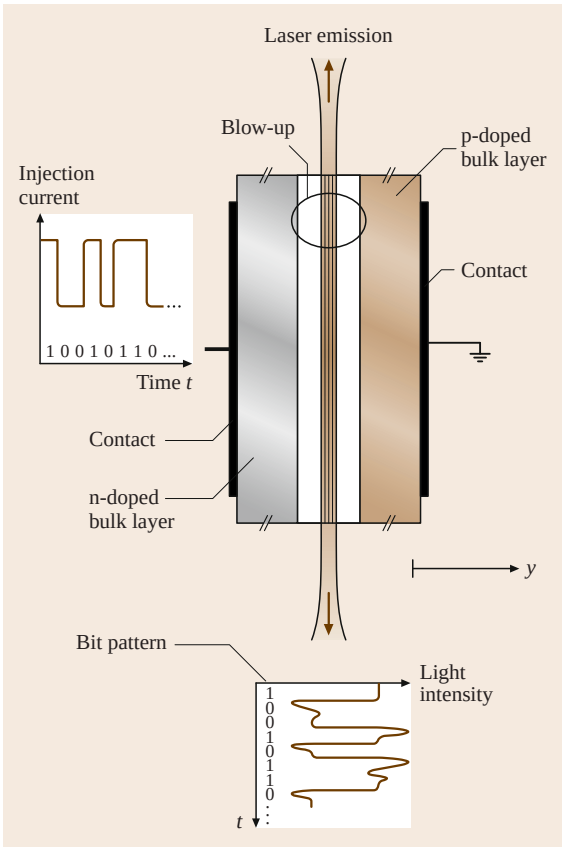

Fig. 11.107 Schematic representation of the direct modulation of a semiconductor laser, translation of an electronic bit pattern (*left*) via a corresponding temporal carrier distribution in the QWs (*center*) into an optical bit pattern (*bottom*). For *Blow-up* – Fig. 11.109 ◀

photon distribution in DFB lasers and the resulting problem of longitudinal spatial hole burning is reduced in gain-coupled devices.

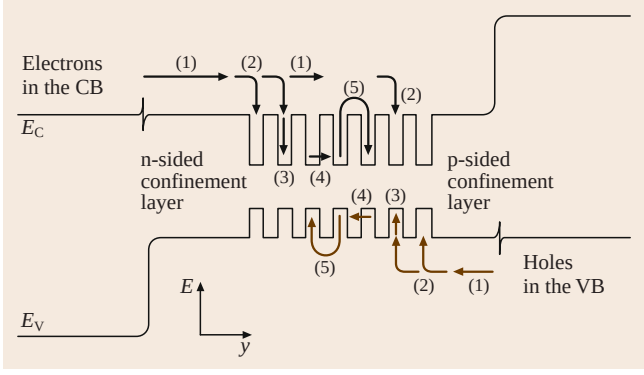

Fig. 11.108 Schematic representation of the charge carrier dynamics close of the active region (here seven QWs) in the band structure in space for an asymmetric laser structure (after [11.1428]) (*enlargement of Fig. 11.107 in the area indicated by the ellipse*)

Basics of Lasers with High Modulation Bandwidth

For the highest-bit-rate fiber-optic data communication (1.26–1.68 μm), the ultrafast conversion of the data from the electronic bit sequence into the appropriate optical bit pattern takes place by means of semiconductor lasers. This is done either with a CW laser combined with a subsequent ultrafast optical modulator or via direct modulation of the laser (intensity or frequency modulation). As the simplest example the intensity modulation of the laser is described. The bit pattern available as a sequence of ultrashort current pulses is translated by the laser into the appropriate sequence of ultrashort light pulses, which then propagate e.g. via a fiber towards the receiver. The photodetector retranslates the light pulses back to the electronic bit sequence. Seen in terms of a two-language dictionary, the laser translates ultrafast from electronics into optics and the photodetector ultrafast from optics into electronics.

For this purpose, the electrons injected through the n contact in the semiconductor laser must arrive as fast as possible at the most deeply bound energy states of the conduction-band QWs and the holes injected through the p contact as fast as possible into the ground states of the valence-band QWs (Fig. 11.107). Several retarding physical transport and relaxation processes are involved, whose combined time delay effect can however be minimized [11.1428, 1429]. Owing to the very high doping in the long conduction paths, which start at the contacts, very short dielectric relaxation times arise there. This can be visualized by means of a pipe completely filled with ping pong balls (high doping throughout the length of the conduction path). A ball injected at one end of the pipe, causes another to be ejected from the other end of the pipe. In this manner, a *current pulse* is transferred to the other end of the pipe almost without delay in heavily doped semiconductors.

In order to reduce optical losses through reabsorption, the confinement layers should be undoped or only slightly doped. Retarding effects arise as a consequence of the charge-carrier transport (number 1 in Fig. 11.108). Using the analogy of the balls and pipe above, a ball in an empty pipe (undoped) must go through the entire length of pipe (the length of a confinement layer) before finally exiting from the other end.

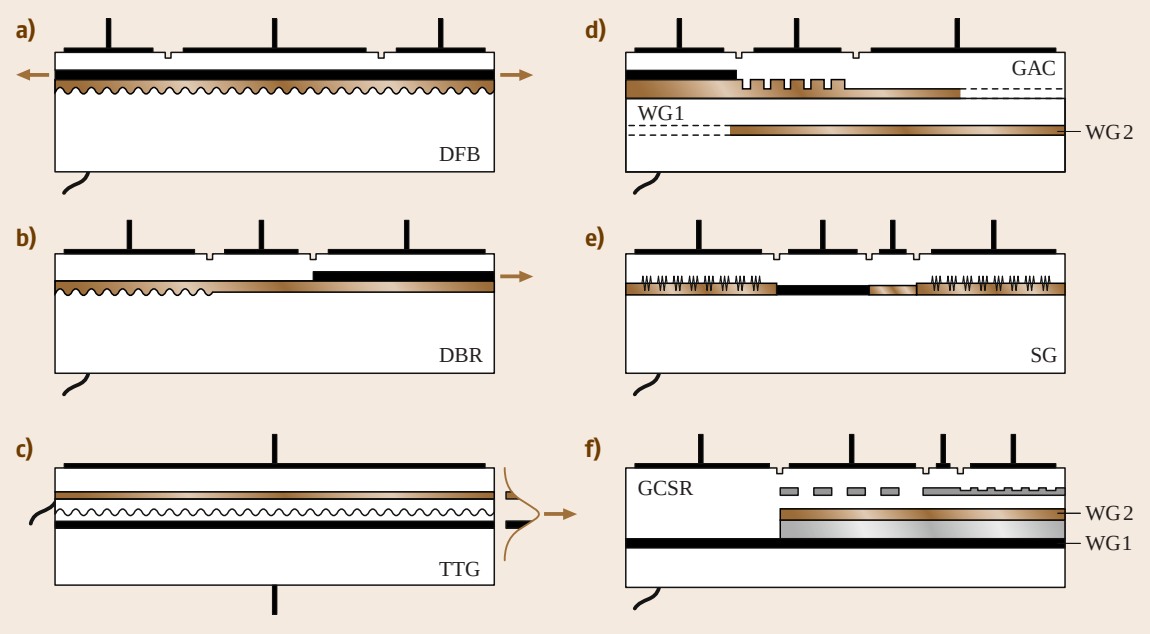

Fig. 11.109a–f Schematic cross-sectional views in the *y*–*z*-plane of different laser types: **(a)** three-section DFB, **(b)** three-section DBR, **(c)** TTG, **(d)** GAC, **(e)** SG, which is related to the SSG laser (not displayed) and **(f)** GCSR

Further retarding effects arise from the charge carrier capture (2), relaxation (3) in the respective QW ground states, by the reconciliation of charge carrier inhomogeneities between the individual pots, through tunneling (4) and thermal reemission (5). Since the mobility of the electrons is substantially higher than that of the holes, in asymmetrical laser structures [11.1428] the p-side confinement layers are reduced in thickness in favor of the n side. This favors the transfer of the less-mobile holes. In addition, this asymmetric laser structure design takes into account the different capture probabilities: the capture of holes into the QWs is much more efficient than that of electrons. Thus, a smaller p-sided confinement layer (reservoir of uncaptured electrons giving rise to bit interfering) is beneficial. In today's fastest laser diodes (largest modulation bandwidth) −3 dB modulation frequencies of up to 40 GHz can be obtained.

Tunable Lasers

Wavelength tuning of an edge-emitting DFB semiconductor laser can be obtained according to (11.92), in the simplest case, by varying the effective refractive index via the injection currents in different sections, either thermally or by using plasma effects (carrier density variations). In these cases rising injection currents lead:

1. To increasing emission wavelengths (red shift) via thermal effects
2. To a blue shift via the plasma effect.

A superposition of both effects is found in multi-section DFB lasers [11.1430] since gain, tuning and DFB grating exist in all sections (Fig. 11.109a). In order to increase the total tuning range it is necessary to separate gain and tuning [11.1431, 1432]. In the three-section DBR laser (Fig. 11.109b) this is done longitudinally by using a gain section (*right*, the active region is shown in black), a grating-section (*left*) and a phase section (*center*) [11.1433]. The phase section only includes the brown waveguide layer(s) and is used to match the phase of the standing light wave after one round-trip. The gain is controlled, e.g., via the current between the top right contact and the bottom contact. In contrast, a vertical separation is used in the tunable twin guide (TTG) laser [11.1431, 1432, 1434] (Fig. 11.109c). A current from the left-side contact to the top contact only controls the carrier density in the brown waveguiding layer. The gain is controlled via the current between the left side contact and the bottom contact. In the three-section DBR and the TTG laser the tuning is based on the plasma effect, if only forward biasing is used.

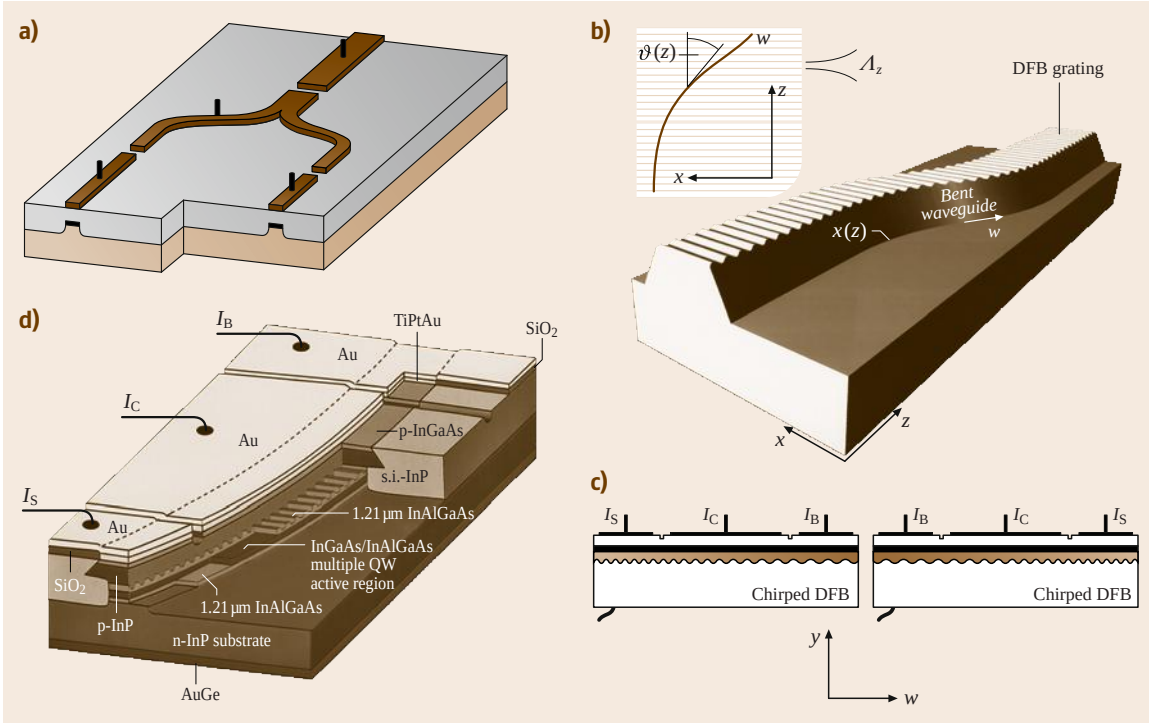

Fig. 11.110a–d Schematic perspective view of **(a)** a Y-laser [11.1437] and **(b–d)** three-section bent-waveguide chirped DFB lasers [11.1438], **(b)** the principle of generating chirped DFB gratings by specifically bent waveguides on homogeneous grating fields, cross section of two independent lasers originating from the bending displayed in **(b)**, **(d)** perspective schematic of a device shown in **(c)**. A scanning electron micrograph (SEM) of such a tunable three-section chirped DFB laser is displayed in Fig. 11.123

Another very important tuning principle is based on two mode combs of slightly different mode spacing. In analogy to a vernier based on two scales [11.1431, 1432], a small detuning of the combs can address individual modes separated widely in the spectrum: only those modes which exactly occur in both combs can oscillate since only this situation provides sufficient reflectivity and, thus, sufficient net gain. This principle is applied in the (C^3) laser, Y laser, Mach–Zehnder interferometer laser, superstructure grating (SSG) DBR laser and sampled grating (SG) laser. Two FP cavities of different length and, thus, *two FP mode combs* are used in the Y laser (Fig. 11.110a) and the C^3 laser (two coupled FP lasers of slightly different length, not displayed). Two superstructure mode combs are shifted against each other in the SSG laser [11.1435] and SG DBR laser [11.1436] (Fig. 11.109e). The codirectional coupling in the grating assisted coupler (GAC) laser between two waveguides realizes an additional spectral filter which can be shifted spectrally in a controlled way against an FP mode spectrum. The two waveguides can be laterally or vertically (Fig. 11.109d) coupled. Depending on the size of the grating period, a grating can reflect light (inversion of the propagation wave vector, contra-directional coupling grating, short grating period, e.g., Fig. 11.109a,b,c,e) or change the magnitude of the propagation vector (maintaining propagation direction, codirectional coupling grating, long period, shown in Fig. 11.109d below the center contact). Table 11.38 includes a comparison of different tunable laser types with respect to important device characteristics and properties.

Generally the types discussed up to now cannot provide excellent characteristics in all features such as simple tuning (low number of control parameters), high SMSR, wide tuning, continuous tuning and high efficiency. This motivates the search for promising combinations of the above principles. Using a GAC to select a mode from an SG yields the grating-assisted codirectional coupler laser with rear sampled grating

Table 11.38 Tuning characteristics of different 1.55 μm laser types, DFB: distributed feedback, DBR: distributed Bragg reflector, TTG: tunable twin guide, SSG: superstructure grating, SG: sampled grating, GAC: grating-assisted coupler, GCSR: grating-assisted co-directional coupler laser with rear sampled grating reflector. The tuning occurs either thermally (t), via the plasma effect (p), via the co-directional coupler (CC) grating, via Vernier effect (V) or via micromachined actuation (MEMS). TR: tuning range

reflector (GCSR) [11.1439, 1440] (Fig. 11.109f). Another laser with 11 sections combines a SSG or a SG with many DBR sections of different grating period each [11.1441]. SSG or the SG laser and the TTG laser has been proposed [11.1442]. Combining the SSG laser and the Y laser yields the modulated grating Y laser [11.1443]. For comprehensive details of tunable lasers we refer to [11.1431, 1432]. Finally, coupled Mach–Zehnder interferometers or arrayed waveguide (AWG) structures can also be used as filter structures in lasers, e.g., in the digitally tunable ring laser using a ladder of ring-resonator filters [11.1444, 1445].

DFB lasers with an axially varying grating period are very attractive to tailor specific device properties. Using bent waveguides on homogeneous DFB gratings ($\Lambda_z = \text{const.}$) enables to generate a local effective pitch length $\Lambda(z)$ that exceeds Λ_z the more, the larger the local tilt angle of the bent waveguide deviates from a vertical intersection of the pitches i. e., the larger the local tilt angle $\vartheta(z)$ is. Figure 11.110b schematically shows a bent waveguide covering a homogeneous grating. Choosing appropriate bending functions $x(z)$ generates chirped DFB gratings with a varying effective pitch length $\Lambda(z) = \Lambda_z / \cos(\vartheta(z))$, as shown in the inset to Fig. 11.110b [11.1421]. The fabrication method is indicated in Fig. 11.110c, which shows two chirped DFB lasers formed after cleaving the structure in Fig. 11.110b in the x-direction in the center of the side of the device oriented in the z-direction. Since the light is strongly guided along the bent w-direction, the light sequentially passes quasi continuously varying pitch lengths $\Lambda(w)$, as displayed in Fig. 11.110c. Since ϑ is largest in the center of Fig. 11.110b, the two chirped DFB lasers have the largest pitch at the center facets.

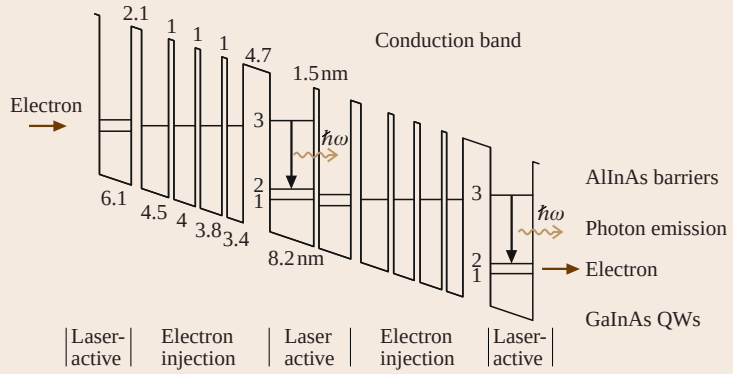

Fig. 11.111 Principle of a quantum cascade laser [11.1455]

Various applications of chirped DFB gratings have been demonstrated [11.1421, 1438, 1446, 1454], including axially distributed phase shifts, higher SMSR, enhanced single-mode stability and lower line widths. In addition, chirped three-section DFB lasers (Fig. 11.110d) have demonstrated enhanced tuning ranges [11.1421, 1438, 1454] (Table 11.38). The mushroom-type laser structure (Fig. 11.102d) is applied in the chirped three-section DFB laser (Fig. 11.110d), which shows a modulation bandwidth of up to 26 GHz [11.1428].

Further Laser Types with Horizontal Resonators

1) In the bipolar lasers considered so far the light emission in the active layer takes place through the recombination of an electron in the conduction band with a hole in the valence band (band–band transition or *inter-band* transition). In unipolar lasers the radiative recombination takes place within a single band between two bound states of a potential well (*intra-band* transition, in Fig. 11.111 shown for the conduction band). Through so-called electron recycling, this process is cascaded in stages (explaining the name quantum cascade laser, Fig. 11.111). The band edges are accordingly tilted by the applied voltage (electric field). The multiple-QW structure [11.1455] shown here is based on a uniform QW composition and a different uniform barrier composition. However, there are in each case six different QW widths (the lower sequence of numbers) and barrier widths (the upper sequence of numbers) involved.

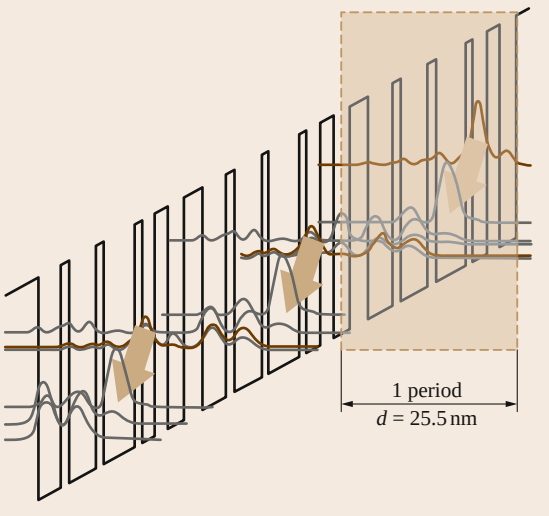

Fig. 11.112 Schematic band diagram of a novel injectorless quantum cascade laser emitting at 6.36 μm (after [11.1456])

Through tailored dimensioning, we ensure that in the case of resonance (for a certain applied voltage) each of the four narrowest QWs exhibits a bound state, and that these four states are energetically identical (i. e., they line up exactly horizontally). Furthermore, the widest QW is dimensioned in such a way that the highest state of the three bound states, marked with a 3 in Fig. 11.111, deviates only insignificantly from the four identical levels mentioned above. Due to the thin barriers and the resulting tunneling processes, an electron injected from the left tunnels horizontally into the excited level 3. After a radiative transition it falls down to level 2. Due to the very thin barriers, the wave functions are generally strongly delocalized. By optimizing the QW geometries the relaxation time from state 2 to state 1 is designed to be very small, so that the maxima of the wave function of state 2 lies on the left and that of state 1 on the right of both of the wider QWs.

This tunneling process proceeds in a stair-like cascade, which is illustrated with just two stages in

Fig. 11.111. This example also illustrates very successful recent complex QW structures, which are based on a variety of different quantum cascade structures. Quantum cascade lasers can successfully produce laser emissions in the mid infrared (3.5–19 μm [11.1457], in some cases even up to several hundred micron [11.1458, 1459]), where there are very few suitable semiconductor materials with extremely small bandgaps for the construction of bipolar lasers.

A classical quantum cascade laser (Fig. 11.111) consists of (i) an active light generating part, and (ii) a passive injector part, which serves as a doping reservoir and improves carrier transport between subsequent stages. Since the injector section is doped additional free-carrier loss occurs and the injector part corresponds to half of the total period length, unnecessarily increasing the device size and epitaxial growth time. A novel design omitting the injector stages [11.1461] is shown in Fig. 11.112 [11.1456]; which is much more compact. Roughly twice the number of active periods can be achieved within same thickness leading to higher gain, faster carrier transport, reduced loss, low voltage, and lowest threshold current densities.

2) A very elegant way to obtain a longitudinal single-mode oscillation of an FP laser is to use one highly reflecting (HR) and one antireflection (AR) coated facet, with a piece of fiber optically coupled to the latter (Fig. 11.113a) including a DBR grating with a period (11.92) such that it filters exactly one single oscillating mode from the spectral amplification profile. This laser design is called a (semiconductor-)fiber laser. In contrast, the active medium for optically pumped fiber lasers is a doped fiber.

3) Laser designs with straight aligned resonators have been considered so far. However, in the ring laser (Fig. 11.113b,c) and the microdisc laser (Fig. 11.113d), the beginning and end of the resonator merge into one another. In the case of waveguiding (Fig. 11.113b) modal solutions result if the length of the circular optical axis is close to an integer multiple of the wavelength in the medium. Similar selection rules apply in microdisc lasers, which can also be illustrated in the ray model with multiple reflections (eight in Fig. 11.113d) at the exterior surfaces. These modes are also known as *whispering-gallery modes* after the acoustic phenomena in the gallery of the St. Paul's cathedral in London and the Gol Gumgaz mausoleum in Bijapur city in India. There, a whispered word is discernible, after multiple reflections from the inner walls of the cupola, back at the ear of the speaker. In ring or disc structures waveguide losses increase for smaller radii and have to be considered during the design of these laser devices in order to obtain low threshold currents.

4) Semiconductor lasers for emission wavelengths $\geq 2.4\,\mu m$ have gained increasing importance for, e.g., sensing applications and could open the promising THz frequency range. Different laser approaches are possi-

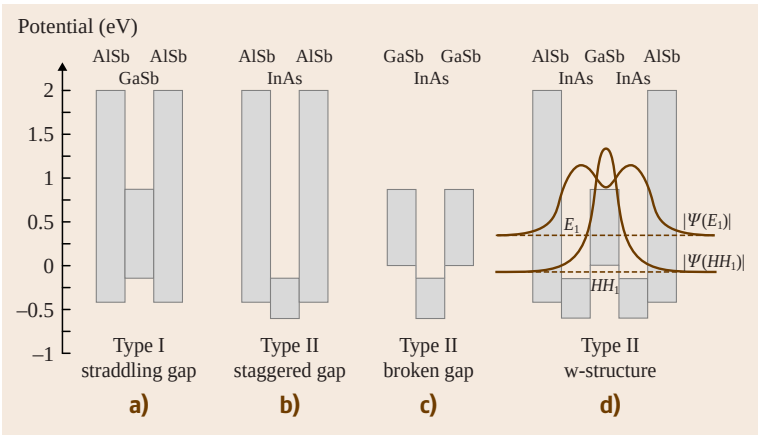

Fig. 11.114 Different heterostructures in a flat band condition (bandgaps shown in *gray*, quantized energy states and wave functions in *brown*)

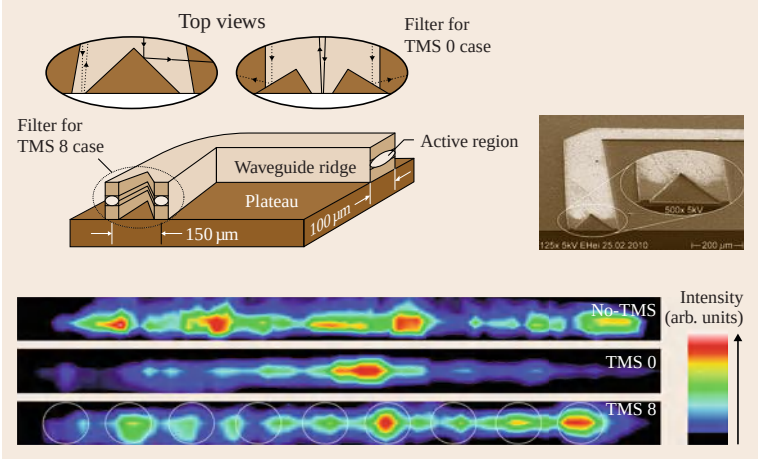

Fig. 11.115 Monolithically integrated AlGaInAsSb Type II QW laser. Experimental near-field patterns are displayed in the *bottom figure* for no TMS showing multimode operation, TMS 0 selects the fundamental mode and TMS 8 the 8th order mode (after [11.1462])

ble. First, intraband recombinations used in quantum cascade lasers (Fig. 11.112) using electron transitions only within CB QWs or only a hole transitions within VB QWs and second, interband recombinations (treated throughout Sect. 11.3) are based on electron–hole pair recombinations and involve CB and VB, simultaneously. Interband recombinations in this long wavelength range have been reported in (i) lead salt compounds Pb-Salz (PbS, PbEu Se) operating only at cryogenic temperatures, (ii) difference frequency generation of the output of two III–V semiconductor lasers oscillating spectrally very close together providing only limited power, and (iii) using type II heterostructures in III/V-semiconductors. In the following type II lasers are considered in more detail since they allow also high output power [11.1462]. In Fig. 11.114 for one type I and three different Type II heterostructures the spectral positions of the band gaps (gray) are displayed and all allow good optical confinement (Fig. 11.90c). In type I heterostructures (Fig. 11.114a) the low band gap is located completely inside the surrounding wide band gap, in the staggered type II the low band gap is located partly inside the surrounding wide band gap (Fig. 11.114b), in the broken type II (Fig. 11.114c) the low band gap is located completely outside the surrounding wide band gap, and (Fig. 11.114d) shows a mixture of (Fig. 11.114b) and (Fig. 11.114c). Therefore, type I (Fig. 11.114a) provides a larger difference of the CB and the VB energy levels and is optimum for higher laser emission energies (shorter wavelengths) and type II (Fig. 11.114b–d) provides a much smaller difference of CB and VB energy levels and is optimum for small laser emission energies (longer wavelengths). In Fig. 11.114c the valence band edge of the large band gap material is located above the conduction band edge of the low band gap material. Due to the mixed situa-

tion in Fig. 11.114d the laser device properties can be tailored and optimized very well, e.g., for high power operation. Note that in type I the maxima of the electron and hole wave functions are located in the same material film (locally direct transitions) and in type II they are not (locally indirect transitions Fig. 11.114d). AlGaInAsSb Type II QW laser show high output power in a conventional broad area geometry to avoid catastrophic optical (mirror) damage. However, this involves many undesirable aspects: several lateral modes, instabilities and filamentation. The following example provides both high power and single lateral mode operation using a monolithically integrated lateral mode selector (TMS) as shown in Fig. 11.115. For non-semiconductor based MIR lasers see Sect. 11.2.1.

11.3.4 Basics of Surface-Emitting Lasers with Vertical Resonators (VCSELs)

The VCSEL presents a large technological challenge in terms of the implementation of DBR mirrors with extremely high reflectivity. In comparison to the edge-emitting DFB or DBR laser, the individual layers of the DBR mirrors in the VCSEL are successively deposited (e.g., by epitaxy). In this way, layer A and the neighboring layer B together make up one period. Since the reflectivity of the DBR mirrors rises with increasing number of periods and refractive index contrast, materials with large refractive index contrast are preferable in order to reduce the total number of periods and thus device cost. The insets in Fig. 11.116 show a DBR mirror (left inset) and the light intensity reflected by the mirror as a function of the wavelength (reflection spectrum, right inset). For $\lambda = 1.55\,\mu m$, the maximum reflectivity R_{max} in the stop-band is presented in the main picture as a function of the number of periods for different material systems. The data result from theoretical model calculations with consideration of the spectral variations of the refractive indices and absorption coefficients [11.1463, 1464]. Large differences appear in the figure due to different absorption and different refractive index contrast $2(n_A - n_B)/(n_A + n_B)$. For semiconductor epitaxial layers, absorption depends on the doping concentration and is well controllable. Absorption in dielectric layers is more difficult to control and depends strongly on the technological process. Unfortunately, no large refractive index contrasts can be realized in the GaInAsP material system. To achieve a reflectivity of 99.8%, 50 periods, a number that is in practice too high, are needed. In comparison, this is achieved in AlAs/GaAs DBRs with just 20 periods.

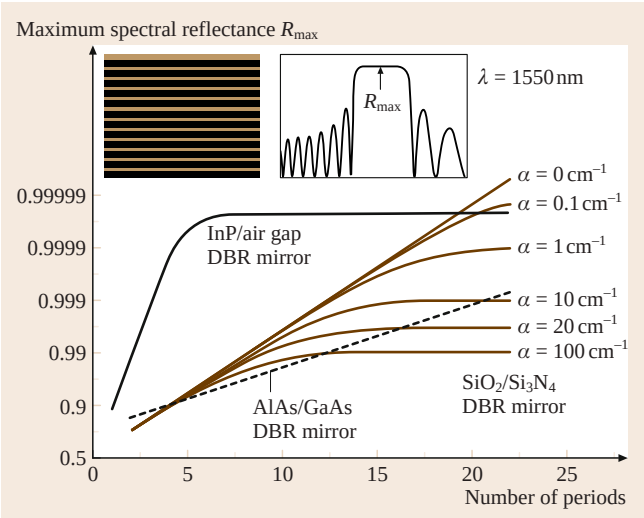

Fig. 11.116 Maximum spectral reflectivity R_{max} in the stop-band for $\lambda = 1.55\,\mu m$ as a function of the number of periods for different DBR mirror systems. *Left inset*: cross section of a DBR mirror. *Right inset*: reflectivity as a function of wavelength

If the two dielectrics Si_3N_4 and SiO_2 are combined, then even 13 periods are sufficient due to the very high relative refractive index contrast.

This enormously high reflectivity is achieved through constructive interference of the partial waves reflected at all heterointerfaces. Note that with a reflection at the interfaces from the optically thinner to the optically denser medium a phase change of π occurs, but not vice versa [11.1465, 1466]. The condition for constructive interference is fulfilled, e.g., by the combination of $\lambda/4$-thick layers A and B, as is the case in Fig. 11.116. Here, d_A and d_B are the physical thicknesses and $\lambda/4n_A$ and $\lambda/4n_B$ are the optical thicknesses. In basic configurations, the following relation applies to achieve high reflectivity using constructive interference

$$n_A d_A + n_B d_A = m\frac{\lambda}{2} \quad (\text{with } m = 1, 3, 5, \ldots)\,. \tag{11.119}$$

On GaAs substrates the almost lattice-matched AlAs/(Al)GaAs combination is ideal for lasers in the wavelength range 800–1300 nm. Although, as with the edge emitters, trials have been made to implement long-wavelength VCSELs on GaAs substrates, 1.55 μm VCSELs are still based on InP. This is due to the fact that the active laser layers (e.g., GaInAsP and AlGaInAs) for the spectral range close to 1.55 μm can

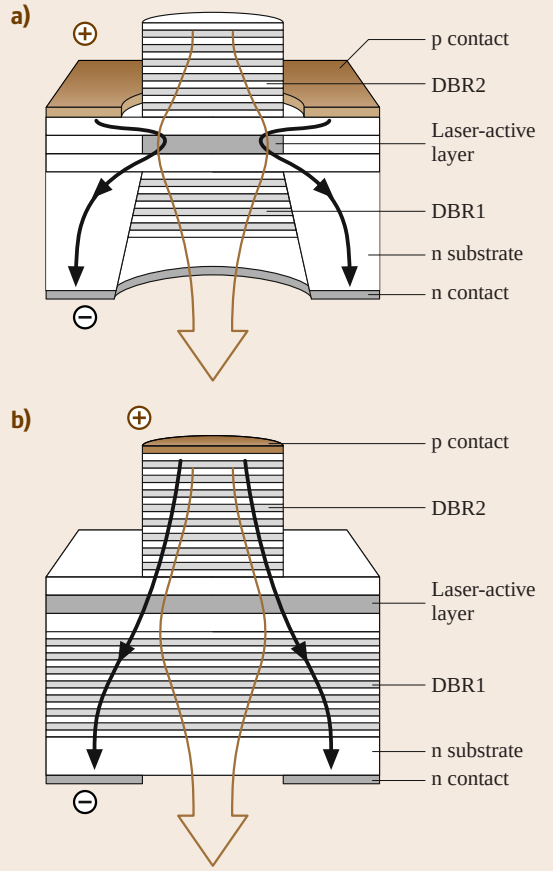

Fig. 11.117a,b Schematic setup of a VCSEL with electrically insulating (**a**) and electrically conducting DBR mirrors (**b**)

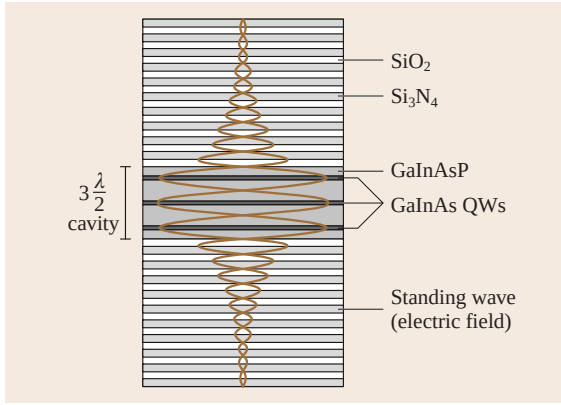

Fig. 11.118 Layered structure of a VCSEL including the standing wave of the electrical field

be best implemented on InP substrates. There are different possibilities for implementing highly reflecting 1.55 μm DBR mirrors on InP substrates: a kind of pressure bonding technique (wafer fusion) of AlAs/GaAs DBRs [11.1467, 1468] to embed the GaInAsP active region, strongly lattice-mismatched so-called pseudomorphic AlAs/GaAs DBRs [11.1469], lattice-matched AlGaInAs, AlAsSb/AlGaAsSb, AlGaAsSb/InP DBRs [11.1470, 1471] or fusing of a low-period GaInAsP/InP DBR with active layers onto a AlAs/GaAs DBR [11.1472].

A resonator results from the combination of two DBR mirrors, where the volume between the DBR mirror-ends towards the center is called the cavity. If the cavity material is passive, the setup is an optical filter, if it is active a VCSEL results. Figure 11.117 shows schematically the structure of a VCSEL with two multiple-layer semiconductor DBR mirrors. In the illustration the upper mirror is highly reflective, so the laser light is emitted essentially downwards (brown arrow). The envelope of the vertical intensity distribution discussed below is indicated by the lateral expansion of the brown arrow (Fig. 11.98, depicted in grey-tone variations). The holes are injected from above through the upper p-doped DBR mirror into the active laser zone; the electrons are injected from below through the lower n-doped DBR mirror. The outer curved black arrows indicate the current flow. Here, it is challenging to reduce the electrical resistance of the p-doped DBR mirror by sophisticated doping (impurity concentration profiles) in order to reduce the operating voltages and the buildup of Joule heating. Figure 11.117a schematically depicts the structure of a VCSEL with two dielectric DBR mirrors. The holes and electrons are injected by means of ring contacts, whereby the current flow bypasses the electrically insulating DBR mirrors. Furthermore, of crucial importance is the lateral electrical confinement to enable the production of high electron–hole-pair densities in the central part of the active zone, and thereby very small threshold current densities. Therefore, an electrically insulating ring is built surrounding the lateral laser mode. The realization of this is technologically demanding and is achieved, e.g., by ion implantation or selective oxidation. A sufficiently high thermal conductivity of the DBR mirrors is of further importance in enabling efficient heat dissipation from the active region to the heat sink and, if necessary, of that heat generated inside the DBR mirrors.

For the VCSEL with two dielectric DBR mirrors and a cavity length of $3\lambda/2$ shown in Fig. 11.117a,

the electric field of the standing light wave is computed [11.1463, 1464] and presented in Fig. 11.118 together with the entire multilayer structure. In order to achieve a high gain in the laser design, the QWs are positioned at the maxima (antinodes) of the half-waves. Ideally, three QWs, three double QWs or three triple QWs should be placed in the $3\lambda/2$ cavity shown. The envelope of the standing light wave field gradually drops outwards from center due to the distributed reflecting effect of the DBR mirrors. We note again that exactly one quarter of a wavelength is allotted to each mirror layer ($\lambda/4$ layers) and that the nodes for the design wavelength lie exactly at the interfaces.

In the following, the VCSEL spectra are intuitively constructed. To derive this, we consider a semiconductor cavity between two mirrors indicated in the top left of Fig. 11.119. Based on the fixed cavity length, (11.91) leads to the three modes displayed as lines in the spectrum on the right of the figure, which become sharper for higher mirror reflectivities. This means that a cavity of this length is suitable for each of these (laser) wavelengths if the standing wave experiences a sufficiently large optical gain at its peak (antinodes). On the contrary case, for a desired (fixed) laser wavelength λ the cavity length can be selected straight away as $\lambda/2$, $2\lambda/2$ or $3\lambda/2$. If the two mirrors are implement as DBRs (bottom left of the figure), then the line spectrum at the top right is *superposed* with the known reflection spectrum (Fig. 11.119 bottom right) of the DBR mirrors, resulting in the laser spectrum already shown in Fig. 11.103d. The stop-band of the VCSEL is substantially larger because of the higher refractive index contrast in the DBR mirrors compared to that of the DFB laser with the relatively small refractive index contrast between the quasi-layers of the DFB grating. Following from Fig. 11.103c,d the $\lambda/4$-phase-shifted DFB laser has many similarities to a VCSEL with a $\lambda/2$ cavity and two very long DBR mirrors with a small refractive index contrast.

Note that the following numerical values are strongly dependent on wavelength and material and that a thoroughly comprehensive treatment would exceed the framework of this volume. For VCSELs, optical power outputs of < 1 mW (lateral single-mode operation) are typical. With a laterally expanded active region, i. e., laterally multimode VCSELs, achieve up to 120 mW. Typical threshold currents lie around 1 mA, with record values of about 0.06 mA (corresponding to 350 A/cm^2). The highest power outputs and the lowest thresholds are achieved in the spectral range 850–1000 nm. Compared to edge emitters the

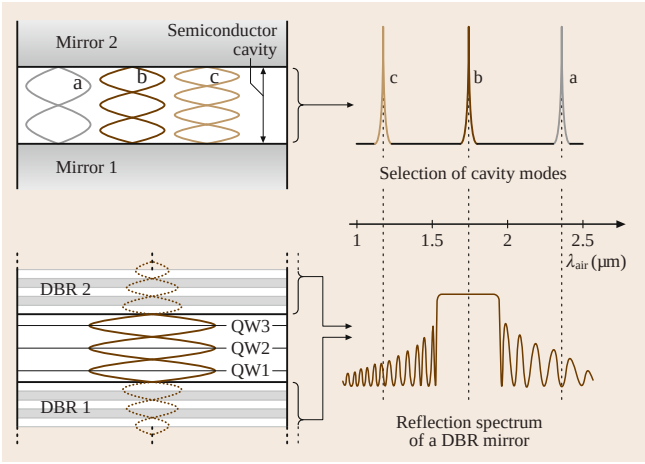

Fig. 11.119 Characteristic spectral components of a VC resonator. Three standing waves in the cavity ((*a–c*) *above left*) cause, as marked by the *bracket*, the build up of the FP modes (*above right*), the DBR mirrors (*bottom left*) are characterized by the reflection spectrum (*bottom right*), as indicated by the two *brackets*. With a very short cavity length only one FP mode is located in the stop band (along the *broken vertical lines*)

thresholds are amazingly low, but with rather moderate maximum power outputs. In broad-area edge emitters for example, up to 19 W CW emission and external quantum efficiencies of over 60% [11.1473] have been achieved. While the VCSEL has enormous advantages in the laser–fiber coupling due to the small beam divergence and the symmetric mode profile, the edge emitter incurs substantial overhead costs for light coupling due to the higher divergence and the elliptical mode profile. This is achieved in practice with aspherical lenses or with complicated tapered waveguide structures in the laser or fiber. The VCSEL offers further substantial advantages as it enables simple optical on-wafer testing similar to the testing of integrated electronic circuits. In contrary, edge emitters must be individually isolated for characterization, i. e., at least cleaved into bars, or additionally for surface out-coupling, a 45° mirror (Fig. 11.98) must be implement in combination with etched mirrors. A typical SEM micrograph of a VCSEL is displayed in Fig. 11.120 [11.1387, 1474].

The modulation bandwidths of VCSELs are around 5 GHz (the record being 17 GHz respectively 23 GHz in the 850 nm wavelength range) compared with typical values of 15 GHz (the record being 40 GHz) for edge emitters. If one compares the laser line widths of devices without external resonators, then VCSELs typically attain 200 MHz (the record being 50 MHz)

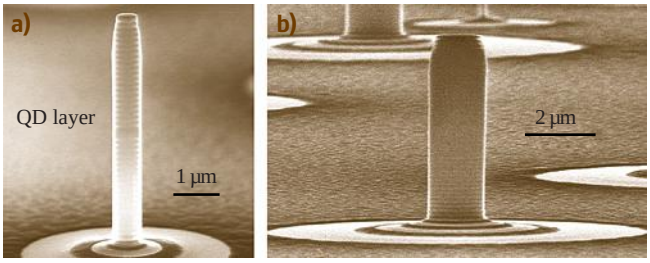

Fig. 11.120a,b SEM micrographs of QD micropillar VCSELs with about 650 nm **(a)** and 1.7 μm in diameter **(b)**. The etch depth is about 5 μm. The position of the QD layer is indicated in **(a)**. Such structures are used to obtain strongly coupled light matter interaction on the single particle level (single excitons and photons) (after [11.1387, 1474])

while edge emitters typically attain 1 MHz (the record being 10 kHz). Edge-emitting semiconductor lasers exist in the range 340–12 μm, while in the green and mid-IR spectral regions there are as yet either no devices or the component lifetimes are not sufficient for practical applications. Electrically pumped VCSELs exist so far within a spectrally much smaller range (420–2.6 μm) [11.1475–1477]. In VCSELs wavelength tuning is particularly difficult using charge-carrier-induced (current-induced) or thermal refractive index changes. A maximum continuous tuning range of 10 nm is attained in $l = 2.3$ μm VCSELs compared to 80 nm in single-mode 1.55 μm edge emitters (Table 11.38).

Electrically-pumped, single-mode, continuous-wave GaSb-based VCSELs using buried tunnel junctions as current apertures have shown emission wavelengths up to 2.6 μm. By utilizing the device's most attractive features, such as electronic wavelength tuning, several absorption lines of a single gas species can be scanned using the full tuning range $= 10$ nm for $\Delta\lambda = 10$ mA at $l = 2.3$ μm [11.1478]. This is not only the longest III/V semiconductor laser emission based on type I heterostructures (Fig. 11.121), astonishingly, it is a VCSEL.

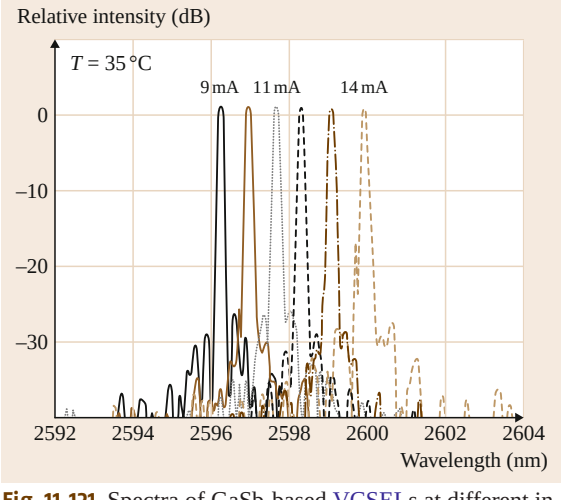

Fig. 11.121 Spectra of GaSb-based VCSELs at different injection currents (after [11.1478]) (VCSEL at 2.6 μm)

In order to increase the modulation bandwidth of VCSELs (i) parasitic limitations are tackled by small chip-diameters to reduce contact-pad and chip-capacitances [11.1479] and (ii) intrinsic modulation-bandwidth limitations are tackled by reducing the photon lifetime by a short-cavity concept [11.1480] with the help of two dielectric laser mirrors. In current research the following values could be achieved. The output power is ≥ 2.5 mW, SMSRs ≥ 50 dB, and the modulation bandwidths is ≥ 17 GHz (Fig. 11.122). These lasers enable 25 Gbit/s error-free transmission over 4.2 km of fiber.

Finally we present a tuning concept for optoelectronic devices with vertical resonators, which permits ultrawide wavelength tuning on the basis of only one control parameter.

Micromechanical Tunable Filters and VCSELs

At perpendicular incident a light wave (wavelength λ_D) is reflected up to 99.9% by a DBR mirror. The period is normally selected in such a way that λ_D lies at the center of the stop-band (Fig. 11.122, bottom right). When a second identical mirror is positioned parallel at a distance of, for example, $1.5 \times \lambda_D$ from the first one, as shown in Fig. 11.122, it is experimentally observed that the first mirror no longer reflects the wavelength λ_D. Although it is at first sight astonishing, the arrangement of the two DBR mirrors is now almost 100% transparent for λ_D but still highly reflecting in the remaining stop band, making this a high-quality optical filter, e.g., for fiber-optic telecommunication based on dense wavelength division multiplexing or sensor systems.

For λ_D in a DBR mirror, all waves are reflected partially and multiple time at each interface leading to constructive interference (99.9% reflection) on the incident side of the mirror and destructive superposition on the opposite side. The light waves penetrate the mirror but transfer no energy. By introducing a cavity between two mirrors all partial waves reflected in both DBR mirrors superimpose to a resonant mode, forming a standing wave in the cavity for λ_D, and interfering constructively (Fig. 11.122).

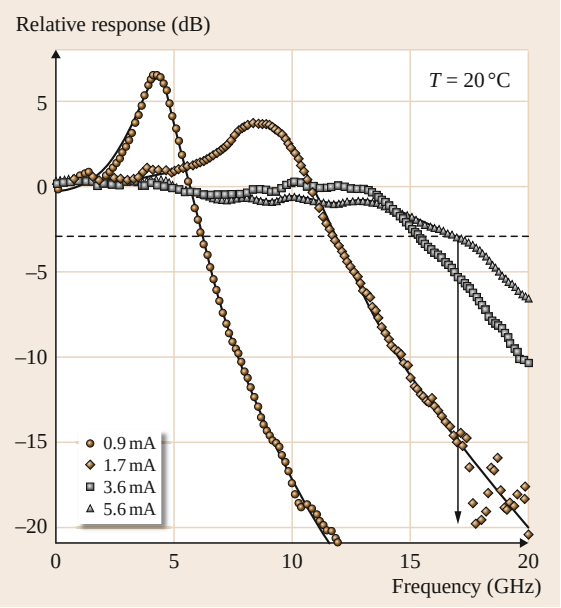

Fig. 11.122 Amplitude modulation response of a 1.53 μm VCSEL for different injection currents

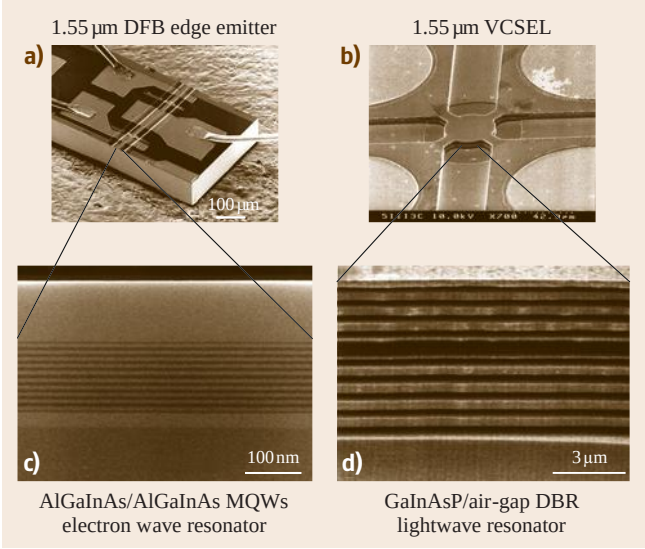

Fig. 11.123 **(a)** Tunable, edge-emitting three-section laser with axially varying DFB grating known as a chirped DFB grating [11.1421], **(b)** strain-compensated multiple QW structure with tensile-strained AlGaInAs barriers and compressively strained AlGaInAs wells[11.1483], **(c)** VCSEL based on multiple InP/air membranes (*center*), each of which is supported by four suspensions connected to the square supporting posts [11.1482], **(d)** cross section of the vertical resonator, consisting of the laser-active GaInAsP QW region, which is embedded between two InP/air-gap DBR mirrors (after [11.1481])

Figure 11.116 contains a further material system, which has not been discussed so far, with an extremely high refractive index contrast ($n_{InP} = 3.2$, $n_{air} = 1$). With only four periods, a reflectivity of over 99.8% can be obtained. This unusual structure can be made, e.g., from a semiconductor multilayered structure with alternating InP and $Ga_{0.43}In_{0.57}As$ layers by selective etching of the GaInAs layers (micromechanical sacrificial-layer technology). If a reverse-bias voltage is applied between the upper p-doped and the lower n-doped DBR mirror the membranes including the sandwiched air cavity can be electrostatically actuated and thus the filter wavelength can be varied in this way with only one control parameter (voltage). With such optical filters, a continuous wavelength tuning range of 142 nm was experimentally achieved with only 3.2 V [11.1463, 1464, 1481, 1482] and for a different device a maximum continous tuning range of as much as 221 nm was obtained [11.1481]. The same tuning principle occurs in Fig. 11.123c,d, which shows a VCSEL with InP/multiple-air-gap DBR mirrors, GaInAsP laser-active QW layers and an InP substrate. These tunable lasers suffer from a quite complicated tuning scheme, a large number of different injection currents (up to 14), and a noncontinuous tuning range. Recently huge progress has been achieved in micromachined tunable VCSELs. A tuning range of 17 nm has been achieved in a 1.55 μm laser addressing 20 channels in 100 Hz separation for a dense wavelength division multiplex [11.1453]. Another 1.55 μm two-chip VCSEL based on a dielectric DBR top mirror membrane and a half-VCSEL including bottom DBR and the active region is shown in Fig. 11.124. The bottom DBR consists of CaF2/ZnS and gold and minimizes the number of periods to 3.5. An extremely large continuous tuning range of = 76 nm was obtained by thermal actuation of the SiO_x/SiN_y top DBR [11.1452].

In conclusion, based on Fig. 11.123 a very interesting parallel between quantum electronics (Fig. 11.123a,b) and quantum photonics (Fig. 11.123c,d) can be drawn. In order to tailor the electronic levels for electrons and holes, semiconductor heterostructures of predetermined composition and thickness are implemented. If the layer thickness of the material with the smaller bandgap is on the order of the magnitude of the electron wavelength, a quantization occurs that leads to defined quantized energy levels in the QWs. These quantized energy levels (eigenvalues) and the corre-

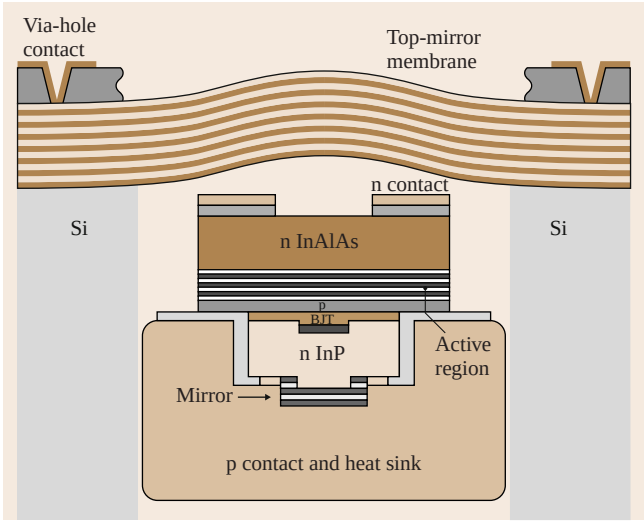

Fig. 11.124 Micromachined tunable 1.55 μm two-chip VCSEL using a buried tunnel junction (BJT) (after [11.1452])

sponding electronic wave functions (eigenfunctions, i. e., modes) are solutions of the Schrödinger equation. The materials, stress and layer thicknesses are set up in this example with the 10 AlGaInAs QWs (Fig. 11.123b) in such a way that the optical emission is at 1.55 μm. These QWs serve as the laser-active medium of an ultrafast semiconductor diode laser (Fig. 11.123a) [11.1428, 1483]. In a very simplified depiction, the multiple QWs define a resonator for electron waves.

The electron microscope micrographs on the right show the exact analogy for photons. In order to select a defined mode in the resonator of a VCSEL, taking into account the refractive indices, layer thicknesses in the order of magnitude of the photon wavelength are chosen. A kind of quantization also arises in this case. The effective refractive indices (eigenvalues) and the corresponding photon wave functions (eigenfunctions, i. e., modes) are solutions of the Helmholtz equation. From the mathematical point of view, the space-dependent parts of the Schrödinger and Helmholtz equations have equivalent behavior. The strong refractive index contrast of InP/air-gap multi-membrane structures is again used in Fig. 11.123d to implement highly reflective DBR mirrors for a 1.55 μm VCSEL (Fig. 11.123c) [11.1481, 1482]. Analogously the periodic refractive index variation defines a resonator for photon waves.

Further analogies in this area are offered by periodic 2-D quantum-dot fields and 2-D photonic crystals, or photonic band structures and electronic band structures.

11.3.5 Edge-Emitting Lasers and VCSELs with Low-Dimensional Active Regions

In commercial semiconductor laser diodes, bulk semiconductor materials (3-D) were exclusively used for the active zones for 25 years. Starting from 1990 edge emitters with QWs (2-D) were implement in research labs and continuously improved. Only after a further five years QW lasers were commercialized and subsequently surpassed the 3-D lasers with lower threshold current densities, higher power outputs, higher characteristic temperatures T_0 and higher bit rates due to more-favorable gain profiles and better electronic confinement. Although quantum wire (1-D) lasers should exhibit even better characteristics, they have so far not been very successful due to technological and geometrical constraints. In particular long carrier-transport and carrier-capture times substantially limit the bit rates in quantum wire lasers. Quantum dot QD (0-D) laser structures [11.1385, 1386, 1390–1397] are a lot more promising. However, a problem at the moment is the strongly varying size of QDs (Fig. 11.94). The theoretically very sharp density-of-state profiles are strongly inhomogeneously spread, so that the predicted high differential gain $\mathrm{d}g/\mathrm{d}n$ does not arise in practice. Compared with the 3-D and 2-D structures so far no spectrally narrower and higher-gain profile has been obtained. Particularly broad gain profiles can be of advantage however for extremely widely tunable lasers (see the section on tunable lasers in Sect. 11.3.3 and that on micromechanical tunable VCSELs in Sect. 11.3.4). However, as already mentioned, additional research and development effort is expected to provide excellent QD lasers.

11.3.6 Lasers with External Resonators

Both edge emitters and VCSELs can be implemented, as shown in Fig. 11.98, with an external resonator mirror, in contrast to Fig. 11.123, which involve a relatively large air gap. This can serve several purposes:

1. The extension of the resonator length to achieve narrower line widths
2. Wavelength tuning by inserting a wavelength-selective, rotating element (prism, etalon, grating)
3. Mode coupling for the generation of periodic sequences of ultrashort pulses
4. Wavelength conversion by insertion of an optically nonlinear crystal.

Examples of the last of these are lasers in which a frequency-doubling crystal in the air gap of the resonator transforms the IR light, which is emitted from an edge emitter with one side antireflection-coated or a half-cavity VCSEL (active region plus one DBR mirror), into the yellow, green and blue range.

11.3.7 Photonic Crystal Semiconductor Lasers

Photonic crystals are structures with periodically varying optical properties in either one, two or three dimensions which provide various options to influence the propagation properties of waves as introduced in Sect. 8.10 of this volume or also [11.1484] and [11.1485]. For semiconductor laser devices these structures offer additional and new design parameters to achieve better control of lateral modes or polarization states and to make use of the Purcell effect. Most of the photonic crystal lasers can be assigned to one of the following three groups.

VCSEL Devices Based on a Fabry–Pérot Layout with Additional Photonic Crystal Structures

By introducing a periodic arrangement of air holes with a centered defect into the facet of the top DBR mirror, occurrence of lateral modes can be controlled and VCSEL with larger emitting areas and laser apertures become feasible while maintaining lateral single-mode operation [11.1486, 1487]. Certain properties of the photonic crystal lattice, for example the shape of the base elements, can also be chosen to break the spatial symmetry and thus adding a stable condition for polarized emission [11.1488]. Finally, the Fabry–Pérot layout can be replaced by a similar 3-D photonic crystal structure having a phase shift layer instead of the conventional cavity leading to low threshold and spatial noise values [11.1489].

Photonic Crystal Semiconductor Membranes Integrated with MEMS VCSEL Devices and Making Use of the Guided-Mode Resonance Effect

Periodic disturbances in a membrane, representing a slab waveguide, lead to interference of resonant modes of the waveguide with free space modes, when a wave is incident vertically on the membrane. By choosing a suitable design the properties of narrowband filters, broadband reflectors and polarization selectivity can be achieved [11.1490–1492]. A typical approach is to replace the top DBR mirror of the laser by a photonic crystal membrane resulting in a very compact device with optional polarization control [11.1493] and even improving tunability of the cavity [11.1494, 1495] due to the reduced size of the actuated top mirror.

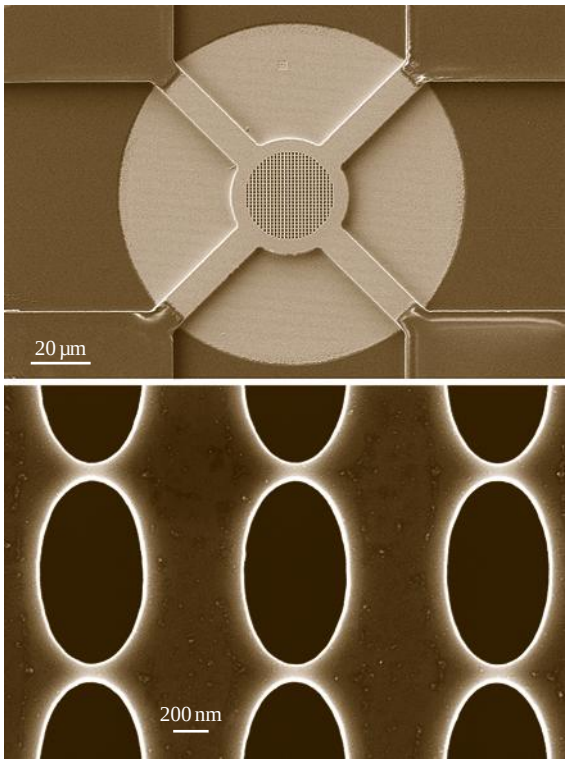

Fig. 11.125 Optoelectronic device for the spectral range at 1550 nm based on a released InP membrane with photonic crystal structure (*top*). Detail of the photonic crystal lattice with elliptical base elements yielding a polarization selective reflector (*bottom*). Fabrication of this particular structure employs FIB milling of a hard mask layer and RIE dry etching embedded into standard MEMS process technology

Laser Devices Based on Thin-Films with Photonic Crystals

Since for these designs the layer with the periodic structures itself has to be the active laser region, quantum wells are introduced at several positions [11.1496]. Concepts of the conventional edge emitting lasers can be adapted to 2-D photonic crystal lasers like for example in the multidirectional DFB laser [11.1497]. But the main interest of the thin-film devices is control of the spontaneous emission ratio as given by the Pur-

cell effect [11.1498]. For this application nanocavities with small volumes are required. Tailoring of the according Q factor can be accomplished by design of defects in photonic crystal structures. By implementing point-shift structures, edge dislocations or monopole mode cavities, which all exhibit small deviations from the regular photonic crystal lattice, a further decrease of the modal volume of the cavities is obtained leading to large spontaneous emission factors and low laser thresholds [11.1499–1501].

Fabrication of real 3-D photonic crystals is still a demanding task and therefore almost all laser devices consist of 2-D periodic structures integrated with index confining slabs or periodic DBR mirrors. Due to the small dimensions of the base elements of the photonic crystal patterns in the order of a few 100 nm (Fig. 11.125), these structures are normally generated by either electron-beam lithography [11.1502, 1503] or a FIB milling process [11.1504, 1505] on a hard mask layer and dry etching processes like ICP-RIE. For the latter step surface damage introduced by ion bombardment has to be considered if carrier transport and recombination properties are important [11.1506]. Released membrane devices are generally fabricated by an additional selective wet-etch process removing a sacrificial layer [11.1507].

11.4 Carbon Dioxide (CO_2) Lasers

Carbon dioxide (CO_2) lasers are one of the most important lasers for industrial, medical, and scientific applications. These include high-precision material processing, cutting and welding of sheet metal, coding and marking of a variety of materials, cutting of paper and fabrics, surface treatments for steel hardening, or medical applications such as tissue coagulation.

CO_2 lasers utilize a gas mixture of helium, nitrogen, and carbon dioxide as the active medium, which is usually excited by an electrical gas discharge. The key characteristics are emission in the mid-infrared at wavelengths around 10 μm and a continuous-wave output power ranging from a few watts for small sealed-off laser modules to more than 10 kW for high-power CO_2 lasers with fast gas flow. Whilst most CO_2 lasers operate in a CW mode with a quite fast power modulation made possible by modulation of the electrical excitation, there are also pulsed systems based on Q-switching or the so-called transverse excited atmospheric-pressure (TEA) laser. The beam quality is often excellent and in many cases nearly diffraction-limited. This is important for applications such as precision cutting, remote welding, or coding and marking applications. The mid-infrared emission implies that standard glass lenses and glass fiber-optic waveguides cannot be used because of the high infrared absorption of silica-based glasses. Transmitting optics such as focussing lenses or partially reflecting mirror substrates are commonly made of zinc selenide, silicon, or germanium. For beam guidance moving-mirrors systems mounted on linear and swivel axes are used. Flexible optical waveguides for CO_2 lasers are available in principle, but due to their rather high absorption losses they can only be used for moderate optical powers [11.1508]. Besides the most common emission wavelength of 10.6 μm, special tunable CO_2 lasers can generate laser light at dozens of distinct emission lines between roughly 9.2–11 μm. Such lasers are used for scientific applications such as molecular spectroscopy and optical pumping of far-infrared gas lasers.

The physical principles and the technical realizations of typical CO_2 lasers are described in the following sections.

11.4.1 Key Principles in CO_2 Lasers

Basic CO_2 Laser Tube Principles

Laser action in a CO_2 gas was first reported by *Patel* in 1964 [11.1509, 1510]. The basic physical principles have changed little since then. An excellent and detailed discussion of CO_2 laser fundamentals is given in [11.1511] whilst general laser physics and principles are also described in [11.1512] and [11.1513]. Figure 11.126 shows a schematic drawing of a basic longitudinally direct current (DC)-excited CO_2 laser. The laser gas usually comprises a mixture of CO_2, N_2, and He with a ratio of typically 1 : 2 : 8. The total gas pressure in such a DC-excited laser is a few tens of hPa. The gas is excited by an electrical gas discharge, for example, by a steady longitudinal DC glow discharge inside a quartz glass tube. The typical required voltage is 15 kV per meter of discharge length, with a DC current of a few tens of mA. However, the voltage needed to start the discharge can be considerably higher. To maintain a stable α-type glow discharge [11.1514] an external ballast resistor R_b is required in series with the high-voltage power supply. This compensates for the

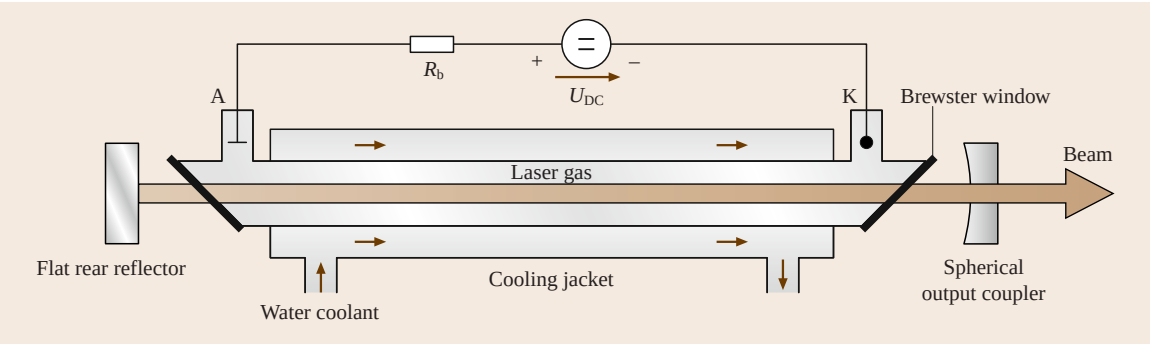

Fig. 11.126 Basic longitudinally DC-excited CO_2 laser

differential negative impedance characteristic of the gas discharge and limits the discharge current in order to prevent arcing. A disadvantage of this simple circuit is the high dissipated electrical power in the ballast resistor R_b. Alternatively, power supplies with fast voltage- and current-regulating electronics can be used. Typical lengths of the gas discharge are of the order of one to several meters, depending on the desired output power.

Such laser tubes can be filled once with the laser gas mixture and are then sealed-off for the lifetime of the laser tube. Other lasers are provided with a gas inlet and outlet to maintain a gas flow through the laser tube. This improves the laser power as fresh laser gas is provided to the laser but also requires additional peripherals such as gas reservoirs and vacuum pumps. Optical windows to seal off the tube can be realized by plane transparent plates at the Brewster angle with respect to the beam axis. One polarization state of the laser light can pass through the Brewster window without any unwanted reflections. Thus, the Brewster windows also act as a polarization-selecting element inside the laser resonator.

The CO_2-N_2 molecule mixture in such lasers is usually excited by collisions with free electrons inside the gas discharge [11.1515]. Another method for excitation is found in gas-dynamic lasers where a very fast gas-flow is used [11.1516]. Such lasers can generate a very high output power but require huge gas circulation installations and have been limited to scientific or military research projects up to now. The excited roto-vibrational states provide optical gain at certain wavelengths in the infrared. A simple plano-concave stable optical resonator with two mirrors located at each ends of the discharge tube can be used to provide continuous laser oscillation. The totally reflecting or rear mirror is often made of copper, optionally with additional gold or protective dielectric layers to enhance lifetime and reflectivity. The output coupler can be made of zinc selenide (ZnSe), germanium or silicon, as these materials have a good transparency in the mid-infrared, in contrast to common silica-based glasses. The required reflectivity can be achieved with dielectric multi-layer coatings on the mirror substrate. As the optical small-signal gain of the active CO_2 gas medium is quite high compared to a helium-neon (HeNe) gas laser and is in the range of $1\,m^{-1}$, reflectivities of output couplers may range from 20–90%. Optimum output coupler reflectivities for a maximum laser power are often determined experimentally. Alternatively, they can be calculated by a so-called Rigrod analysis if parameters such as the small-signal gain and the saturation intensity of the medium are known [11.1517, 1518].

Typical efficiencies η_E, defined as the ratio of the extracted optical laser power P_L to the electrical power P_E applied into the discharge, are in the range of 10–20%. The largest part of the electrical excitation power is dissipated as thermal energy within the gas volume. In order to avoid a high thermal population of the lower laser energy levels, the CO_2 laser gas must be kept cool at temperatures below 400–500 K, depending largely on the different CO_2 laser types. A simple cooling method is shown in Fig. 11.126. It comprises the use of an outer, coaxial glass tube, which acts as a cooling jacket. Water or air may be used to cool the inner tube.

A rough estimate for these diffusion-cooled DC excited lasers is an output power per discharge length of 80 W/m. This cannot be scaled by using larger cross sections of the laser tube since this would reduce the amount of thermal energy that can be removed from the middle of the gas discharge to the walls by diffusion cooling to the walls. The overheating of the gas and the resulting thermal population of the lower energy level of the laser transition would reduce the

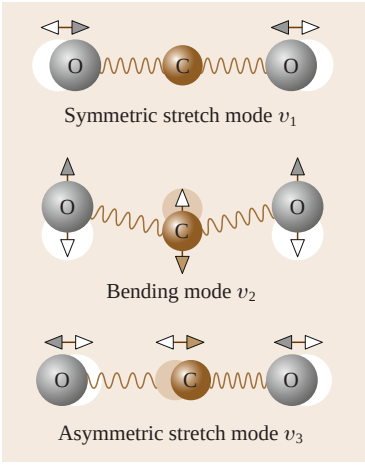

Fig. 11.127 Vibrational modes of the CO_2 molecule

optical gain. In fact, for optimized cooling the diameter of the glass tube should be as small as possible without introducing significant aperture losses by truncating the free-space laser beam. Typical diameters are 5–10 mm, depending on the tube length and the optical resonator design [11.1519]. Smaller diameters can be used in so-called waveguide lasers and larger diameters in lasers with a fast gas flow for cooling, as described in Sect. 11.4.2.

Vibration and Rotation of the CO_2 Molecule

The emission wavelengths of the CO_2 laser are determined by the vibrational and rotational energy levels of the CO_2 molecule, which are discussed in more detail in [11.1520, 1521] or [11.1522]. All data in the following sections are given for the naturally most abundant isotopolog $^{16}O^{12}C^{16}O$. Figure 11.127 shows the three fundamental vibrational modes: the symmetric stretch mode v_1, the bending mode v_2 with motion of the C atom in a plane perpendicular to the molecule axis, and the asymmetric stretch mode v_3. The bending mode has a twofold degeneracy because of the possible bending motions in the two orthogonal coordinates of the plane.

In the classical model of the unperturbed harmonic oscillator [11.1520] each mode has an associated vibrational frequency

$$f_1 = 40.51\,\mathrm{THz}\,,\ f_2 = 20.15\,\mathrm{THz}\,,$$
$$f_3 = 71.84\,\mathrm{THz}\,. \qquad (11.120)$$

In the quantum-mechanical model the energy of any vibrational state of the molecule can only have discrete values called the vibrational energy levels. Using the integer vibrational quantum numbers n_1, n_2, and n_3 that describe the degree of excitation of the vibrational modes, the total vibrational energy W_v of the molecule can be written as a sum of the single vibrations

$$W_\mathrm{v} = h f_1 \left(n_1 + \tfrac{1}{2}\right) + h f_2 \,(n_2 + 1) + h f_3 \left(n_3 + \tfrac{1}{2}\right)\,. \qquad (11.121)$$

A more detailed analysis of the vibrational oscillator would include anharmonic forces which result in small deviations from the simple harmonic model, especially at high vibrational and rotational quantum numbers.

Even if there is no vibrational excitation present (all $n_\mathrm{i} = 0$) and the molecule is in its ground state there is energy stored within the molecule that cannot be exchanged. As we are mainly interested in energy differences between vibrational modes, we can therefore neglect this zero-point energy as it is common to all modes.

To characterize the vibrational state completely another quantum number l for the angular momentum is required to define the distribution and the phase of the bending vibration quanta in v_2 into the two orthogonal coordinates. For each value of n_2 there are $n_2 + 1$ possible values for the angular momentum l

$$|l| = \begin{cases} n_2,\ n_2-2,\ n_2-4,\ \ldots,\ 0\,; & n_2 \text{ even} \\ n_2,\ n_2-2,\ n_2-4,\ \ldots,\ 1\,; & n_2 \text{ odd}\,. \end{cases} \qquad (11.122)$$

As an example, for $n_2 = 2$ the value $l = 0$ describes a linear bending motion, and $l = -2$ or $l = 2$ describe two circular motions of the C atom in opposite directions in the plane perpendicular to the molecule axis. A vibrational state of the CO_2 molecule is labeled with the common Herzberg notation $(n_1 n_2^l n_3)$, for example $(00^0 0)$ for the ground state or $(12^2 0)$ for a state with simultaneous excitation of several vibrational modes [11.1520].

Figure 11.128 shows the energies of some of the lowest vibrational states. The energy levels observed by emission and absorption of radiation, as shown in Table 11.39, are slightly different to those calculated using the simple-harmonic-oscillator theory (11.121). Therefore, more precise calculations using anharmonic corrections and considering the mutual coupling of the three vibrational modes are required.

The so-called Fermi resonance is of particular importance for the laser process in the CO_2 laser. Vibrational states with equal values of the term $2n_1 + n_2$

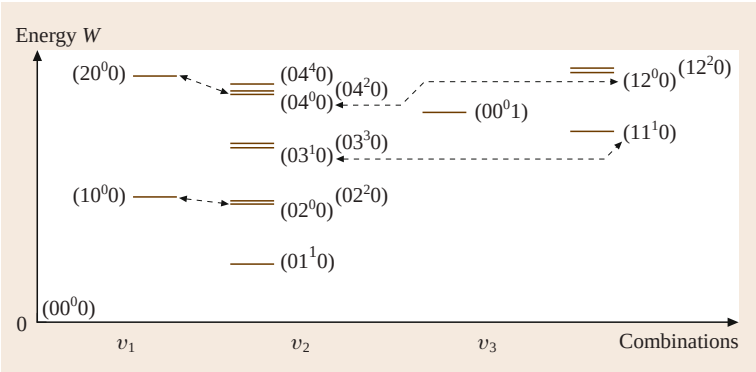

Fig. 11.128 Some of the lowest vibrational energy levels of the CO_2 molecule. The Fermi resonance couples energy levels as indicated by the *dashed lines*

Table 11.39 Labeling, symmetry/parity classification and energies of some low-lying vibrational states of the CO_2 molecule [11.1525]

Vibrational state			Wavenumber, frequency and energy		
Herzberg	AFGL	Type	$\bar{\nu}$ (cm^{-1})	f (THz)	W (meV)

and $l = 0$ have almost the same energy and are strongly coupled. Due to Fermi resonance the (10^00) state is shifted up and the (02^00) state is shifted down in energy. The population densities of these states can be readily exchanged by molecular collision. Also the quantum-mechanical wave functions and the vibrational motion of the two resulting levels are a strong mixture of the unperturbed vibrational states. In the CO_2 laser literature the resulting levels are sometimes labeled (I) for the more (10^00)-like state and (II) for the more (02^00)-like state. Spectroscopic databases, which are an excellent reference for accurate absorption and emission wavelengths of the CO_2 molecule, often use a different labeling scheme than the simple Herzberg scheme, for example, the so-called AFGL (Air Force Geophysics Lab, USA) notation, which gives a better treatment of the Fermi resonance [11.1523, 1524].

The rotational motion of the CO_2 molecule as shown in Fig. 11.129 is superimposed on the vibration. Only the rotation around an axis perpendicular to the molecule axis has a significant moment of inertia and is considered further. The discrete energy levels in the quantum-mechanical rigid-rotator model are given by

$$W_r = B \cdot J(J+1)\,, \tag{11.123}$$

where B is the rotational constant and J is the quantum number for the rotational state. The higher the value of J, the faster the rotation of the molecule in the classical mechanical model. For the (00^01) vibrational state, for example, B has a value of

$$B = 48.0\,\text{meV} = h\,f_r = h\;11.6\,\text{GHz}\,. \tag{11.124}$$

More precise calculations show that the rotational constant B is slightly dependent on the vibrational state because of the anharmonicity and is also dependent on the rotational quantum number J itself because of centrifugal forces [11.1520].

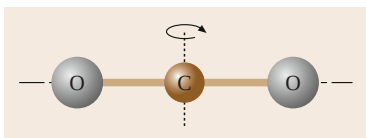

Fig. 11.129 Rotation of the CO_2 molecule

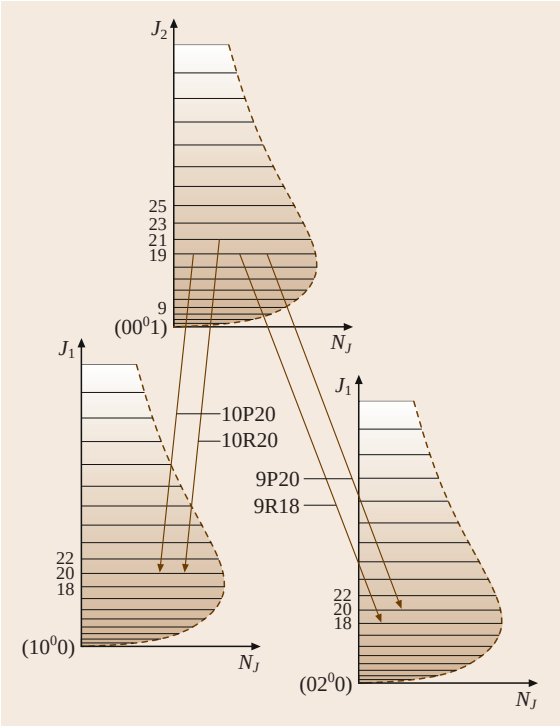

Fig. 11.130 Examples of names for allowed roto-vibrational transitions of the regular bands. The rotational distribution has been calculated for $T = 400\,\mathrm{K}$

The total internal energy $W = W_\mathrm{v} + W_\mathrm{r}$ of the CO_2 molecule is the sum of the vibrational and the rotational energies. The energy stored in the rotational motion is usually much smaller than in the vibrational motion. Thus, the rotational energy levels can be thought of as superimposed on each vibrational level.

Emission Lines of the CO_2 Laser

Absorption and spontaneous and stimulated emission of light can occur when the energy of a photon $W_\mathrm{p} = h f_\mathrm{p}$ equals the energy difference $\Delta W = W_2 - W_1$ between two given energy levels of the respective atom or molecule. Additionally, selection rules based on the conservation of the spin or angular momentum and due to symmetry properties of the wave functions have to be considered. Based on the formalism of vibrational matrix dipole elements only certain transitions are allowed [11.1522]. The strongest allowed CO_2 laser emission lines result from the vibrational transitions $(00^01) \rightarrow (10^00)$ centered at wavelengths around $10.4\,\mu\mathrm{m}$ ($10\,\mu\mathrm{m}$ band) and $(00^01) \rightarrow (02^00)$ around $9.4\,\mu\mathrm{m}$ ($9\,\mu\mathrm{m}$ band). For these regular transitions the following selection rule for the rotational quantum numbers of upper and lower energy levels apply

$$\Delta J = J_2 - J_1 = \pm 1\,. \tag{11.125}$$

For a given lower rotational state J_1 there are two different possibilities for the emission of photons, as shown in Fig. 11.130. Transitions are named after the rotational quantum number of the lower state. Additionally, the transitions are labeled P (the P branch) for $\Delta J = -1$ and R (the R branch) for $\Delta J = +1$. For example, one of the strongest emission lines of the CO_2 laser is labeled 10P(20), indicating a transition from the $10\,\mu\mathrm{m}$ band with the lower rotational state $J = 20$ and $\Delta J = -1$. Different transitions have different energy differences ΔW and thus different emission frequencies f or wavelengths λ due to the fact that according to (11.123) the rotational energy scales quadratically with the quantum number J. This is the origin of a multitude of possible emission lines of the CO_2 laser.

Figure 11.131 shows the calculated relative gain of the regular bands of a typical CO_2 laser. Both vibrational transitions have characteristic R and P branches due to the superimposed rotational energy levels and the selection rules. Exact line positions are listed in [11.1511] based on [11.1526], or in spectral databases such as [11.1523], which also lists transition dipole moments that are useful for the calculation of the absorption and gain of a transition [11.1527]. Note that in Fig. 11.130 only rotational states of even order J are present for the lower states (10^00) and (02^00). The odd states are missing because of the symmetry properties and parity rules (Σ_g^+) of these states in the $^{16}O^{12}C^{16}O$ isotopolog [11.1521]. Similar considerations are valid for the upper state of the regular band (00^01) (Σ_u^+ state), which only has odd rotational quantum numbers J.

In addition to the regular bands discussed above, there are further vibrational transitions with slightly shifted wavelengths that can be operated as lasers. These are so-called hot bands and sequence bands. Table 11.40 shows a summary of vibrational transitions. One way of achieving suppression is by using passive absorption cells filled with hot CO_2 gas located within the resonator [11.1511]. Such hot-band or sequence band lasers are used in spectroscopy if their particular emission wavelengths are required. However, almost all technical lasers operate in the regular bands.

The optical small-signal intensity gain per unit length g_0 of a given transition is proportional to the population density difference of the upper and the lower

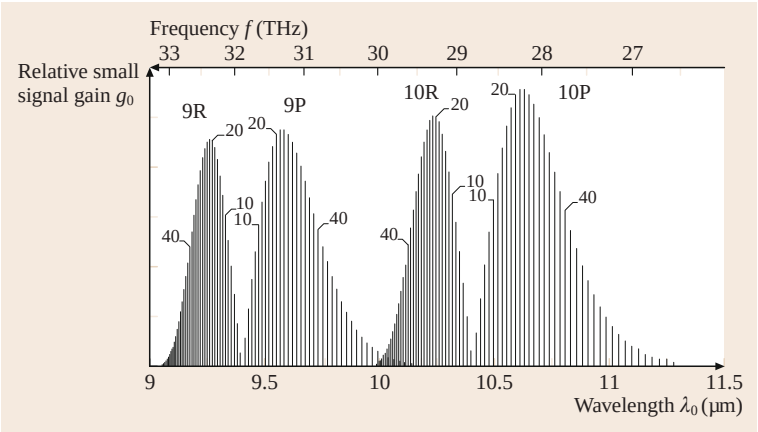

Fig. 11.131 Calculated relative small-signal gain for the regular bands of the CO_2 laser at $T = 500\,\mathrm{K}$

Table 11.40 Possible vibrational lasing transitions

Vibrational band	Comment
$(00^01) \rightarrow (10^00)$	Regular band, 10 μm
$(00^01) \rightarrow (02^00)$	Regular band, 9 μm
$(01^11) \rightarrow (11^10)$	Hot band
$(01^11) \rightarrow (03^10)$	Hot band
$(00^02) \rightarrow (10^01)$	Sequence band
$(00^02) \rightarrow (02^01)$	Sequence band

states, weighted with the respective degeneracy factors

$$g_0 \propto \left(N_{n_2 J_2} - \frac{2J_2 - 1}{2J_1 - 1} N_{n_1 J_1} \right) . \qquad (11.126)$$

The population densities N_{nJ} are the numbers of molecules per volume in the roto-vibrational energy levels n and J. Within each vibrational state n with a total population of N_n the distribution of the molecules in the different rotational states N_{nJ} is described by a thermal Boltzmann distribution, weighted by the total rotational partition sum and the degeneracy factor for each J

$$N_{nJ} = N_n \left(\frac{2B}{kT} \right) (2J + 1) \exp\left(-\frac{W_r}{kT} \right) , \qquad (11.127)$$

with the translational gas temperature T and the Boltzmann constant k. The rotational level of the maximum of this distribution at a given temperature can be approximately calculated as

$$J_{max} \approx \sqrt{\frac{kT}{2B}} - \frac{1}{2} . \qquad (11.128)$$

For typical gas temperatures of $T = 400\,\mathrm{K}$ the levels around $J = 19$ have the strongest population. In CO_2 lasers without any further wavelength-selective elements normally only one transition around the 10P(20) line at a wavelength of 10.59 μm will lase, as this one has the strongest gain (Fig. 11.131). However, especially in lasers with a short resonator length, an effect called line-hopping can be observed. When a resonator eigenfrequency f_q starts to drift on the frequency axis due to thermal expansion, it can happen that on the edge of the line profile, i. e., of the 10P(20) line, the gain at this frequency f_q gets lower than the gain of a quite different eigenfrequency f_x within the gain profile of a totally different transition line, i. e., the 10P(28). Thus, a roto-vibrational transition line can lase even if it has a lower maximum gain than the more stronger 10P(20) line. Typical values for the small signal gain g_0 are in the range from 0.5 to $1.5\,\mathrm{m}^{-1}$.

Even under lasing conditions the rotational distribution will maintain its thermal Boltzmann shape because of a fast population exchange between the rotational levels by molecule collisions. Thus, the population of almost all rotational states within the upper vibrational level can contribute to a single lasing transition rather than just the population of the particular upper level, for example the $J = 19$ state of the (00^01) vibrational level. This mainly affects the saturation intensity I_s of the optical gain, which is much larger than expected from the population N_{nJ} of a single rotational level J itself. The saturation intensity I_s is in the range from $100\,\mathrm{W\,cm}^{-2}$ for sealed-off large-bore DC-excited lasers to over $1000\,\mathrm{W\,cm}^{-2}$ for fast-flow systems. Note that the saturation intensity I_s is also dependant on the particular transition line which is actually lasing [11.1528].

Electrical Excitation and Gas Composition

Without any excitation and in thermal equilibrium the population of the vibrational states is given by the Boltzmann distribution. As the energies of the lower

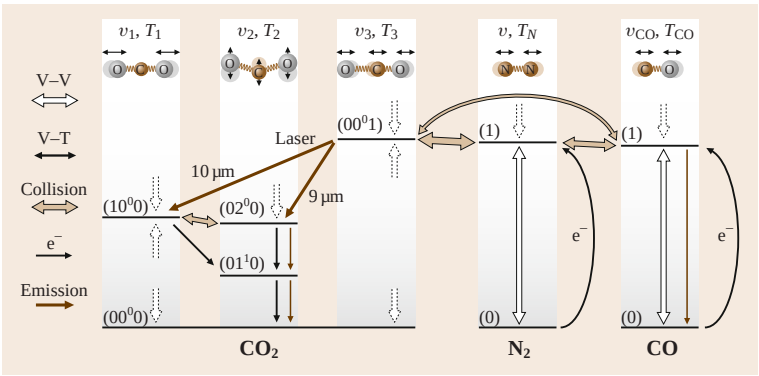

Fig. 11.132 Energy-level diagram of the CO_2 laser process with excitation and decay paths

vibrational levels are almost of the same order as the thermal energy $kT = 25.5\,\text{meV}$ at 296 K, the thermal population of levels above the ground state cannot be neglected. The population N_n of a given vibrational level n is given by

$$N_n = N_0 \frac{\exp\left(-\frac{d_n W_n}{kT}\right)}{Q_{\text{vib}}}\,, \tag{11.129}$$

where N_0 is the total density of CO_2 molecules, d_n is the degeneracy factor, W_n the energy of level n, and Q_{vib} is the total vibrational partition sum. Without excitation the population of the upper laser state (00^01) is always smaller than the lower laser levels (10^00) or (02^00). This is the normal case for passive media, which show absorption lines on the respective transition wavelengths.

To achieve an inversion, and thus optical gain, in an active medium an electrical gas discharge is usually used to excite the CO_2 laser. Accelerated electrons that are present in the discharge collide with the molecules and lose part of their kinetic energy. A part of this energy can be transformed into vibrational excitation energy of the molecules or into kinetic energy by a pure translatory motion. The effectiveness of the excitation of a certain vibrational state of a molecule is normally described by the excitation cross section, which is in turn a function of the energy of the electrons. For inversion of the regular CO_2 laser lines, a selective and high population of the upper laser state (00^01) is required (Fig. 11.132). This is hardly possible in a pure CO_2 gas discharge as the cross sections for excitation of the different vibrational states are of the same order of magnitude. Therefore, nitrogen (N_2) is added to the laser gas [11.1515]. As a molecule with two atoms it only has one vibrational mode. As a homonuclear molecule it has no electric dipole moment in all vibrational levels and hence, no radiative decay of excited vibrational states. Thus, nitrogen can efficiently store energy in its vibrational excited states. More than 50% of all N_2 molecules can be excited to higher vibrational levels inside a gas discharge. The first excited vibrational state, $n = 1$, has nearly the same energy (289 meV) as the upper laser level (00^01). Due to resonant collisions between excited nitrogen atoms vibrational energy is readily transferred to the desired CO_2 state

$$\begin{aligned} &N_2(n) + CO_2(00^00) \\ &\rightleftharpoons N_2(n-1) + CO_2(00^01) + \Delta W\,. \end{aligned} \tag{11.130}$$

The energy difference $\Delta W = -2.2\,\text{meV} \ll kT$ is easily available from the thermal kinetic energy of the molecules. This similarity of the energy levels is a very fortunate coincidence, without which the laser would not work as well. Carbon monoxide (CO) can also be used for selective excitation of the upper laser level, but with less efficiency due to a larger energy difference and an allowed radiative decay of its vibrational excitation, see also the section on dissociation and gas additives.

Figure 11.132 shows the energy-level diagram of the CO_2 laser process. Accelerated electrons from the gas discharge excite nitrogen molecules to higher vibrational levels by collisions. These excited nitrogen molecules transfer their energy to the upper laser level (00^01) of the CO_2 molecule and thereby induce a significantly higher population compared to the lower laser levels. Hence, a population inversion of the CO_2 molecules is achieved. From the upper laser level (00^01), two strong lasing transitions by stimulated emission of photons are possible: the 9 µm band with (02^00) as the lower laser level and the 10 µm band with (10^00), respectively.

To maintain a large inversion the thermal population of the lower laser levels must be avoided by efficient cooling of the laser gas. Therefore, helium (He) is added to the laser gas. Helium is the gas with the

second-largest thermal conductivity after hydrogen. It also plays an important role for the population decay of the (02^00) and (01^10) levels by vibrational–translational (V–T) relaxation. Thereby, the vibrational energy of the CO_2 molecule is transferred to kinetic energy, the translatory motion of the molecules. Radiative decay by spontaneous emission is also possible for the (02^00) and (01^10) levels, but not for the (10^00) level, which shows no change in the dipole moment during vibration. It can reduce its population by V–T relaxation directly to the (01^10) level, but also by the Fermi resonance via collisions and energy exchange with the (02^00) state. In fact, the degree of vibrational excitation of these two vibrational modes is almost the same due to Fermi coupling. After relaxation to the ground state (00^00) the CO_2 molecule is available for renewed excitation and the laser process starts again.

Within one vibrational mode, for example v_1 of the CO_2 molecule, there is a strong interaction of the vibrational levels by vibrational–vibrational (V–V) relaxation and excitation processes during collisions

$$CO_2(n_1') + CO_2(n_1'') \rightleftharpoons CO_2(n_1'+1) + CO_2(n_1''-1) + \Delta W\,, \quad (11.131)$$

where the small energy difference ΔW coming from the anharmonic forces can almost be neglected. By this fast thermalization the population distribution of the vibrational levels within one mode v_i can be described by a Boltzmann distribution similar to (11.129) with a specific vibrational temperature T_i for this particular mode. Three vibrational temperatures T_1, T_2, and T_3 are required to describe the three vibrational modes v_1, v_2, and v_3 of the CO_2 molecule. Together with the vibrational temperature of the nitrogen T_N and the physical gas temperature T they form the so-called five-temperature model of the CO_2 laser. This model can be used to quantify the degree of vibrational excitation in a given laser system and to calculate the optical gain of different transitions [11.1511, 1529–1531].

Note that the vibrational temperatures inside a gas discharge can be significantly higher than the usual physical gas temperature T, which describes the translatory kinetic energy only. For typical laser conditions the temperatures T_3 and T_N can be in excess of 1000 K, even if the physical gas temperature T is only 450 K, for example. This describes the desired high level of excitation of these modes for a strong inversion, especially if there is no laser action to reduce the population in (00^01) by stimulated emission. The vibrational temperatures T_1 and T_2 are almost equal because of their strong coupling. They are also slightly larger than the physical temperature, because their excess population decay to the ground state takes place at a finite rate only. Here, as low as possible vibrational temperatures are desired for a low population of the lower laser levels. Of course, no vibrational temperature can be lower than the physical gas temperature T. It is also the temperature T that is valid for the rotational population distribution.

A gas mixture for a typical CO_2 laser would be $He : N_2 : CO_2 = 8 : 2 : 1$, but there is some variation depending on the specific design of the laser. Gas mixtures are typically optimized experimentally for optimum output power. The gas pressure p is typically a few tens of hPa for longitudinally DC-excited lasers, in the range of 100 hPa for lasers with a transversal RF discharge or can equal the atmospheric pressure in so-called TEA (transversely excited atmospheric pressure) lasers with a pulsed transversal discharge. The gas pressure affects the stability of the gas discharge and the electric field strengths required to start and maintain a stable discharge at the different excitation frequencies and geometries. Together with the applied electric field E within the discharge the gas pressure p affects the electron energy distribution function (EEDF). For efficient excitation of the desired nitrogen vibrational states electrons with energies of 2–3 eV are required, where the effective cross section for vibrational excitation of N_2 has a maximum [11.1511].

Dissociation and Gas Additives

The shape of the electron energy distribution function (EEDF) can be rather complex in a laser gas discharge, but it will always have a tail extending to quite high electron energies. High-energy electrons may induce chemical dissociation processes of the CO_2 molecule within the gas discharge that have an adverse effect on laser performance and life time. Examples of such reactions are the following:

$$CO_2 + e^- \rightleftharpoons CO + O^-\,,\ \Delta W = -3.85\,\text{eV}\,, \quad (11.132)$$

$$CO_2 + e^- \rightleftharpoons CO + O + e^-\,,\ \Delta W = -5.5\,\text{eV}\,. \quad (11.133)$$

This is the origin of the complex gas chemistry that leads to a reduced CO_2 concentration and the formation of a significant CO concentration within the laser gas tube [11.1532]. By the law of mass action a typical equilibrium ratio in the order of 1 : 1 between CO_2 and CO is established if no means to reduce the dissociation are present. Clearly this reduces the overall laser output power and efficiency.

Table 11.41 Some commercial gas premixes for different industrial CO_2 laser types [11.1533, 1534]

Premix name/ (Maker)	Composition							Laser type, model series
	He	N_2	CO_2	CO	O_2	Xe	H_2	
Lasermix 322 (Linde AG)	65.5	29	5.5					Fast axial-flow, Trumpf TLF Series
Lasermix 690 (Linde AG)	65	19	4	6	3	3		Diffusion-cooled sealed-off, Rofin Slab DC 0XX
Lasal 81 (Air Liquide)	80.8	15	4				0.2	DC excited slow-flow, FEHA SM Series

In lasers with a continuous flow of laser gas (as opposed to sealed-off systems) the laser gas can be replaced with gas from a premix bottle; alternatively it can be partially regenerated by forced circulation through catalysts to prevent excessive dissociation. Naturally, the gas dissociation is more crucial for sealed-off lasers without any gas exchange. To decrease dissociation processes and maintain a high output power, many different gas additives to the basic mixture have been studied [11.1511]. Table 11.41 shows the composition of some commercial laser gas premixes for high-power CO_2 lasers.

Xenon (Xe) is without doubt the most efficient and most widely used additive for sealed CO_2 lasers [11.1535–1537]. Xe has a first ionizing potential of 12.1 eV, which is some eV less than other gases. Hence, the same current density in the discharge can be maintained at a lower applied electric field. This in turn shifts the EEDF towards lower energies, which are more efficient for vibrational excitation, and there are fewer fast electrons to cause dissociation processes. On the other hand, Xe has a very low thermal conductivity due to its high atomic weight. Also, it is a very rare and expensive noble gas. Sealed laser mixtures typically contain a few percent Xe.

Water vapor (H_2O) and molecular hydrogen (H_2) have also been extensively studied [11.1511, 1538]. Both gases react inside the gas discharge, for example with the oxygen radical to form the hydroxyl radical OH. This hydroxyl radical is an efficient catalyst for oxidizing CO back to CO_2. On the other hand, water vapor with its multitude of vibrational states rapidly deexcites the upper laser state (00^01) and quenches the desired population densities of this level. The reported water vapor concentrations for optimum catalysis and yet low vibrational quenching are quite low [11.1511] and were found to be difficult to control in real laser systems. In other laser systems no clear evidence for the existence of an optimum water vapor content was found [11.1539, 1540]. As a rule of thumb the dew point of the laser gas should be below −40 °C, equivalent to a water vapor partial pressure of 0.13 hPa. Contamination of water residues from the cooling system must be avoided. However, some laser gas premixes may contain small amounts of hydrogen, as found appropriate in experiments of the manufacturer of the laser system.

Other gas premixes include carbon monoxide (CO) or oxygen (O_2). By the law of mass action both additives can shift the equilibrium of the dissociation reactions (11.132) and (11.133) towards the left. Too high an O_2 concentration has a detrimental influence on the discharge stability and the EEDF, as it is a strongly electronegative gas. CO as a diatomic molecule has similar vibrational energy levels to nitrogen and can also transfer vibrational energy by resonant collisions to the upper laser state of the CO_2 molecule (Fig. 11.132). Another benefit of adding CO and O_2 initially to the gas premix for filling the laser is that the gas is already near its equilibrium composition for the dissociation process, so no overshoot or undershoot of the laser power occurs when the laser is operated for the first time after refilling with a fresh gas mixture. However, CO is not as effective as nitrogen for vibrational excitation. The energy difference between the CO:($n = 1$) vibrational level and the CO_2:(00^01) level is 25.5 meV, which is large compared to the corresponding difference between CO_2 and N_2 (2.2 meV). Furthermore, CO has allowed dipole transitions to the ground state by spontaneous emission, which decreases vibrational excitation compared to nitrogen. On the other hand, this faster relaxation of stored vibrational energy in CO reduces the decay time of the laser emission after the electrical excitation is turned off. This is important for fast modulated lasers, for example those used for coding and marking. Finally, CO is the only toxic gas of the species discussed here. Care has to be taken when handling such gas mixtures.

Materials for CO_2 Lasers

Materials for the laser tube must be chosen carefully and in accordance with the laser principles and technical

issues described in the above sections. The production of reliable CO_2 laser systems for commercial applications requires a solid knowledge in vacuum technology and cleanroom practices. Materials with low out-gasing and low vapor pressure must be used. This normally inhibits the application of plastics and polymer-based glues in CO_2 laser tubes. Additionally, the UV radiation of the gas discharge will degrade most organic compounds rapidly. There are only a few epoxy-based adhesives that may be used.

Many low-power sealed-off lasers and even high-power lasers with slow or fast gas circulation use quartz glass tubes to confine the laser gas. Quartz (SiO_2) glass is thermally stable, chemically inert, robust against UV radiation, and has low dielectric losses. However, silica-based glasses have high infrared absorption, even for grazing incidence of light to the surface. Thus, the diameter of the quartz glass tube needs to be considerably larger than the laser beam formed by the resonator mirrors. For waveguide lasers (see Sect. 11.4.2) tubes made from other materials must be used [11.1541, 1542]. Alumina (polycrystalline Al_2O_3 ceramics) is often used. It is a dense and vacuum-tight ceramic material, which is also dimensionally and thermally stable. Its infrared absorption is lower than quartz glass, making it suitable for hollow dielectric waveguides. Moreover, it has very low dielectric losses at radio frequencies, making it an ideal material for transversal capacitively coupled RF (CCRF) discharge excitation.

Good material choices to confine the gas volume are also inert passivated metals such as stainless steel [11.1543] and passivated aluminum. Steel can easily be welded, both with conventional techniques or with lasers, to build a vacuum-tight laser tube. Welding of aluminum is more difficult. On the other hand, aluminum has a far better thermal and electrical conductivity and a higher infrared reflectivity. This makes aluminum a very good material for waveguide plates and electrodes for transversal RF discharges [11.1544].

Electrolytic copper or oxygen-free high-conductivity (OFHC) copper can also be used because of their excellent thermal and electrical conductivity and infrared reflectivity. On the other hand, copper can be oxidized by oxygen radicals from the dissociation process inside the gas discharge. Copper does not form stable, inert oxides on its surface but rather absorbs and binds the oxygen in the volume. This shifts the equilibrium of the dissociation towards a lower CO_2 content in the tube. Therefore, uncoated copper is not well suited as a material in direct contact with the gas discharge. Away from the discharge, however, copper is an excellent material for mirrors. Copper mirrors can be cooled effectively by water channels from the rear side. This is important for resonator and deflecting mirrors inside high-power lasers. For example, with an output coupler reflectivity of 50% the circulating light power inside the resonator is twice the rated laser power of the system. Even if the infrared reflectivity is very high, this can lead to considerable warming and mechanical stress if the mirrors are not cooled. Copper can be electroplated with nickel (Ni) and then coated with gold (Au). This makes the copper surface more stable against oxidation.

Catalysts and Gas Analysis

Much research has been carried out to find proper catalysts to reduce the dissociation of CO_2 and to maintain a high output power. In lasers with gas flow, the laser gas can be circulated through external catalysts. Common catalysts such as hot platinum [11.1545] or platinum on metallic oxides such as tin oxide with a large surface area [11.1546, 1547] can be used. However, fast-flow systems require gas replenishment of a few liters per hour to compensate for residual vacuum leaks or material contamination. As high-purity laser gas mixtures are very cheap compared to the costs of the installation of catalytic systems, the latter are usually not applied in fast-flow systems.

For sealed lasers without any gas flow the situation is quite different. The dissociation reactions inside the gas discharge are fast and equilibrium is reached in a tenth of a second within the discharge. On the other hand, diffusion time constants to catalytic surfaces outside the discharge region or in a separate gas reservoir are in the range of minutes. Thus, any catalytic surfaces need to be in close contact with the discharge itself. For example, catalytic active platinum cathodes [11.1538] and distributed platinum [11.1548] or sputtered gold coatings on the inner side of a longitudinal discharge tube [11.1549] have been reported. For waveguide lasers, gold-coated electrodes were found to be effective in some reports [11.1550, 1551]. The catalytic activity and the advantages for laser output power of these approaches depend on the preparation of the catalytic surfaces, the gas composition and the laser geometry itself, leaving many questions open and an impression of alchemy. Some commercial laser designs embody some of these techniques, as deemed best for the given laser design.

To study the effects of catalysts on the gas composition or, more generally, to have more data about the active medium such as rotational and vibrational temperatures, various methods can be applied. Mass

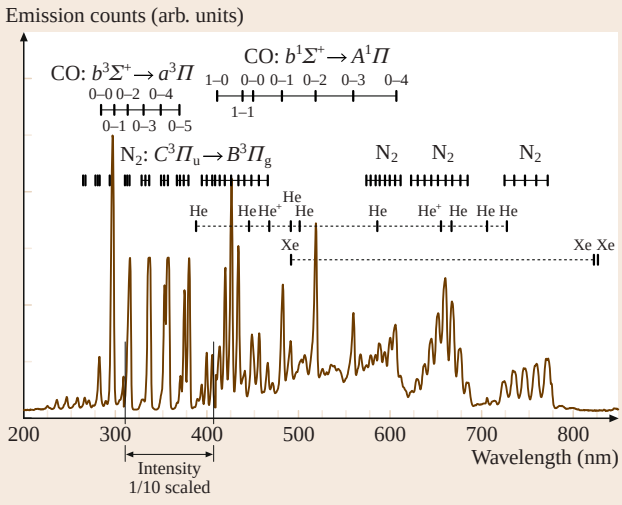

Fig. 11.133 Visible spectrum the sidewards spontaneous emission of a CO_2 laser gas discharge (after [11.1540, 1553])

spectrometers are commonly used for gas analysis. However, short-lived species from the discharge cannot be easily measured. The required pressure reduction from some tens of hPa down to 10×10^{-7} hPa tends to change the original gas compositions. Care must be taken because of the ambiguity resulting from N_2 and CO, which both have the same mass number. Special techniques in experimental laser systems have been used to measure gas compositions directly from the gas discharge, and have given insight into the complex gas chemistry [11.1532, 1552].

Another method is to study the visible and UV spontaneous emission from electronically excited states inside the gas discharge [11.1554]. This can even be done with the naked eye. Figure 11.133 shows a typical spectrum. A gas discharge without much CO appears pink or redish-purple because of vibronic nitrogen emission lines in the red and blue visible spectrum. With a significant carbon monoxide content there are additionally some CO emission lines spread over the visible and a strong emission band in the blue-UV spectral region. Thus, a gas discharge with a higher degree of dissociation looks more blueish-white. The color change can be observed in slow-flow DC-excited gas lasers with glass tubes from the gas inlet to the gas outlet, for example. For quantitative studies fiber-coupled spectrometers with fast readout can be used to gain time-resolved concentration data [11.1553]. With high-resolution spectroscopy, for example of the UV nitrogen emission band, the rotational temperatures of the gas can be measured. Using an imaging system, spatially resolved data for these parameters have even been measured in the discharge gap of an RF-excited high-power slab laser [11.1555].

Absorption spectroscopy with tunable diode lasers is also very effective for measuring species concentrations and roto-vibrational temperatures directly inside the laser tube or gas discharge. Therefore, a wavelength-tunable diode laser is adjusted to the various absorption transitions of the relevant molecules (i. e., CO_2, CO, N_2O, NO). By aiming the diode-laser beam through the gas volume and measuring the relative intensities of several rotational and vibrational transitions an accurate diagnostic of the active medium is possible [11.1556–1560]. Recently, the catalytic activity of special gold coatings on electrodes for RF-excited slab lasers was verified using this technique [11.1561].

Output Spectra and Line Broadening

Due to the fast population relaxation between the rotational levels typically only the rotational transitions with the largest gain are usually observed. A similar competition as for the rotational lines is also given for the two regular vibrational transitions (Fig. 11.132). As both share the same upper laser level (00^01), and the population levels of the lower states (10^00) and (02^00) are coupled by the Fermi resonance and have similar decay rates, only the vibrational transition with the largest gain will survive. Typically this is the 10P(20) transition or one of its neighbors for many lasers.

Every roto-vibrational transition line is broadened by several broadening mechanisms. At gas pressures above 10 hPa collisional or pressure broadening dominates over Doppler broadening. The collision-broadened line shape is described by a Lorentzian function having a line width (FWHM) Δf_L proportional to the total gas pressure p

$$\Delta f_L = 2p\left(\psi_{CO_2} b_{CO_2} + \psi_{N_2} b_{N_2} + \psi_{He} b_{He}\right) \times \left(\frac{300}{T}\right)^n , \quad (11.134)$$

where the ψ_i are the fractions of the respective gases and T is the gas temperature. The temperature exponent n is 0.58 for constant pressure [11.1562], with values ranging between 0.5–0.7 also found in the literature. b_i are the pressure-broadening coefficients resulting from collisions with species i and are given in [11.1562] to be

$$b_{CO_2} = (3.40 - |m| \cdot 0.0272)\,\text{MHz hPa}^{-1} , \quad (11.135)$$

$$b_{N_2} = (2.35 - |m| \cdot 0.0127)\,\text{MHz hPa}^{-1}\,, \quad (11.136)$$

$$b_{He} = (1.77 - |m| \cdot 0.00083)\,\text{MHz hPa}^{-1}\,, \quad (11.137)$$

where $m = -J$ for the P branch and $m = J + 1$ for the R branch. For example, the most common 10P(20) line at 100 hPa and 500 K in Lasermix 322 from Table 11.41 has a Lorentzian line width (FWHM) of 284 MHz. The Doppler line width at this temperature would be $\Delta f_D = 36.2$ MHz and can be considered if a Voigt line shape instead of a pure Lorentzian is used [11.1563].

Within this line width one or more longitudinal resonator eigenfrequencies f_q may be located. For the example length of a CO_2 laser resonator of $L_{res} = 2$ m the spacing between adjacent eigenfrequencies is $\Delta f_q = c/2L = 75$ MHz. As the collision-broadened line saturates homogeneously, only the eigenfrequency closest to the center frequency of the transition can lase in the steady state after saturation, as shown in Fig. 11.134. Thus, CO_2 lasers are typically longitudinally single-mode lasers.

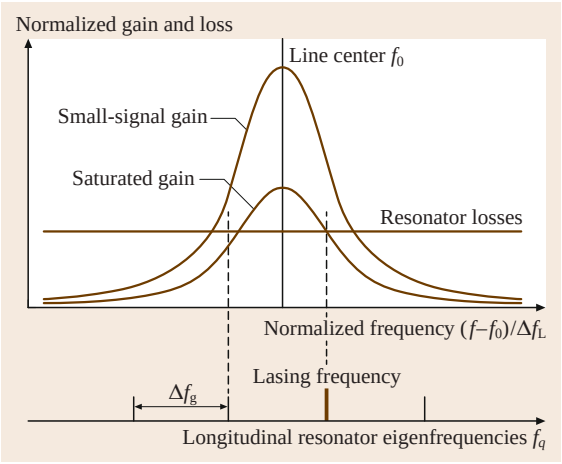

Fig. 11.134 Homogeneous saturation of a Lorentzian gain profile leads to lasing of a single longitudinal resonator eigenfrequency

Efficiency, Output Power, and Cooling

Small variations in the resonator length L_{res} result in shifts of the resonator eigenfrequencies f_q. Such variations typically result from thermal expansion of the laser tube or housing materials or from mechanical forces. When a single eigenfrequency f_q starts to move under the gain profile (Fig. 11.134) this will generate output power fluctuations as the laser power is dependent on the gain excess over the losses at a given frequency. As soon as a next eigenfrequency f_{q+1} or f_{q-1} is closer to the line center f_0 as the initial f_q, the lasing frequency will jump to this new frequency (mode hopping). As this new frequency also will move under the gain profile, a new cycle of rising and then decreasing output power starts. This is the reason for the typical power fluctuations after turn-on of a laser until thermal equilibrium is reached. Note that this effect is more pronounced in lasers with short resonator lengths as the eigenfrequency spacing δf_q is larger for such lasers. This effect can be reduced by using materials with a low coefficient of thermal expansion, by actively stabilizing the resonator length with piezo actuators or optically instable resonators. If only the power needs to be stabilized, then a fast closed control loop by measuring the output power and settling the electrical excitation power can be used.

The theoretical limit for the efficiency of a laser is the internal quantum efficiency η_q. For the CO_2 laser this is the ratio of the energy of the laser photons to the energy of the upper laser level (00^01) and is roughly 40%. This is quite high for a gas laser. Real technical lasers have significantly lower efficiencies for several reasons. The electrons inside the gas discharge do not only excite the required vibrational states of the molecules but also other states. Also a significant part of the kinetic electron energy is transferred into pure translatory motion of the molecules and thus transferred into heat. Additional energy is lost in the ionizing processes required to maintain the gas discharge and in chemical dissociation processes. Moreover, not every vibrationally excited molecule contributes to the laser process. Vibrational energy decays by vibrational–translational relaxation, which again produces again and by radiative decay by spontaneous emission of excited states. Finally, optical energy is dissipated in absorption losses of the mirrors and waveguides or by limited aperture diameters.

Typical electrical efficiencies η_E, defined as the ratio of the extracted laser power P_L to the electrical power P_E applied directly to the discharge tube, are in the range of 10% for slow-flow DC-excited lasers, up to 15% for RF-excited waveguide lasers, and up to 20% for fast-flowing systems. The overall wall-plug efficiency η_{tot} defined as the ratio between laser power P_L and mains supply power P_{mains} is always lower than η_E. This is due to conversion losses in the electronic power supplies to provide the required DC high-voltage or RF power. A considerable amount of energy is also dissipated in the gas circulating system of fast-flow lasers.

The output power of a given CO_2 laser can be roughly estimated by simple thermodynamics. If all aspects of optical design, electrical excitation, and gas composition are optimized, an electrical efficiency η_E as discussed above can be assumed. The laser power is then ultimately limited by the cooling and heat removal capacity of the laser system. The power dissipated by the electric excitation P_{diss} should not heat the laser gas above a certain temperature, for example 450 K.

In diffusion-cooled lasers no forced gas flow contributes to the heat removal. The thermal conductivity of the gas mixture and the diffusion of excited vibrational states to the housing walls determine the thermal transport processes. For a given tolerable temperature rise ΔT of the laser gas in the discharge area, the maximum applicable dissipated thermal power P_{diss} can be calculated by solving the differential heat-transfer equation for the given geometry. For fast-flowing systems the amount of heat removal is given by the specific heat capacity c_p of the gas and the mass flow $\dot{m}$.

Under the assumption that almost all electrical excitation power P_E is finally dissipated into heat P_{diss}, the maximum permissable excitation power $P_{E,max}$ for the given temperature rise ΔT can easily be calculated. The maximum possible output power $P_{L,max}$ of this laser system can then be calculated with the assumed electrical efficiency η_E. This exaggerates the importance of the cooling methods for high-power lasers. Different approaches will be discussed in the next section on technical lasers.

11.4.2 Typical Technical Designs

Although CO_2 lasers with a longitudinal DC discharge within a glass tube as described in Sect. 11.4.1 are still being used and sold because of their simplicity, many other types and realizations of the CO_2 laser have been developed over the last decades. They can by systematically categorized according to various characteristics, as below.

Gas Flow Inside the Laser.
- No gas flow, sealed-off
- Quasi-sealed-off, periodic gas exchange
- Slow gas flow axial to the laser beam
- Fast gas flow axial to the laser beam
- Fast gas flow transversal to the laser beam

Gas Cooling.
- Diffusion-cooled, cooled walls of the gas discharge
- Fast gas flow with external heat exchanger.

Electrical Excitation.
- Longitudinal DC discharge, continuous
- Transversal DC discharge at high gas pressure, pulsed
- Capacitively coupled transversal RF discharge
- Inductively coupled RF discharge
- Microwave-excited gas discharge.

Optical Resonator.
- Stable optical resonator
- Unstable optical resonator
- Free-space propagation between the mirrors
- Optical waveguide between the mirrors
- Combinations of these in different planes.

In principle, almost any of these characteristics could be combined to give specific advantages. The three axes of the optical laser beam, the gas flow and the exciting electrical field can be mutually parallel or orthogonal in general. Some of the most important designs with their specific technical characteristics are discussed further in the next sections. Commercial manufacturers of CO_2 lasers often have quite different approaches, also depending on their own intellectual property and patents. General design aspects are: as efficient a heat removal as possible, a compact optical resonator for a small footprint even at very high power levels and a rugged and robust design for maintenance-free long-term industrial operation.

More-exotic laser types such as optically pumped CO_2 lasers, black-body radiation-pumped lasers, lasers with electron-beam sustained gas discharges and gas-dynamic CO_2 lasers are not further considered in detail here.

DC-Excited Fast-Axial-Gas-Flow Lasers

Longitudinally DC-excited lasers have the advantage of a rather simple and cost-effective design. Modern DC-excited lasers use sophisticated electronically regulated high-voltage (HV) supply circuits with both voltage and current control to omit the ballast resistor shown in Fig. 11.126. This reduces ohmic losses in the HV circuit. Vacuum-tube-based or more modern semiconductor-based current regulators and switched-mode voltage converters are applied.

For high-power lasers a fast axial gas flow can be used to cool the gas. Lasers with a power in the kW range [11.1564, 1565] were demonstrated in the late 1970s. Figure 11.135 shows an example of a modern DC-excited fast-flow high-power laser. The gas discharge in the gas tube is divided into four independent

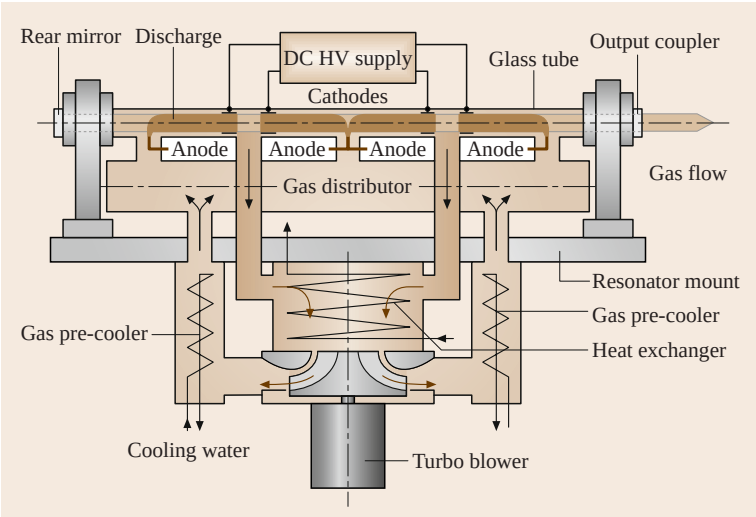

Fig. 11.135 Longitudinally DC-excited high-power CO_2 laser with fast axial gas flow (after [11.1566])

sections to keep the required high-voltage levels moderate. Two of the discharge and flow tubes shown can be used in parallel, with a U-shaped folded light path and resonator to double the length of the active medium. This is because the output power scales with the length of the gain medium.

As discussed in Sect. 11.4.1, the maximum output power of a CO_2 laser is also largely determined by its heat removal capacity. A fast gas circulation can be driven by a turbo blower. From thermodynamic considerations, the maximum laser power $P_{L,max}$ of a fast-flow laser can be calculated with a given electrical efficiency η_E

$$P_{L,max} = \eta_E P_{E,max} = \left(\frac{\eta_E}{1-\eta_E}\right) P_{th} = \left(\frac{\eta_E}{1-\eta_E}\right) \dot{m}\, c_p\, \Delta T\,, \quad (11.138)$$

where $P_{E,max}$ is the maximum applicable electrical power, P_{th} is the thermal power dissipated in and removed from the discharge, $\dot{m}$ is the mass flow, c_p is the specific heat of the gas mixture, typically $2500\,J\,kg^{-1}\,m^{-3}$, and ΔT is the maximum gas temperature rise that can be tolerated, typically 250 K. It can be seen clearly that the laser power scales with the mass throughput and thus with the flow velocity, which is limited by the onset of turbulence and the speed of sound. For an assumed efficiency of $P_E = 15\%$, one yields an approximate required mass flow of 0.1 kg/s per kW of laser power. The heat dissipated in the gas is removed by a heat exchanger after the gas has passed the discharge sections. The additional heat resulting from the gas compression by the turbo blower is removed by precoolers before the gas enters the discharge tube again.

Besides the fast gas flow there is also a permanent slow gas exchange with a fresh gas mixture, for example at a rate of 37 l (standard pressure and temperature) per hour in a ratio $He : N_2 : CO_2 = 25 : 12 : 2$ for a particular commercial system. Longitudinally DC-excited lasers up to several kW laser power are available. Depending on the laser power and the application, such laser systems can emit a mixture of an ideal TEM_{00} mode and a hybrid TEM^*_{10} donut-shaped mode.

RF-Excited Gas Discharges

Radio-frequency (RF) excitation of the gas discharge is widely used in CO_2 lasers. In this context RF means a frequency range of roughly 1–500 MHz. Figure 11.136 shows cross sections of typical geometries found in CO_2 lasers. In capacitively coupled RF (CCRF) discharges the electric field is applied by two metallic electrodes with the gas volume in between. The electric field $\boldsymbol{E}$ in the volume of the gas is sufficiently high to start and maintain a self-sustained glow discharge [11.1514]. The RF voltage U_{RF} and the RF electric field $\boldsymbol{E}$ are typically applied transversally to the laser beam. Thus, much lower voltages U_{RF} are required compared to longitudinally excited discharges. U_{RF} is roughly 100 V per mm discharge gap width d, depending largely on the gas pressure.

The electrodes can be electrically insulated from the discharge by a dielectric material, for example a glass or alumina tube as shown in Fig. 11.136a. No direct contact of the gas with the electrodes is necessary.

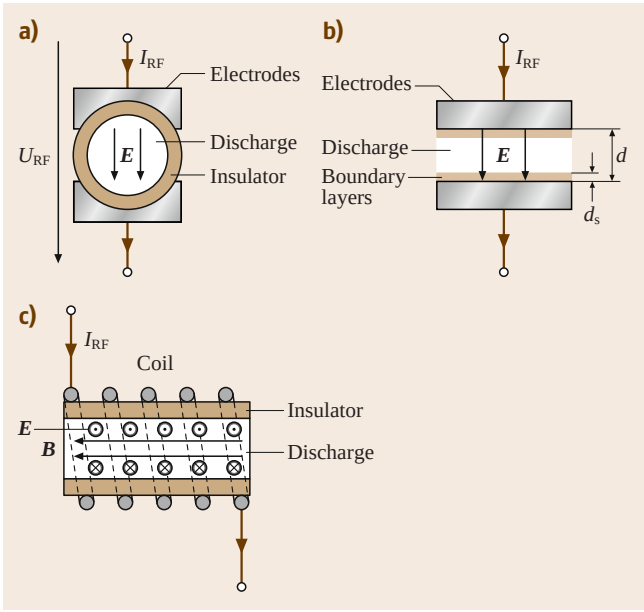

Fig. 11.136a–c Geometries for RF excitation with current I_{RF} and electric field $\boldsymbol{E}$: **(a)** capacitively coupled RF discharge, insulated electrode, **(b)** capacitively coupled RF discharge, non-insulated electrodes, **(c)** inductively coupled RF discharge

The current flow is closed by the displacement current, which is $\propto \partial \boldsymbol{E}/\partial t$ according to Maxwell's laws.

Alternatively, the metallic electrodes can be placed in direct contact with the gas volume (Fig. 11.136b). In this case the surface regions on both electrode boundaries have reduced free-electron densities and are called ion sheaths. In these ion sheaths no efficient excitation of vibrational states takes place. Power dissipated in the sheaths does not contribute to the laser power. The width of the sheaths d_s is inversely proportional to the excitation frequency $d_s \sim 1/f$ and is, for example, 0.35 mm at $f = 125$ MHz at a pressure of $p = 90$ hPa [11.1567]. The electrode separation must be significantly larger than this value to ensure sufficient excitation of the gas volume. On the other hand, this reduces the efficiency of diffusion cooling for heat removal from the gas to the electrodes. For small gaps and efficient cooling, excitation frequencies in the 100 MHz range are often chosen. An optimized value for the electrode separation d is typically 2 mm under these conditions.

With insulated electrodes a so-called dielectric barrier discharge has been reported, which allows efficient excitation at much lower frequencies around 1 MHz while still maintaining a stable discharge with efficient vibrational excitation and good cooling of the gas [11.1568].

The α-type RF discharge is a volume discharge with all ionizing and electron-collision processes taking place throughout the entire gas volume. No ionizing processes at the electrodes are required. Such RF discharges are hence called electrodeless discharges. However, in the case of non-isolated electrodes (Fig. 11.136b) there is also an onset of a γ-type discharge at higher current densities, where surface ionizing processes play an important role [11.1514]. This is usually not the desired discharge type for laser excitation.

RF gas discharges can also be inductively coupled (Fig. 11.136c). The RF current I_{RF} through a coil generates a time-varying magnetic field $\boldsymbol{B}$ which is accompanied by an electric field $\boldsymbol{E}$ according to $\mathrm{curl}\,\boldsymbol{E} = -\partial \boldsymbol{B}/\partial t$. Inductively coupled discharges are not commonly used for CO_2 lasers because the gas cooling and electrical field geometry are not as favorable as for CCRFs.

RF-excited discharges have several advantages. One advantage is that such an electrodeless discharge shows no material sputtering from the cathode or anode and no resulting contamination of the laser gas or degradation by material ablation. Very high energy densities can be applied to the gas volume while still maintaining a stable glow discharge without arcing. Higher gas pressures can be used, typically around 100 hPa. Thus, more active medium and more laser power is available per volume. The required voltages are lower than for DC excitation. Insulation of electric wires and components on the air-pressure side is easily done by sufficient large air gaps or common dielectrics. The impedance of the gas discharge, which can be modeled as a strongly lossy capacitor [11.1569], can be matched to the RF generator impedance with almost lossless reactive components (LC matching circuit). No ohmic ballast resistors are required to stabilize the discharge.

However, there are also some issues to be properly considered in the design of RF-excited lasers. One of those is voltage and discharge homogeneity along the RF electrodes. At a frequency of 100 MHz the vacuum wavelength λ_0 is 3 m. Wave propagation effects and electrical transmission line theory have to be considered if structures with one dimension ℓ larger than $\lambda_0/10$ are used. This is often the case for the length of typical RF-excited waveguide lasers. Therefore, regularly spaced inductors parallel to the electrodes are used [11.1536, 1570, 1571]. Figure 11.137 shows an example for an electric circuit model of the electrodes with

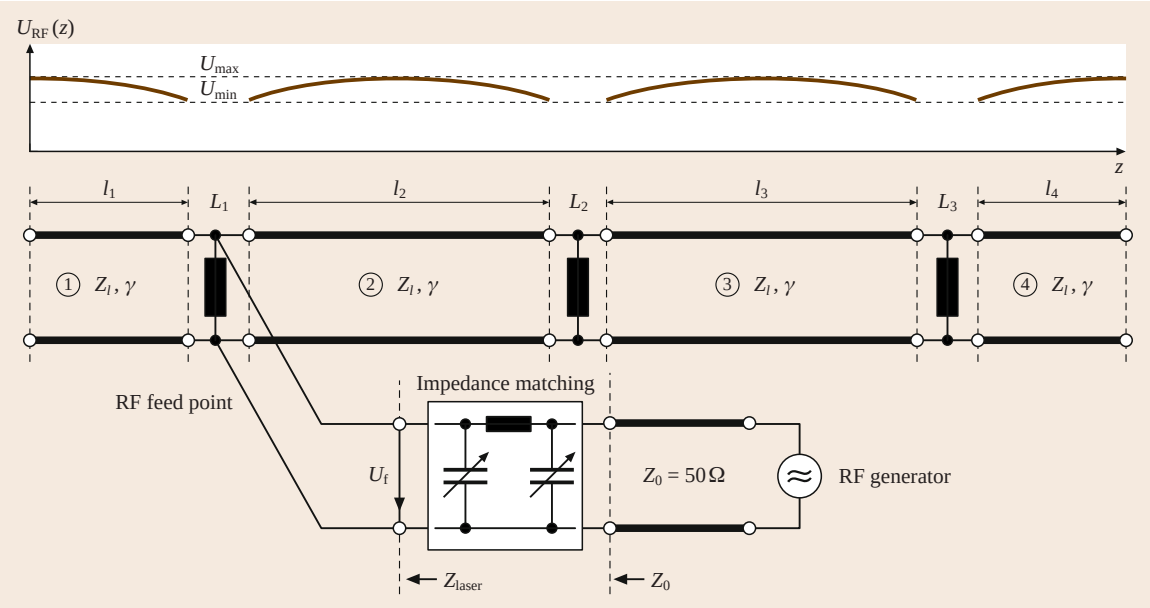

Fig. 11.137 Homogenization of the RF voltage distribution $U_{RF}(z)$ on long electrodes with parallel inductors (after [11.1572])

a gas discharge. The wave propagation of the electrical RF excitation field along the electrodes is described by a characteristic impedance Z_ℓ and the complex-valued propagation constant of a lossy transmission line γ. Parallel inductors L_i are used to compensate for the capacity per unit length of the electrodes to homogenize the voltage distribution. The higher the RF frequency, the more inductors in a shorter distance l_i must be used. Also shown is an impedance-matching network to match the complex impedance of the laser Z_{laser} to the system impedance Z_0 of 50 Ω of common RF generators.

Alternatively, an array of segmented electrodes much smaller than the wavelength of the electrical RF excitation can be used. This can be problematic if the electrodes also act as waveguides for the laser light. Mechanical misalignment of the electrode segments may then cause excessive optical losses.

RF power generators are somewhat more complex than DC high-voltage supplies. They must provide roughly ten times the nominal laser power as electrical power at RF frequencies. For low- and medium-power CO_2 lasers up to 500 W, solid-state RF power generators based on semiconductor transistors (mostly metal–oxide–semiconductor field-effect transistors (MOSFETs)) are available at the required frequencies. Such RF generators can be integrated directly into the laser system housing with air or water cooling of the power supply.

For an RF power much beyond this level electron-tube-based generators are required. Coaxial power tetrodes, as commonly installed in amplitude-modulation (AM) short-wave radio transmitter stations, are used. This is a mature and reliable technique to generate RF powers of tens of kilowatts in the desired frequency range. Such tubes can tolerate large reflected power levels from badly matched loads without permanent damage. Electron tubes are more robust against overvoltage and current transients than transistors. A drawback is that the tubes itself need a high-voltage DC power supply and that they dissipate additional power for cathode heating. The lifetime of such tubes is on the order of 10 000 hours. However, costs for replacement tubes are moderate.

Finally, issues of electromagnetic compatibility (EMC) have to be considered. Therefore, many RF-excited lasers operate in the ISM (Industrial Scientific and Medical) bands of 13.6, 27 or 40.6 MHz, where less-stringent regulations apply. Systems at different frequencies, especially in the frequency-modulated (FM) radio bands around 100 MHz need to have properly shielded housings, best made of all metal and with contact strips for all service flaps of the laser housing.

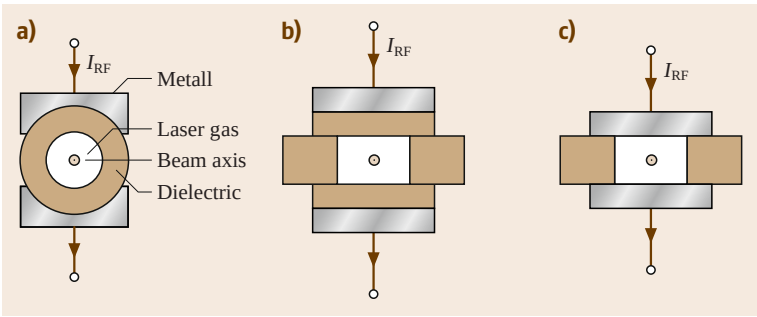

Fig. 11.138a–c Cross sections of some waveguides for CO_2 lasers with RF electrodes: **(a)** circular dielectric waveguide, **(b)** all-dielectric rectangular waveguide, **(c)** hybrid metal–dielectric waveguide

Microwave excitation at a frequency of 2.45 GHz has been studied intensively [11.1573–1575]. Powerful magnetrons are very efficient microwave-generating tubes at this frequency and are available at low cost, because of their use in mass-produced products such as kitchen microwave ovens. However, the short wavelength makes it difficult to realize large-area discharges with good uniformity. Additionally, the power density required to maintain a microwave-excited gas discharge is larger than at common RF frequencies and tends to overheat the gas. Thus, microwave-excited CO_2 lasers have been realized mostly in pulsed operation [11.1576] or with a fast gas flow [11.1577]. Diffusion-cooled laser systems have also been demonstrated [11.1578]. In spite of the cost advantages of microwave generation with magnetrons, the mentioned disadvantages and the progress of RF-excited lasers has hindered the commercial success of microwave excitation to date.

Waveguide Lasers

For the basic laser design in Fig. 11.126 it would be desirable to reduce the diameter of the glass tube to achieve better cooling of the laser gas. However, this would introduce excessive optical losses by obstructing the laser beam within the resonator. Losses from such limiting apertures with a radius of a for common Gaussian TEM modes in two-mirror stable resonators of length l are calculated in [11.1579]. These losses rise quickly if the Fresnel number $N = a^2/\lambda l$ gets smaller than 1.

This problem can be overcome if the gas tube has waveguide properties at the optical laser frequency. A comprehensive overview of waveguide laser design is given in [11.1570]. Figure 11.138 shows the principle geometries of waveguides used in CO_2 lasers. The simplest form is a circular hollow dielectric waveguide, which is theoretically described in [11.1580]. Circular metallic waveguides are not an option because they will obviously shorten any electrical field required for the discharge excitation. Rectangular waveguides can have dielectric walls on all four sides or one pair of dielectric and one pair of metallic walls [11.1581, 1582]. Such waveguides support hybrid EH_{mn} modes at optical frequencies with very low losses. These modes can be thought of as a superposition of electromagnetic waves propagating at different angles to the waveguide axis, reflected by the walls at grazing incidence. Therefore, the materials used should have low absorption losses in the infrared [11.1541, 1542]. Alumina or beryllium oxide ceramics are a good choice for the dielectrics because of their high mechanical, chemical and thermal stability and their high thermal conductivity for heat removal. Aluminum or gold-plated copper surfaces can be used as metallic waveguide boundaries.

The lowest circular mode EH_{11} is very similar to the Gaussian free-space mode TEM_{00}, with a power overlap of 98%. Thus, waveguide lasers operating only in the lowest possible mode have excellent beam quality.

To build a waveguide laser, such waveguides are filled with laser gas. The excitation of the gas discharge is therefore often realized by a transversal RF discharge. A pair of metallic electrodes are placed on opposite sides of the dielectric waveguide (Fig. 11.138a,b) or are part of the waveguide itself (Fig. 11.138c). The optical resonator is realized by mirrors at both ends of the waveguide. Design rules for low-loss coupling and good mode discrimination are given in [11.1583] and in [11.1584]. Plane mirrors close to the waveguide can be used.

The power of a waveguide laser scales almost linearly with the length. Up to 110 W of laser power per meter length have been reported [11.1585].

Many commercial CO_2 lasers use waveguide technology. Figure 11.139 shows the cross section of a particular commercial waveguide laser [11.1586]. The resonator light path is folded in a zigzag shape three times through multiple waveguide channels formed by a ceramic plate and an aluminum profile. This results

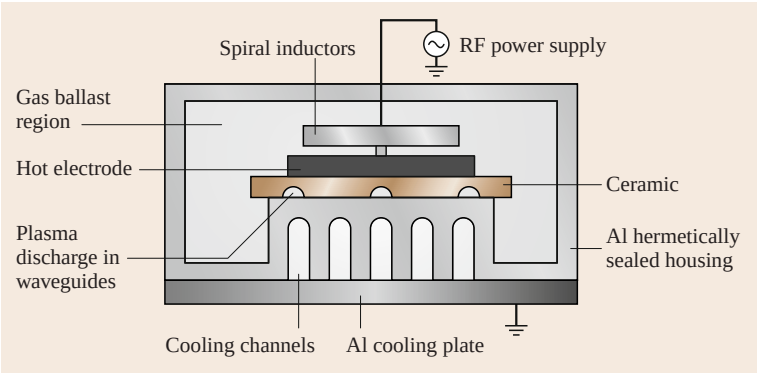

Fig. 11.139 Cross section of a commercial RF excited waveguide laser with a folded resonator light path

in a compact laser head design with high power, as the laser power scales with the length of the waveguide. The aluminum profile serves as the RF ground electrode, as one side of the optical waveguide, as a cooling plate and as an RF- and gas-tight housing for sealed operation. The second RF electrode is on top of the ceramic plate. Regularly spaced spiral inductors homogenize the RF voltage distribution along the structure. Air or water cooling can be realized by the cooling channels within the profile. An output power of 100 W is available from a compact package size [11.1587]. *Q*-switching can optionally be applied to realize pulsed lasers with high peak power, especially for marking applications.

Another interesting waveguide laser structure is shown in Fig. 11.140 [11.1588]. The waveguide is formed by two pairs of metallic aluminum electrodes and two ridges from the metallic housing profile. RF power is applied to both electrodes in a push–pull mode with respect to the grounded housing. That means that the RF voltage amplitude on both electrodes is the same but with a 180° phase shift relative to one other. The electrodes are separated from the ridges by small gaps which enable gas circulation in the whole structure for cooling and heat removal. The electrodes are anodized such that the oxide layer provides sufficient insulation to the grounded ridges of the housing. Additional insulators are used to hold the electrodes in the housing. A homogeneous gas discharge is formed in the middle of the structure with lateral dimensions of a few mm. In spite of the small gaps, the structure can act as an optical waveguide in all directions to form a laser beam with good beam quality.

The advantage of this all-metal structure is that no ceramic–metal joints are required. Such joints can potentially cause failure because of the mismatched thermal expansion coefficients. Both the electrodes and the housing can economically be manufactured by extruded aluminum profiles. Heat is easily removed by conduction or passive thermal convection. Without ceramics with their high dielectric constants between the electrodes, the capacitive loading of the electrical waveguide is low. Fewer inductors are thus required for voltage homogenization. The metal housing can be sealed with metal brazing to build long-living sealed-off lasers. A range of medium-power compact lasers up to 240 W is available in this technology [11.1589], partially using folded resonators for power scaling with the waveguide length.

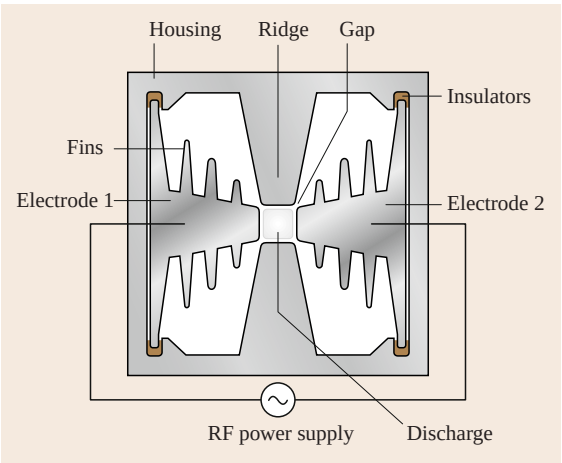

Fig. 11.140 Cross section of an all-metal waveguide laser

The Slab Laser

Figure 11.141 shows the structure of an RF-excited slab laser. This design has been pioneered by several groups [11.1590–1593], accompanied by the well-known *Tulip* patent [11.1594]. It is formed by two large-area metallic electrodes separated by a small gap. The length of the electrodes can be 1 m with a width of

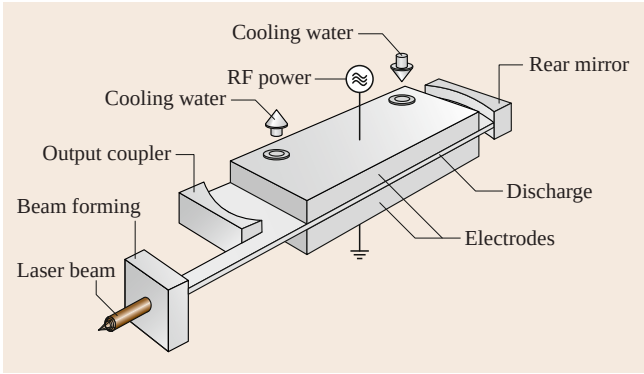

Fig. 11.141 RF-excited slab laser with hybrid waveguide-unstable resonator (after [11.1595])

some tens of centimeters. A typical gap height would be 2 mm. An RF voltage at a frequency in the range of 100 MHz is applied between the electrodes to maintain a gas discharge in the laser gas mixture between the electrodes. The electrodes are provided with channels for cooling water. Thermal energy dissipated in the gas discharge is effectively removed by conductive or diffusion cooling. Gas discharges with very large areas can be operated stably within this geometry.

In a plane perpendicular to the large-area surfaces the electrode pair acts as a waveguide for optical frequencies. A low-order mode is easily obtained in this waveguide direction. In the plane parallel to the electrode surfaces free-space conditions are valid as there are no limiting boundaries on the sides of the electrodes. With such broad dimensions this would result in a strongly multimode beam profile in this direction, if

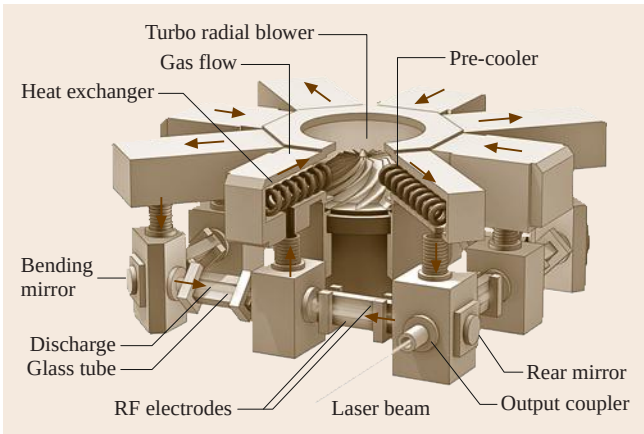

Fig. 11.142 RF-excited fast axial gas flow with a folded resonator (after [11.1596])

common stable resonators were applied. Therefore, an unstable resonator is used which has advantages for the extraction of high-quality beams from active laser media with large transversal dimensions [11.1512, 1597]. An unstable resonator is characterized by two mirrors with radii of curvature ρ_1 and ρ_2 and a mirror separation L that do noes fulfill the stability criterion for stable Gaussian beam resonators

$$0 \le \left(1 - \frac{L}{\rho_1}\right)\left(1 - \frac{L}{\rho_2}\right) \le 1 \,. \qquad (11.139)$$

Such a resonator does not reflect a Gaussian beam backwards into itself but rather uses the partial transmission of the beam on one mirror side as the output coupling. It can be shown that the beam profile can have an almost diffraction-limited beam quality in the unstable-resonator plane. In the waveguide plane, the surface curvature of the mirrors can be almost flat. Both mirrors can be made of solid copper and can be cooled to withstand very high power densities. By a proper design, the coupling losses between the mirrors and the slab waveguide can be minimized [11.1598].

The laser beam emitted directly from this type of resonator has an elliptical shape and has different divergence angles in the waveguide and the free-space plane. This is corrected by beam-shaping optics with at least one cylindrical mirror. Additionally, a spatial mode filter is used to eliminate shadows on the beam wings in the free-space unstable-resonator direction. After that, the beam has a nearly circular shape with an excellent beam quality of $M^2 = 1.1$.

The main advantage of this structure is that the laser power can be scaled by the area A_e of the gas discharge, which extends in two dimensions. This is in contrast to tube-type or waveguide lasers where the power scales only over one dimension, namely the tube length L. From thermodynamic calculations and based on extending results from conventional waveguide lasers, the maximum laser power P_L of a slab with an electrode area A_e and an electrode separation d_e is approximately given by

$$P_L = C\frac{A_e}{d_e} \,, \quad C \approx 3\frac{\mathrm{W\,mm}}{\mathrm{cm}^2} \,. \qquad (11.140)$$

By this area scaling over A_e, very compact and yet powerful lasers can be made. As with all large RF-excited laser systems, parallel inductors are used for homogeneous RF voltage distribution along the electrodes. The efficient diffusion cooling requires no gas flow, which saves system and operating costs. Medium-power lasers can be operated completely sealed and are available

at power levels up to 500 W [11.1599], partially with transistor-based RF generators. High-power slab lasers operate typically with a periodic gas exchange, for example after 72 h of continuous operation, to compensate for residual gas leaks from the large structure. Commercial slab lasers with powers up to 8 kW integrate the slab structure and the electron-tube-based self-oscillating RF generator within one compact housing and with an integrated premix gas supply which lasts for approximately 12 months of continuous use [11.1595].

RF-Excited Fast-Flow CO_2 Lasers

The basic principle of a fast-axial-gas-flow laser as described in Sect. 11.4.2 can be combined with the advantages of RF excitation. Figure 11.142 shows such a laser system. The gas circulates through glass tubes driven by a turbo radial blower in the center of the structure. The optical resonator is quadratically folded. For an even longer discharge length and more output power, the resonator can be folded in two planes with 16 discharge sections (Fig. 11.143). Optically stable resonator configurations are used. The RF discharge is capacitively coupled with pairs of electrodes, two pairs on each side. The electrodes are mutually rotated by an angle of 45° to ensure a homogeneous excitation in the cross section, averaged over one resonator cycle. A heat exchanger cools the gas coming from the discharge section. A pre-cooler removes compression heat after the blower before the gas enters the discharge sections again. Typical gas pressures are in the range of 150 hPa. The power scaling with mass flow according to (11.138) is also valid for this system. Volume flow rates are up to 500 m^3/h per kW extracted laser power with gas velocities of 100 m/s. Lasers with output powers up to 20 kW are commercially available while laser powers above 30 kW have been demonstrated experimentally [11.1601]. The beam quality is near a perfect diffraction-limited TEM_{00} mode with an M^2 of 1.1 for high-quality series up to 4 kW. At the high-power end the 20 kW system still has an M^2 value as low as 5. The wall-plug efficiency of these systems is 10% including the losses in the RF power supply and the gas-circulating system. Electron-tube-based high-power RF oscillators at an industrial ISM standard frequency of 13.6 MHz are used.

Other RF-Excited CO_2 Laser Systems

There are many other commercial laser designs based on RF excitation and with specific resonator or cooling geometries. Some interesting designs will be discussed briefly here.

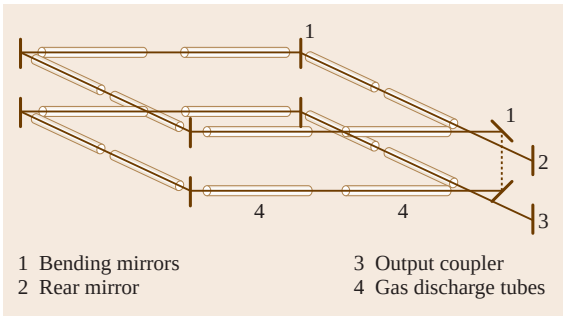

Fig. 11.143 Quadratically folded resonator in two planes (after [11.1596])

Figure 11.144 shows a folded free-space resonator between two large-area RF electrodes. Only three mirrors are required for beam folding. The output coupler and the plane total reflector can even be integrated in one mirror with inhomogeneously reflecting coatings. Compact and robust sealed original equipment manufacturer (OEM) laser modules up to 120 W are available [11.1600].

A combination of large-area electrodes with a hybrid stable–unstable resonator is described in [11.1602] and [11.1603]. In contrast to the slab laser with its plane-parallel electrodes, the electrodes do not act as a waveguide here. Instead, they have a slightly V-shaped surface geometry along the beam propagation direction between the mirrors to select the lowest-order free-space mode in a plane perpendicular to the electrodes, whereas an unstable resonator is used in the free-space plane again. Sealed-off OEM modules in an all-metal design and a maximum power of 400 W can be realized [11.1604].

Large-area RF-excited gas discharges can also be combined with a fast gas flow between the electrode plates transversally to the optical resonator and the laser

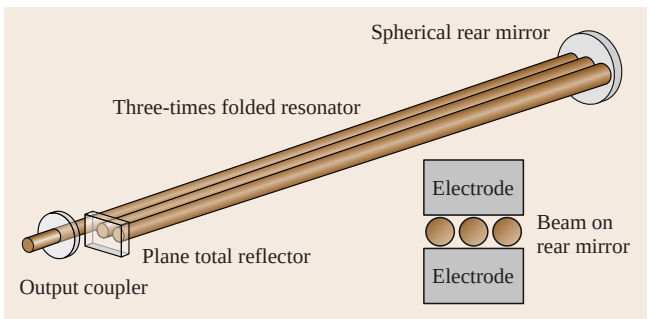

Fig. 11.144 Folded free-space resonator between large-area slab electrodes (after [11.1600])

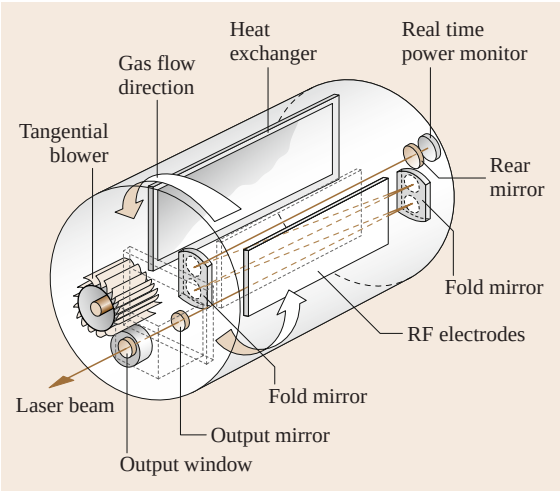

Fig. 11.145 RF-excited laser with fast transversal gas flow (after [11.1605])

beam (Fig. 11.145). The gas flow is driven by a tangential blower integrated into the large-diameter cylindrical gas vessel. A folded resonator is used to extract the energy from the large active medium. Such lasers can produce 8 kW of laser power from a very compact footprint. The beam quality with $M^2 \approx 5$ is still well suited for welding and surface-treatment applications.

Coaxial laser systems with an annular gas discharge as shown in Fig. 11.146 can be thought of as slab-type lasers with an electrode pair rolled up to form coaxial tubes [11.1607]. RF power is applied to the inner tube, while the outer tube is grounded. This is similar to a coaxial cable, but with an inner-conductor diameter of approximately 10 cm and a discharge gap

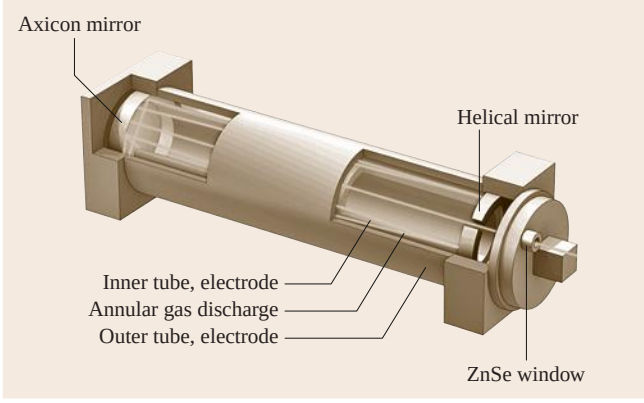

Fig. 11.146 Coaxial laser with an annular gas discharge (after [11.1606])

width of 7 mm, for example. In this design, the electrodes have no optical waveguiding properties, thus such lasers are less susceptible to power and beam-quality variations under mechanical and thermal stress. The resonator is formed by a helical mirror and an axicon mirror, bending the beam to the opposite side of the tube while slightly shifting the azimuthal angle after each pass [11.1608]. In the radial direction the optical resonator configuration is stable, while in the azimuthal direction an unstable resonator is used. The laser gas is diffusion-cooled by water-cooled electrode tubes. The laser can be operated quasi-sealed-off with a regularly scheduled gas exchange. Compact and robust lasers with 2 kW power can be realized [11.1609]. They are well suited for mounting on moving systems such as robots without bending mirrors for beam steering.

Pulsed TEA Lasers

All the laser designs discussed so far are continuous-wave (CW) lasers by principle. Their power can be modulated by the electrical excitation power with frequencies of a few kHz for DC excitation and up to 100 kHz for some RF-excited lasers. In contrast, the tranversal-excited atmospheric-pressure (TEA) laser is a CO_2 laser that can inherently operate only in pulsed mode, but is capable of generation very high pulse energies and peak powers that are not possible with CW CO_2 lasers. This is achieved by a high gas pressure, at atmospheric pressure or above. A homogeneous DC discharge can only be operated for a short time of 1 µs under these conditions before filamentation and arcing would occur. The required voltages at this pressure are in the order of magnitude of 100 kV per meter. Longitudinal discharges would need voltages that are not practical and would not produce stable discharges. Therefore, pulsed transversal discharges are used. Figure 11.147 shows a basic TEA laser circuit. A high-voltage power supply (HV) charges a storage capacitor C slowly via the resistors R_{V1} and R_{V2}. When the maximum voltage

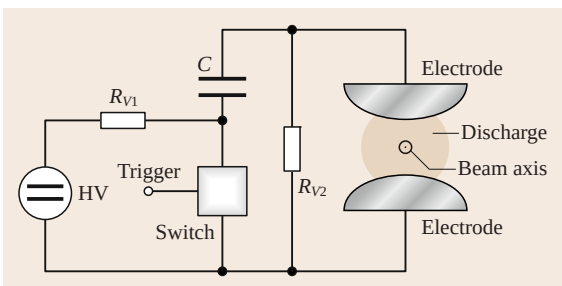

Fig. 11.147 Excitation circuit for a basic TEA laser

Table 11.42 Emission range of a tunable CO_2 laser [11.1610]

Band	Wavelengths (μm) min – center – max	Lines min – center – max
9R	9.158 – 9.271 – 9.367	9R(44) – 9R(20) – 9R(4)
9P	9.443 – 9.552 – 9.836	9P(6) – 9P(20) – 9P(50)
10R	10.095 – 10.247 – 10.365	10R(46) – 10R(20) – 10R(4)
10P	10.441 – 10.591 – 10.936	10P(4) – 10P(20) – 10R(50)

at the capacitor is reached, a fast high-voltage switch, which is also capable of carrying high currents, is triggered to close the circuit to the electrodes quickly. The capacitor voltage is applied to the electrode pair, where a short but intense discharge transversal to the resonator axis and the laser beam starts. The discharge self-terminates when all the energy stored in the capacitor is dissipated. Afterwards the high-voltage switch resets itself to an open state and charging of the capacitor starts again before the next pulse can be triggered.

With TEA lasers pulse energies in the range of 10 J per liter of active volume and per bar of pressure can be achieved, with peak intensities in the MW range [11.1611, 1612]. Pulse repetition rates are a few 10 Hz for high-power systems and kHz for mini-TEA lasers [11.1613].

Critical design issues are the electrode profile to maintain a stable and homogeneous discharge in the cross section and also over the length of the electrodes. Often pre-ionization techniques by additional electrodes, UV light from corona discharges or even electron beams are therefore applied. The high-voltage switch is also a crucial part. Typically, triggered spark gaps or thyratrons are used, which must be replaced after a given number of pulses. Recently, progress in semiconductor technology has made it possible to replace these vacuum tubes by solid-state switches. A device called a silicon controlled rectifier (SCR) is capable of switching high currents very fast. In combination with a step-up transformer and a saturable inductor/capacitor ladder network the high-voltage level and the fast rise time required for the electrode voltage can be achieved.

Much research was done on TEA lasers in the 1980s, especially in the fields of plasma physics, LIDAR and military applications. Partially due to the success of high-power fast-flow and RF-excited systems, only a few commercial TEA lasers are available. Systems with pulse energies of 2.4 J at a repetition rate of 125 Hz are available, for example. Applications include non-metal processing such as marking and paint or rubber-compound stripping from surfaces in the automotive industry [11.1614].

Wavelength Selection and Tunable CO_2 Lasers

Without any wavelength-selective elements, a CO_2 laser emits at wavelengths around 10.6 μm in the vicinity of the 10P(20) line. Some commercial lasers are optionally available at the wavelengths of the strongest lines of the other bands, for example at 9.3, 9.6 μm or 10.3 μm (Fig. 11.131). This is done by weakly wavelength-selective elements such as mirror coatings to select one of the four regular emission bands where the strongest line will start to oscillate. For example, this is interesting for plastics machining, coding or marking, as these materials can show a strong variation of absorption over wavelength.

For precise selection of a particular roto-vibrational transition, a diffraction grating is used. Figure 11.148 shows a DC-excited tunable laser in the Littrow configuration. Depending on the angle α of the incident beam in respect of the surface normal of the grating, only a light beam at a specific wavelength λ_L is reflected exactly backwards into the incident beam is

$$\lambda_L = 2\Lambda \sin\alpha \,, \tag{11.141}$$

with Λ being the grating period. For this particular wavelength λ_L the grating acts as a flat reflector aligned on axis to the second resonator mirror. This wavelength is selected to lase. Other wavelengths λ_x, if they would be present at all, would be reflected at a different angle not parallel to the resonator axis. They would suffer significant losses from the aperture of the laser tube, which prevents them from lasing. By rotation of the grating the angle α can be varied to select different roto-vibrational transitions one by one. Such gratings are mostly made of copper or steel with precision-ruled grooves and a gold coating to enhance IR reflectivity. The grating period Λ is chosen to be slightly smaller than the laser wavelength in order to suppress higher diffraction orders. The groove geometry can be adjusted such that the reflectivity in the desired minus-first diffraction order at a given wavelength is maximized (blazed gratings, blazing wavelength).

Table 11.42 shows for example the tuning range of a commercial tunable CO_2 laser. Note that, because of

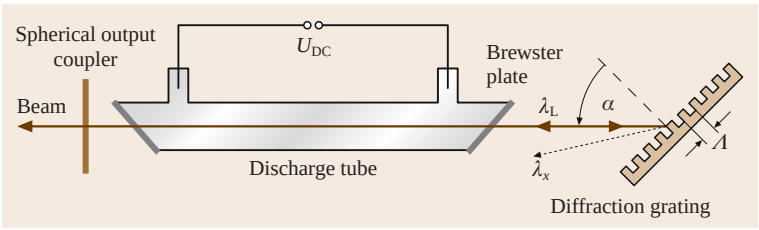

Fig. 11.148 Tunable CO_2 laser in Littrow configuration

the separation of the rotational lines in the range of 30–90 GHz and a pressure-broadened line width Δf_L of only some 100 MHz, continuous tuning over the entire spectral range is not possible. Within one line width, fine-tuning can be done by changing the resonator length with a piezo actuator. An output power of 180 W can be achieved for the strongest lines and more than 20 W on the weak lines at the band edges, for example.

Applications include scientific spectroscopy, industrial trace-gas monitoring by absorption spectroscopy or optically pumping of far-infrared molecular gas lasers. By using gas mixtures enriched with special isotopologues, for example $^{13}CO_2$, emission lines at additional wavelengths can be realized. Tables of such wavelengths are given, for example, in [11.1511].

Besides longitudinally DC-excited lasers, RF-excited waveguide lasers are also good candidates for being tuned by a standard Littrow grating. Tunable slab-type lasers with their broad active medium require special grating structures for the extraction of a low-order mode. This can be realized by apodized Littrow gratings where the splitting ratio between the diffraction orders $m = 0$ and $m = -1$ is variable over the direction of the grating [11.1615]. Such gratings can act as an output coupler with spatially variably reflectivity for beam forming and as line-selective element for wavelength tuning at the same time. They have been realized on copper mirror substrates with photolithography and a microgalvanic process as well as on silicon substrates with photolithography and anisotropic etching [11.1616].

11.5 Ion Lasers

Ion lasers became a success very soon after their invention in the 1960s. In the following decades, low-power air-cooled argon lasers were made in the tens of thousands for use in printing, color separation, and medical technology. Mid-power ion lasers were a staple of the entertainment industry, used in light shows, special effects, and for holography, as well as in disc mastering. Large-frame ion lasers were ubiquitous in well-equipped chemistry and biology laboratories around the world. Ion lasers were the flagship products of the major commercial laser manufacturers.

But even in their heyday, alternatives to ion lasers were eagerly sought. There were several reasons for this, including early problems with reliability and lifetime, as well as high cost, but the major dissatisfactions resulted from the fundamental low efficiency of the devices. This poor efficiency meant ion lasers were large, of considerable weight, and needed substantial power supplies drawing large utility loads. They also had to be cooled aggressively either by air or water.

With the development of solid-state lasers in the 1990s, in particular diode-pumped lasers with frequency-doubled green output at 532 nm, many expected ion-laser technology to become obsolete. This has not happened. While not nearly at the levels they experienced in the 1980s, sales continue to be steady, ion lasers are still found in their traditional applications, and are a significant contributor to the bottom line of a number of companies, both as new systems and in the replacement market. While there are fewer types of new ion lasers available now, these systems still vary considerably in performance, size, utility requirements, and cost.

An ion-laser system consists of a power supply, control electronics, and the laser head. The laser head itself contains the plasma tube placed within a resonator (or *cavity*) structure. Control of the laser is typically through an interface included in the power supply, which itself can vary considerably in size, complexity, and cooling requirements.

Small ion lasers are air cooled, require only standard wall-plug electrical service, have a laser head roughly

the size of a toaster, and are most commonly used to produce only a single blue–green output at 488 nm in the range 5–100 mW. When operated in the low-current range, these lasers can be expected to last for years in a stable environment. Tube replacement when necessary can be performed by the user and is relatively quick and inexpensive.

The greatest variety of product offerings is in the mid-range of performance of 1–5 W of laser output. These systems range from simpler models based on the original ion technology, with air cooling and ceramic plasma tubes, to specialized systems with single-wavelength output intended for specific industrial applications, to only slightly smaller versions of the sophisticated large-frame systems used in advanced laboratories.

A high-performance ion system has a laser head about a meter and half long and can weigh 100 kg. It may require 70 A per phase of three-phase electrical service at 480 V and in addition a cooling-water flow of several liters per minute. But in compensation, these lasers are capable of producing many watts of continuous laser power in a range of selectable wavelengths not available from any other commercial laser system.

Wavelengths available from ion lasers extend from the infrared well into the ultraviolet, with argon, the most common type of ion laser, emitting light primarily in the blue–green to ultraviolet range [11.1617, 1618]. Specific wavelength output is determined either by the choice of the coating for the laser output mirror, or by tuning to the desired wavelength using a Littrow prism placed in the laser resonator. The section below discussing the laser resonator will further describe control of the spectral characteristics of the ion-laser output.

Krypton is not nearly as popular an ion laser as argon, in part because of its lower power, but it remains commercially viable because, like argon, it offers significant levels of continuous output power at wavelengths not easily achieved by other means. For example, more than 1 W CW is available from a single line in the yellow, a color region where laser sources are scarce, and lines in the violet and ultraviolet have important applications as well.

The output power of an ion laser depends on two sets of variables. One set derives from the design of the laser resonator, and includes, for example, the cross-sectional area of the laser beam. This set of variables will be discussed in the section which describes the resonator. The other set of variables that determines laser power results from the physics of the laser process in the plasma created from the noble gas. These variables include the total light amplification available from the plasma.

11.5.1 Ion-Laser Physics

An energy-level diagram is used to show the wavelengths available from a laser material that has been excited into a condition of population inversion. A simplified version illustrating the transitions in singly ionized argon that produce visible laser light is shown in Fig. 11.149 [11.1619]. The transitions shown result from energetic electrons that have decayed to the 4p upper laser level from a still higher level not shown in the figure. From the upper laser level, the electrons are stimulated to fall into the 4s states. The most important individual transitions, which result in the highest output power, are those for 488.0 nm, a blue–green color, and 514.5 nm in the green.

Having many upper laser levels transitioning to only two lower levels raises the possibility of competition for the lower states, which can limit laser output. In the case of argon, however, the lower states depopulate to the ground state very rapidly, avoiding this potential bottleneck. The lifetime of an electron in one of the upper 4p states is about 10 ns, while the lower 4s states make their transition to the ground state in a favorable 0.5 ns. With a proper choice of mirror coating, *all-lines* visible operation can produce laser power from most of these visible lines simultaneously, and the power present in any one of the lines will not be much less than that obtained from single-line operation.

An energy-level diagram can also illustrate problems or requirements in the design of a specific laser system. Figure 11.150 shows the 4p and 4s laser levels of ionized singly argon in relation to the argon

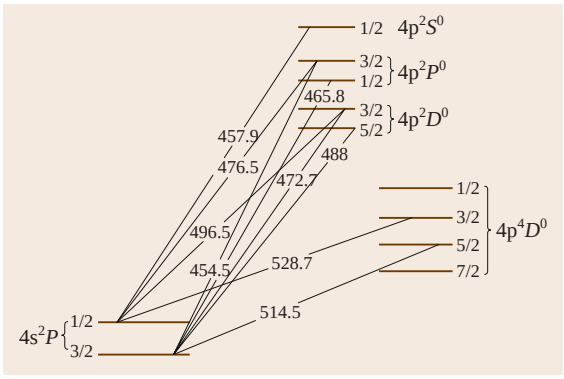

Fig. 11.149 The visible laser transitions of ionized argon (wavelengths in nanometers)

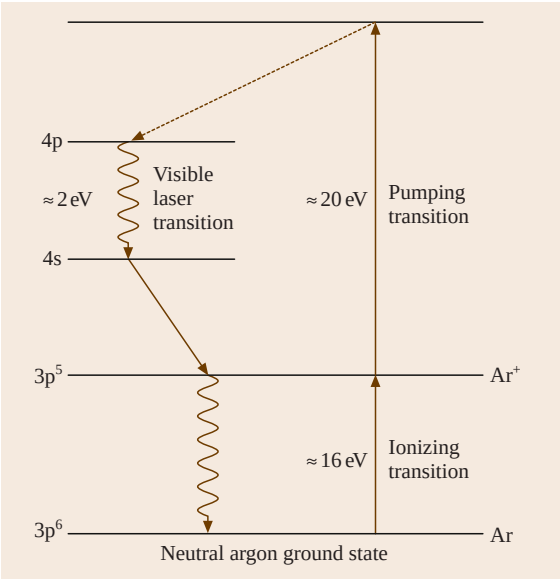

Fig. 11.150 The two-step ion-laser excitation. One electron collision ionizes neutral argon and a second pumps the ion to an excited state from which it decays to the upper laser level

ground state. The energy needed to ionize the argon to start the population inversion is about 16 eV, and an additional 20 eV is required to reach the states that decay to the upper laser level. Comparing this total energy input of 36 eV to the energy emitted by the laser transition itself, about 2 eV, it is evident that the efficiency of an argon ion laser will be low. In addition, the temperature of the gas discharge needed to produce electrons with sufficient kinetic energy to achieve the required level of ionization is in the vicinity of 3000 K. This, combined with the low efficiency, indicates that heat management is a primary concern in ion-laser design [11.1620].

Ion lasers use an electric discharge to energize the gas. As can be seen in Fig. 11.150, two collisions with free electrons are required to excite an electron in an argon ion to the upper level of visible lasing transitions. The gain available from the ionized gas therefore varies as the square of the current density, up to the point where the gain saturates (i. e., other gas-phase processes begin to limit the gain) [11.1621].

The optimum gas pressure that produces the maximum laser output is a balance between competing factors. High pressure provides a greater number of potential ions to stimulate laser emission, while low pressure allows the voltage drop along the plasma more time to accelerate the free electrons to a greater energy between collisions. Different wavelengths have different optimum pressures, and the final choice for a laser designed to operate at multiple wavelengths is a compromise. In general the optimum is in the low-pressure regime. Argon plasma tubes have a fill pressure on the order of 1 Torr [11.1622].

Performance is improved by a magnetic field directed along the length of the plasma discharge, which helps confine the discharge towards the center of the plasma tube [11.1620]. The benefit is greatest for lasers operating at high current. Again, different wavelengths have different optima, and a compromise value of magnetic field strength is employed. Air-cooled lasers typically do not use magnets, as the benefit of a magnetic field for low powers does not justify the added expense, and the addition of magnets would complicate the flow of cooling air.

If the argon is doubly ionized (i. e., stripped of two electrons), a new set of transitions become available that produce ultraviolet laser light [11.1623]. The ground state of Ar^{2+} is about 43 eV above that of the neutral atom, compared to the Ar^{+} ground-state difference of 16 eV mentioned, so operating in the ultraviolet can be expected to be even less efficient. Once above a higher threshold current, UV output rises more rapidly than the visible output does.

The energy diagram for krypton is similar to that for argon, with laser transitions shifted to somewhat lower photon energies in the visible from the upper 5p to the lower 5s bands [11.1624]. Important lines are at 647.1 nm in the red, corresponding to the green 514.5 nm argon line, and at 568.2 nm in the yellow, corresponding to the blue–green line at 488 nm in argon. Unlike argon, however, in krypton these strong lines do experience competition for the same lower state, and so all-lines operation in krypton does not produce the power that might be expected judging from single-line output.

Argon and krypton can be mixed together in the same laser tube to produce a laser offering a dazzling variety of visible wavelengths. A compromise must be reached in the parameters such as fill pressure and magnetic field that allows for the differences in the optimization for each type of laser. Such a mixed-gas laser using broadband mirror coatings has even been used to produce a *white-light* laser, but the argon–krypton mixture becomes unbalanced fairly quickly due to the difference in gas sputtering rates, and the white-light balance is lost as the component wavelengths change in relative strength of output.

11.5.2 Plasma Tube Design

The heart of the ion laser is the plasma tube, which amplifies laser wavelengths available from a low-pressure noble gas by confining a high-current discharge within a narrow bore. The demands placed on the tube structure are extreme, resulting from the need to confine and sustain a discharge as high as 70 A for hours at a time. The bore of the tube must withstand the bombardment of high-energy ions (sputtering) and the heat from the discharge, which can exceed 50 kW under some operating conditions. This heat must be efficiently removed from the tube or tube components will melt or rupture.

Early tube designs relied on cylinders of the ceramic beryllia, or BeO, about 1–2 cm in diameter with a centrally drilled hole of about 1 mm to form the bore. Beryllia cylinders about 10 to 15 cm long are still in use today in lower-power ion lasers, particularly for air-cooled argon. Figure 11.151 shows a cross section of an air-cooled plasma tube. However beryllia proved incapable of sufficiently withstanding the sputtering from the plasmas of high-power or ultraviolet ion lasers, and alternative designs were sought.

Years of intensive research and development have resulted in sophisticated designs for high-current tubes that replace beryllia with a tube structured of composite materials [11.1622, 1625]. These complex (and more expensive) designs can withstand high current densities for an extended period, thus making practical the operation of ion lasers at higher powers or less-efficient wavelengths. The description that follows is based on the segmented-bore technology used by Spectra-Physics in the manufacture of its water-cooled ion lasers. The overall design is illustrated in Fig. 11.152.

The exterior of the plasma tube is a long, hollow thin-walled ceramic pipe or sleeve a few centimeters in diameter. Inside this sleeve, spaced about one centimeter apart, are many thin discs brazed to the interior of the ceramic. The discs are copper with a central tungsten ring with a hole a few millimeters in diameter. The bore of the plasma tube is defined by the diameter of the hole in the tungsten segments (Fig. 11.153).

The tungsten bore segments are extremely resistant to sputtering action and can withstand the high temperatures of the discharge. The copper discs to which they are bonded conduct the heat of the discharge from the tungsten to the thin ceramic wall of the exterior sleeve, which is bathed outside by a cooling water flow of several liters per minute. The flow of this cooling water is designed to prevent local thermal stresses affecting the tube.

The plasma tube must ensure uniform gas pressure along the length of the bore. In arc discharges in low-pressure gases, the ions lose their momentum in frequent collisions with the tube walls. In contrast, the electrons lose little momentum, so an imbalance is created in the net momentum in the gas. As a result, the neutral gas atoms are driven to the anode end of the plasma tube. To equalize the gas pressure along the length of the tube, holes in the copper discs provide a return path to the cathode end, which also allows the copper discs to help cool the gas in the return flow.

The design of the bore where it opens to the cathode, the so-called *throat* region, is critically important to achieve good laser lifetime. Damage to the bore from sputtering is maximum in the throat. The diameter of

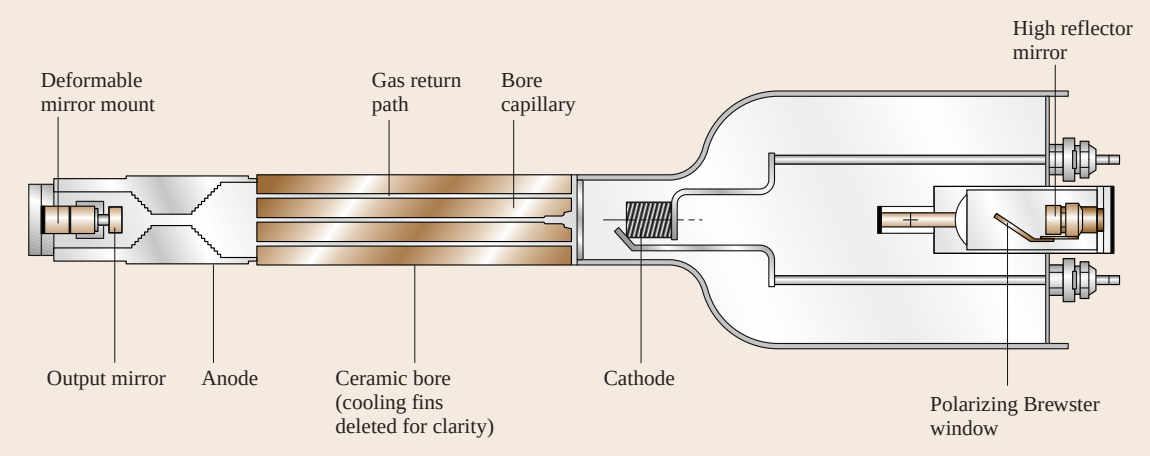

Fig. 11.151 Design of an air-cooled plasma tube

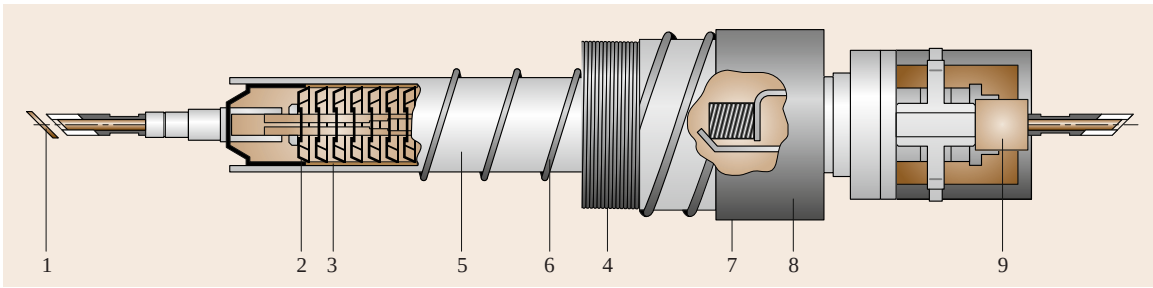

Fig. 11.152 Design of a water-cooled plasma tube

the bore segments (or, in lower-power tubes, the conically shaped opening drilled in the beryllia to form the throat) is tapered to match the contour of the electrical field as it enters the bore.

The design of the cathode element itself is also critical. The cathode is helical and is made from a spongy material formed of tungsten powder. It may also include some admixture of calcium, aluminum, barium, and strontium. These additives reduce the work function of the cathode surface so that the temperature needed to produce electron emission is reduced [11.1625].

The efficiency of laser amplification is a function of the gas pressure in the discharge. However ionic sputtering not only erodes the tube materials, but also over time embeds a significant amount of gas in the tube walls and components. Low-power lasers compensate for this effect by widening the body of the plasma tube to form a reservoir, so that the gas lost from sputtering action is a small fraction of the total volume in the tube. Mid- and high-power designs incorporate an active fill system to replenish the gas as it is lost.

To determine when the gas must be replenished, a microprocessor compares the operating voltage of the laser to values stored in a look-up table, taking into account the current, magnetic field and warm-up time. When the voltage indicates that the tube pressure is low, a high-pressure reservoir automatically injects a small quantity of gas into a plenum. A separate valve then opens to allow the plenum to add a precise quantity of gas to the plasma tube. Since this fill process briefly disturbs laser operation, the fill system may be manually disabled for short periods to ensure that critical experiments are not effected.

For air-cooled lasers, which do not employ a magnetic field, copper cooling fins are brazed onto the exterior of the beryllia cylinder that forms the plasma tube. Cooling air is forced over the fins at a rate of a few hundred cubic feet per minute (about 10 m^3/min). Care must be taken that heat removal is evenly distributed so that the tube does not warp and move the laser beam (the laser output mirror is attached directly to the tube), and the air flow should not induce vibrations in the fins which might translate into motion of the beam.

For larger lasers, the entire plasma tube is encased in a large electromagnet which also forms the confining wall for the water flowing next to the tube. The field chosen for the magnet depends on the diameter of the bore and the details of how the laser is operated, but is usually in the neighborhood of 1000 G. The magnetic field is particularly important for ultraviolet output, which requires stronger magnetic fields for optimum performance.

The ends of the plasma tube are sealed with optics that allow the laser light to exit the tube. These optics are either laser mirrors with dielectric coatings, used in essentially all low-power and some mid-power lasers, or quartz windows oriented at Brewster's angle. Tubes are constructed with Brewster windows to polarize their output, generally oriented vertically. Mirror-sealed tubes will have an internal optic to achieve polarization.

The light emitted from the discharge of high-current tubes poses a challenge for optics. The transitions from the lower laser levels back to the ground state of neu-

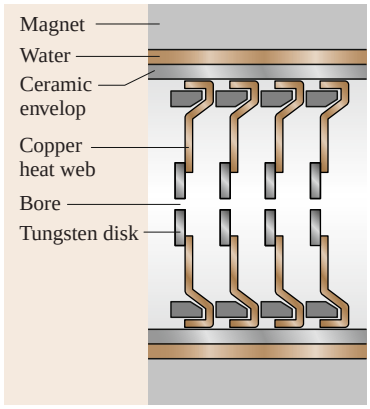

Fig. 11.153 Segmented bore design

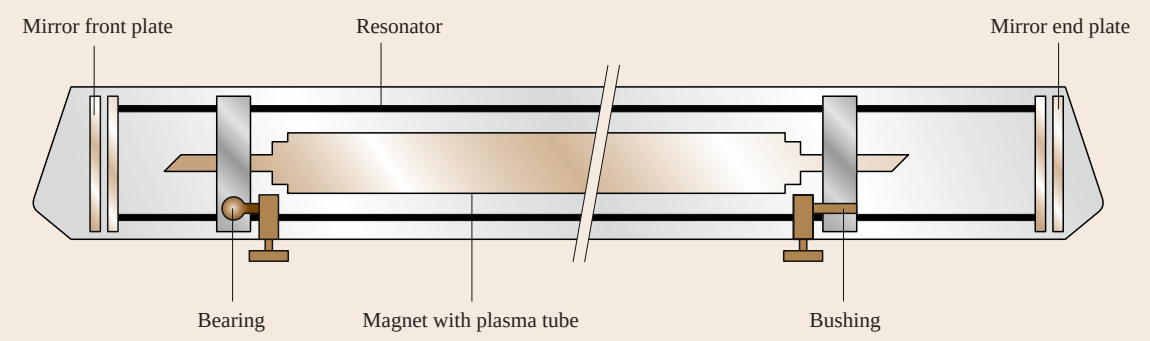

Fig. 11.154 Open resonator design

tral argon shown in Fig. 11.150 emits a highly energetic photon around 80 nm. This vacuum UV radiation is very deleterious to optical materials. The coatings on the mirrors that seal low-power and some mid-power tubes are made of many alternating layers of dielectric materials, such as silica and alumina, that are capable of withstanding this radiation. Brewster windows used to seal mid-power lasers are typically made of fused silica.

The levels of the vacuum ultraviolet of high-current discharges present a greater problem for the Brewster window seals of these tubes [11.1626, 1627]. Fused silica cannot be used because, when exposed to these radiation levels, it forms color-center defects which then absorb even more radiation in a runaway effect that will degrade laser action. To meet the challenge of sealing high-current plasma tubes, manufacturers use crystalline quartz, carefully cut and oriented on the tube so that the crystalline axis of the two windows on each end of the tube are in alignment.

11.5.3 Ion-Laser Resonators

To complete the ion-laser structure, the plasma tube must be placed between suitable mirrors that provide light feedback for amplification by the discharge. These mirrors are a high reflector at one end of the laser, and a partial transmitter or output coupler that allows a portion of the circulating light to exit the laser. These mirrors, together with the structure that holds them in position, form the laser resonator [11.1628]. For small ion lasers and some mid-frame systems, this resonator structure is very simple: the mirrors are bonded onto the plasma tube itself.

Air-cooled ion lasers sacrifice flexibility for simplicity. Except for the power level, their output characteristics cannot be changed. A mirror position is fixed at manufacture by the plastic deformation of the thin metal tube to which the mirror is bonded. The output wavelength, mode structure of the beam, and so on remain fixed. For many applications this is acceptable, even desirable, but other applications benefit greatly by retaining the flexibility of output that is a hallmark of the ion laser.

The external or open resonator commonly employed with mid- and large-frame systems retains this flexibility. This design requires the use of Brewster-window seals for the plasma tube, as discussed in the preceding section. The resonator mirrors are held in place by a rigid structure that frames the plasma tube (hence the use of *mid-frame* or *large frame* as an indication of laser size). While it outwardly appears simple, the design of the resonator is critical to the performance of the laser.

The resonator frame, as shown in Fig. 11.154, must keep the mirrors aligned to each other and pointing through the laser bore within a very tight tolerance over the entire range of operating and environmental conditions. The choice of materials affects the stability of the resonator. The ideal material has both a low thermal expansion coefficient and a high ability to distribute heat evenly. Graphite and low-expansion compounds such as iron-nickel alloys are typically used for the long rods that form the length of the frame.

Stability also depends on the rigidity of the resonator. Jitter impressed on the laser output due to the microphonic movement of the mirrors can be caused by cooling-water flow, vibration of the resonator structure, and acoustic noise. Isolation of the resonator from both the plasma tube, the magnet, and the cover of the laser head helps reduce jitter.

The mechanical design of the structure is also critical to stability. The most stable configuration is an arrangement of three resonator rods in an equilateral triangle. As a practical matter, this ideal structure does not leave sufficient room for the plasma tube and magnet.

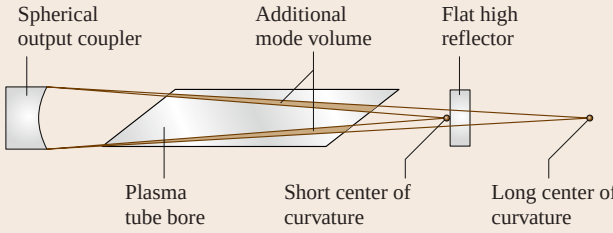

Fig. 11.155 Active mirror positioning allows resonators to extract more power from the discharge

As one of the angles of the resonator triangle increases, the resistance to flexure is reduced. The closer the design can be to the ideal equilateral triangle, the better will be the mechanical stability provided for stable power and beam pointing [11.1629].

A significant advantage that modern large-frame lasers have over their forerunners is the use of active mirror positioning. The output coupler is mounted on three-point piezoelectric positioner that provides small corrections to the mirror alignment in response to changes in laser output power, most commonly experienced when the laser is warming up. This active resonator also allows for a more aggressive optical design to extract power from the plasma tube.

With active mirror positioning, the cross-sectional area of the beam, and therefore the volume of the plasma discharge used to provide laser amplification, can be increased by enlarging the bore and using a longer-radius output coupler (Fig. 11.155). This is especially beneficial for wavelengths with lower gain. However active control alone cannot provide all of the stability required by this design: the use of long-radius optics requires an extremely rigid resonator structure.

The open resonator allows the user to employ different mirrors to obtain different wavelength output. To obtain *all-lines* argon-ion output in the visible, for example, mirrors are used with coatings that reflect over about 70 nm in the blue and green. A prism on a rotatable mount placed before the high reflector allows the laser to be tuned to single-line output throughout the all-lines range. (The dispersion of the prism directs only one wavelength at a time to the high reflector.) A similar arrangement using different optics enables the same operation for all-lines ultraviolet output.

The open resonator also allows the spatial mode of the beam to be controlled. An adjustable aperture placed between the Brewster window and the output coupler, where the beam is large, provides a variable amount of loss to the edges of the beam while it is inside the

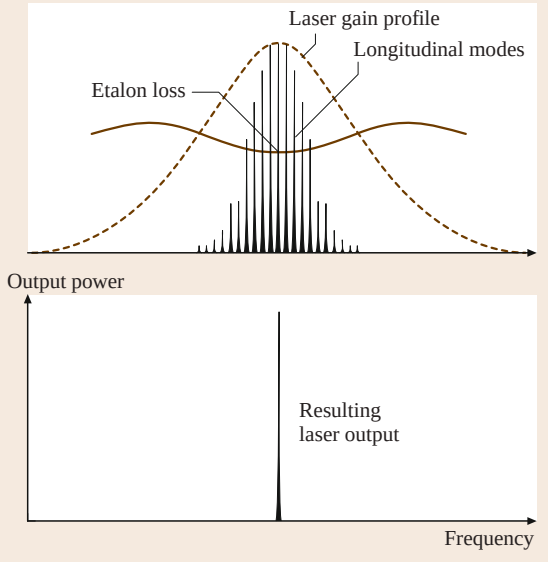

Fig. 11.156 Using an etalon to narrow the spectrum of the laser output

resonator. The aperture, when opened to allow the highest power output, will permit a number of transverse modes, or if reduced will result in TEM_{00} mode operation. An aperture diameter between 1.5 and 2 times the TEM_{00} mode diameter is used to achieve this [11.1630].

The spectral content of the laser output may also be changed by insertion of an etalon into the laser resonator. An etalon is a thin optical cavity, such as a plate of glass. When inserted into the resonator, the internal reflections from its surfaces act to narrow the frequency content of the laser output, its *line width*. The resonator produces standing waves of light between its mirrors, called longitudinal modes, many of which have frequencies that fall within the bandwidth of the laser amplifier. The etalon acts as a bandpass filter that introduces variable loss and favors oscillation on only one of the longitudinal modes (Fig. 11.156).

Active mirror positioning may also be used to stabilize the line width further, resulting in an even narrower spectral output. The coherence length – the distance over which the output beam maintains a fixed phase relationship – is inversely proportional to the line width. When the laser output is changed from single line to single frequency, the coherence length increases from about 50 mm to 20 m.

A drawback of the open resonator is that the space between the mirrors and the Brewster windows is not

vacuum-sealed. Laser performance strongly depends on keeping these optical surfaces clean. In addition, the vacuum UV light from the arc discharge, transmitted by the Brewster windows, converts oxygen to ozone, which is deleterious to the laser optics. This intracavity space must be sealed and its atmosphere controlled to maintain cleanliness and avoid optical damage. Lasers producing short-wavelength UV may employ a nitrogen purge to avoid ozone production. Longer-wavelength lasers can use a simpler technique of placing a catalyst in the enclosed space that converts ozone back into oxygen.

11.5.4 Electronics

A variety of electronic subsystems are required to operate an ion laser, as shown in the block diagram of a large-frame system in Fig. 11.157. Typically packaged in the laser head along with the plasma tube are the start circuit and the light pick-off. Lasers that are not sold as OEM components for a larger system are required to have an interlock switch that will reliably terminate laser operation if the head cover is opened. For water-cooled lasers, the laser head will usually also contain the flow- and temperature-control circuits for the cooling water, and the fill circuitry to monitor and replenish the gas in the plasma tube.

The start circuit provides a high-voltage spark to initiate the discharge. Typically, a pulse of several kV is injected in series with the tube by a pulse transformer or a spark-gap circuit. The light pick-off is the sensor for the feedback loop that measures and regulates the laser output power, and usually consists of a beam splitter with a silicon photodetector. Since an ion laser may be capable of producing a wide spectrum of wavelengths over a considerable range of powers, multiple preamplifier ranges are usually used in the feedback loop, as well as wavelength sensitivity correction color filters or electronic gain modification.

The power supply that drives the plasma tube is almost always packaged as a separate unit. This is because the supply itself is roughly the same volume as the laser head, and separating it from the laser allows much greater flexibility in positioning the laser system. The drive current for the plasma tube is delivered to the laser head through a robust umbilical. Since the power supply also serves as the control interface for the laser, cables that carry monitoring and control signals are typically bundled in the umbilical as well.

Ion-laser power supplies show the same range of variation in size and design as the laser heads. The power supplies of small air-cooled argon units can be as

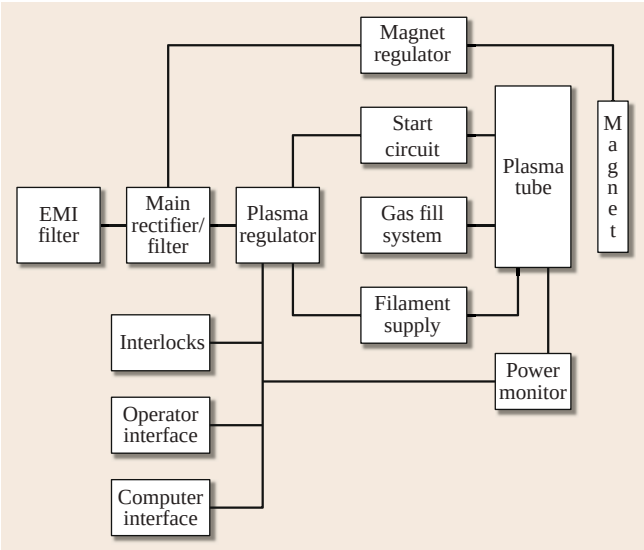

Fig. 11.157 Block diagram of a large-frame ion-laser system

small about 15 cm on a side, while supplies that drive large-frame systems are roughly 0.7 m on a side and weigh almost 100 kg. These larger units may require cooling water. Table 11.44 displays typical service requirements and loads for the three main classes of ion lasers.

The electrical characteristics of the arc discharge are such that it essentially requires a constant-current supply in order to be sustained [11.1628]. The heart of an ion-laser power supply is the plasma current regulator. The plasma current needs to be well regulated in order to prevent line ripple and other variations from being impressed on the laser output. The plasma current may be regulated by a linear transistor passbank, or more efficiently by various switching-type power supplies.

In the patented regulator used by Spectra-Physics, a switched resistor regulator consisting of a pulse-width modulator (PWM) controlling a switch transistor is connected to a low-impedance high-power water-cooled resistor. This resistor is connected to the plasma load. The PWM varies the percent of the time that the transistor is turned on and the resistor is conducting current. A parallel capacitor provides a current path to the load when the transistor is off. This regulator looks like a variable resistor that can vary from infinity down to the minimum resistance of the circuit. A shunt regulator is used to provide ripple rejection and high-speed small-signal regulation.

The power supply must power the electromagnet when an axial magnetic field is employed. The electro-

magnet requires about 10–25% of the power supplied to the arc discharge. Thus a large-frame supply is really two supplies: a 36 kW plasma supply and a regulated 8 kW magnet supply. The power supply must also provide power to heat the tungsten cathode in the plasma tube. Typically a filament transformer provides 15–25 A at about 4 V_{AC} for this purpose.

11.5.5 Ion-Laser Applications

The operator interface to control power and the basic on/off function is through the power supply. In inexpensive models of air-cooled systems, the control interface typically consists of hand-wired knobs and switches on the front panel of the supply. The next step in sophis-

Table 11.44 Power supply characteristics of typical ion-laser systems

Ion-laser type	Maximum laser power	Electrical input	Plasma discharge	Discharge power requirement
Air-cooled	20 mW	115 V_{AC} single phase	90 V 8 A	0.7 kW
Small frame	5 W	208 V_{AC} three phase	240 V 55 A	13 kW
Large frame	25 W	480 V_{AC} three phase	550 V 65 A	36 kW

tication is a hand-held system controller with a visual display that attaches to the power supply with a long flexible cable. Upon turn-on, all functions of the laser can be accessed from the system controller. High-end models offer a fully functioning computer interface for automated remote operation and monitoring of the laser.

Ion lasers operate in either current mode or power mode (also called light mode). Current mode holds the plasma discharge current at a fixed value and allows the laser output to vary. Power mode, a much more common method of operating the laser, adjusts the plasma current as necessary to match the output power to a user-requested value. When the current can no longer be increased to achieve the power set-point, it may be time to replace the plasma tube.

Like many modern laser systems, most ion lasers are designed for hands-free operation. Air-cooled argon systems in particular are intended to provide a constant laser source available from a simple flip of a switch. Large-frame systems in laboratory applications in contrast trade on the flexibility they provide the user.

Small air-cooled systems continue to be economical and reliable sources of coherent, polarized. TEM_{00} blue–green laser light. They are usually operated at a power significantly derated from their maximum, which can extend their useful lifetime for years. Biological and medical applications for these lasers include cell sorting. Desoxyribonucleic acid (DNA) sequencing, bacterial analysis, confocal microscopy, and hematology. Many of the dyes used in these applications were originally developed for argon-laser wavelengths.

These lasers are also used in many applications related to producing text and images. The blue beam is valuable for exposing printing plates for high-speed printing, and to provide the color separation required for full-color printing. Similar applications are found in photoprocessing and other photographic sources.

Mid-frame systems are used in many of the same applications as lower-power lasers. In addition, they are used in entertainment, especially for laser light shows, and have laboratory applications in Raman spectroscopy or as a pump sources for tunable laser systems such as a Ti:sapphire. In ophthalmology, the beam can be focused on the retina to repair diabetes – induced retinal detachment, for instance.

The deep-blue and UV outputs of ion lasers have been used in the semiconductor industry for wafer inspection and lithography. The ability of the output to expose photoresist is also used in producing masters for compact discs, which then serve as the molds in the injection-molding manufacture of high-volume CD production.

11.6 The HeNe Laser

The HeNe laser is an electrically pumped continuously emitting gas laser. Its basic principle is a gas discharge in a glass tube filled with a mixture of helium and neon under low pressure. The gas discharge is set up by a cathode and an anode placed at opposite sides of the glass tube. The laser mirrors are usually fixed to the end of the tubes.

The HeNe laser was one of the first lasers to be realized. It was developed in 1960 as the first laser emitting light continuously [11.1631]. However, this was not the well-known bright red line (632.8 nm) that has been discovered, the first laser emitted light at 1.15 μm, which is one of the strongest lines of the HeNe laser. Red laser emission was achieved shortly after, in 1962 [11.1632]. Though other possible transitions delivering light in the visible had been found theoretically, it took a certain time to demonstrate this practically. Improvements in resonator design and the performance of the mirrors had to be achieved. Especially the well-known 543.3 nm line, with its low gain, needed several attempts by researchers until it was demonstrated for the first time in 1970 [11.1633].

Shortly after its first demonstration, the HeNe laser found more and more applications and became the most common laser worldwide with millions of units sold, until laser diodes appeared on the market. More than

40 years after its first appearance the HeNe laser is still of great importance in the worldwide laser market. Around 44 000 units were sold in 2005 [11.1634].

The HeNe laser has been used for adjusting and positioning but also, because of its excellent optical properties, in interferometers, sensors or spectrometers. It was applied in the first scanner tills and even the first CD players were equipped with HeNe lasers. Although these applications have been taken over completely by diode lasers, HeNe lasers still find their use in many fields of analytics, instrumentation, sensor technology, science and education.

Its advantages are excellent beam quality, long lifetime and an unbeatable price–performance ratio. Because of the mature technology and the still large sales numbers manufacturing costs have decreased continuously. Against the trend for shorter product lifetime the HeNe laser has asserted itself for 40 years and is still a competitive product. Many OEM manufactures still choose the HeNe laser for there new products, irrespective of the competition from diode lasers and solid-state lasers. Considering especially the laser diodes we see that, in fact, the diode itself is a rather cheap component. To achieve a beam quality comparable to the HeNe laser, however, requires considerable effort and additional cost, which compensates for the higher costs of a HeNe laser. For example, the strongly elliptical beam of the diode has to be made circular and, in order to avoid wavelength drift, temperature stabilization has to be provided. Another advantage is the longer coherence length of a HeNe laser compared to that of standard diodes.

Further advantages of the HeNe laser are:

- Excellent mode purity, typical $> 95\%$ Gaussian TEM_{00}
- A favorable relation between resonator length and resonator width (diameter)
- A nearly diffraction-limited beam
- High beam-pointing stability
- High reproducibility in manufacturing.

11.6.1 The Active Medium

Energy-Level Diagram

The most detailed energy-level diagram which we could find in the literature is given in [11.1635] (Fig. 11.158). Nowadays, however, the green and yellow laser lines are of much more importance than the infrared ones, so it was necessary to add these new visible lines to the diagram. It can be seen that neutral helium is excited by electron collisions and transfers its energy by nearly resonant inelastic atomic collisions to the excited states of neon. This means that the lasing atom is the neon, helium is only necessary for energy transfer from the gas discharge to the upper neon levels. The energy transfer from the lower laser levels 3p and 2p ends at the 1s level due to spontaneous emission and the 1s level is depopulated by wall collisions to the ground state of neon. For this reason it is necessary to have a small-diameter discharge tube, in order to secure a quick emptying of the 1s level. It should be mentioned that the rare ^{3}He isotope is used and not ^{4}He. The reason is that the lighter ^{3}He isotope has a higher velocity difference to neon, resulting in better energy transfer to the upper laser levels [11.1636] and consequently a higher gain and output power (about 25% better at 633 nm).

It is known that electron collisions and stimulated absorption of visible light can cause transitions from the 1s to the 2p level, resulting in a higher lifetime of this lower laser level (2p). This leads to a higher inversion for the 3.39 μm laser line as for the other lines, since it has the 3p level as the lower laser level.

Table 11.45 lists the commercially available laser lines and some typical parameters. The gain [11.1635, 1637] depends strongly on the inversion and the noted values should only give an impression of how the gain changes with wavelength ($g_0 \propto \nu_0^{-3}$). This illustrates that the most difficult laser to build is the green one (543.3 nm).

Another difficulty in making a green laser is that, within each group of energy levels (2s, 3s, 2p, 3p, and so on), the energy distribution of the sublevels (e.g., $2p_1$ to $2p_{10}$) is determined by thermic Ne–Ne collisions, resulting in a Boltzmann distribution, which means that the population rises with falling energy. Thus, the lower laser level for the 543.3 nm line ($2p_{10}$) has a much

Table 11.45 Typical laser transitions

Wavelength (in air) (nm)	Transition	Gain (m^{-1})	Typical power (mW)
543.3	$3s_2$–$2p_{10}$	0.03	0.5–3.0
594.1	$3s_2$–$2p_8$		2.0
611.8	$3s_2$–$2p_6$	0.1	2.0
632.8	$3s_2$–$2p_4$	0.5	0.5–50
640.2	$3s_2$–$2p_2$		
1152.3	$2s_2$–$2p_4$		2.0
1523.1	$2s_2$–$2p_1$	4	1
3391.3	$3s_2$–$3p_4$	100	10

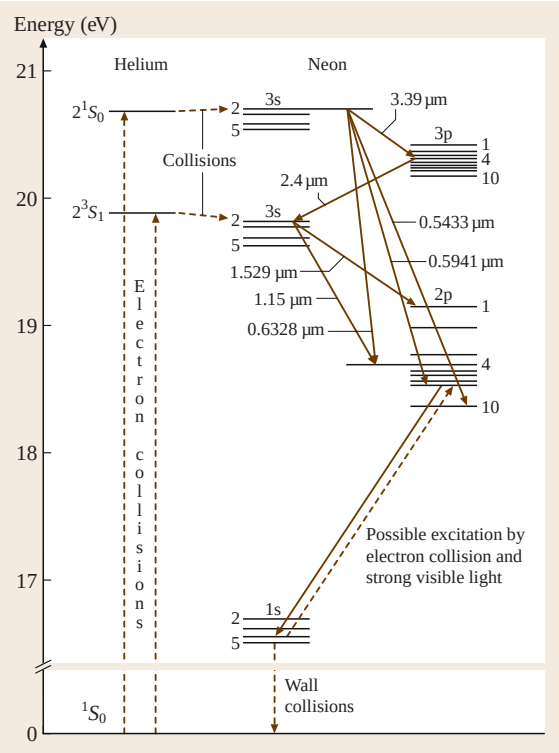

Fig. 11.158 Energy-level diagram of the HeNe laser

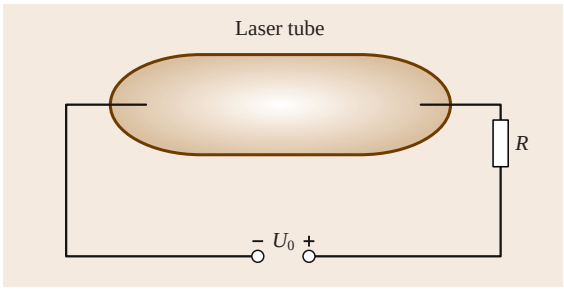

Fig. 11.159 Electrical scheme of the laser

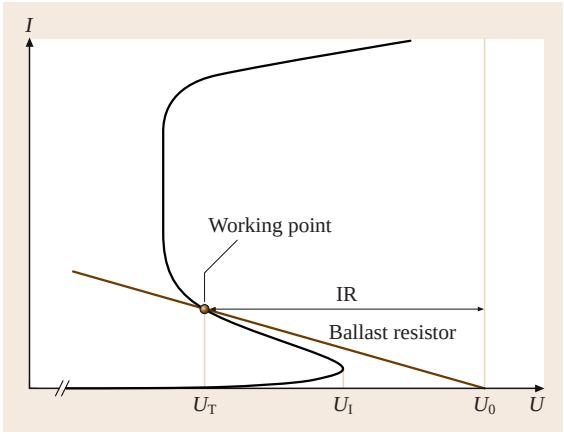

Fig. 11.160 Characteristic voltage–current curve of a HeNe laser

higher population as the $2p_4$ level for the red line. In order to achieve population inversion for this laser line it is necessary to reduce the number of Ne–Ne collisions by reducing the neon pressure. The consequence is a lower output power at this line and a lower lifetime for green lasers (about 10 000 h) compared to red lasers (> 20 000 h).

Table 11.45 lists only the most important laser lines. A good compilation of laser lines at different elements is given in [11.229], which also contains references to the original literature. Sometimes in an experiment one may have unwanted light from scattering from the discharge tube itself (not laser light). Such discharge lines can be found in [11.1638].

Gas Discharge

The gas discharge is the most important process in the laser, since it has to transform the electrical energy of the power supply into the laser light. This process determines the laser power, power stability, optical noise and lifetime of the laser. Hence, the key know-how of a laser manufacturer is not the resonator design but how to optimize the discharge.

As shown in Fig. 11.159 the HeNe laser tube is filled with a helium–neon gas mixture, having a total pressure of about 4–7 mbar and a neon content of about 10%. The operating DC current is in the range of 3.5–11 mA and the corresponding tube voltage is about 1–5 kV. This is a cold-cathode glow discharge, where the active laser medium is formed by the positive column of the discharge, which is located in a capillary of diameters of 0.5–2 mm. Since such a glow discharge has a decreasing voltage–current characteristic curve (Fig. 11.160), a ballast resistor R of about 60–100 kΩ is used to bring the whole system to an increasing voltage–current curve.

In Fig. 11.160 the black curve shows the electrical behavior of the discharge tube and the brown line the corresponding ballast resistor. After switching on the laser, the power supply has to raise voltage to the ignition point ($U_I \approx 10$ kV). After the ignition, the power supply switches to its normal fixed-current operating mode. The corresponding voltage is determined by the crossing point of the discharge curve and the resistor

line (voltage at the tube U_T). It is important to choose the resistor in such a way that only one crossing point exists.

Whereas in the tube design a small metal anode is used, the cathode is considerably larger, and is mostly made of aluminium because the cathode has to deliver the electrons for the discharge and to transfer the heat of the cathode fall, the region where the electrons are accelerated from zero to the colliding velocity, outside the laser tube. The capability of the cathode to emit electrons depends on the properties of the cathode surface. Normally the current density at the cathode surface is constant, so the cathode surface must be large enough for the applied operating current, otherwise sputtering occurs and the tube is quickly damaged. The typical cathode size is in the range of some 10 cm^2. In order to avoid sputtering, at the surface a nanometer-scale layer of Al_2O_3 is formed. Normally this oxide layer withstands sputtering for some 10 000 h. If this layer is destroyed, the laser fails within a few hundred hours.

11.6.2 Construction and Design Principles

Construction of a HeNe Laser

Figure 11.161 shows a cross-sectional view of a modern HeNe laser. The principal setup is very similar for all major manufactures of HeNe lasers and differs in details only. The laser tube consists of a glass tube (8) which is melted at both ends to metal end caps (3, 10). To these end caps the laser mirrors (1, 12) are connected using a metal–glass soldering technique. These metal–glass connections provide long-term vacuum sealing of the laser tube. Inside the laser tube the cathode (6) and the gas discharge capillary (7) are located. The glass of the capillary is melted to the glass of the outer tube (8), so the discharge is concentrated inside this capillary. If the mirror (1) is a flat mirror and mirror (12) is concave, the end of the capillary (9) acts as a mode field aperture. If linear polarized laser radiation is required, a Brewster window (2) is placed inside the laser. A favorable position for this window is near the flat mirror, because at this position the beam diameter is the smallest in the tube and there is no angular displacement between the laser beam and the window (the beam is always perpendicular to the mirror surface). The tube is evacuated and filled using the pipe (4), which is sealed after filling the tube by means of a cold soldering process. The spring (13) centers the capillary end. At the mirror holders (3, 10) a region of reduced material thickness is formed (5, 11). This is used for the alignment of the mirrors by means of plastic deformation of the metal.

The setup according to Fig. 11.161 represents the basic design of commercial laser tubes up to about 25 mW output power which has been used for about three decades with minor changes only. It provides long-term gas stability, clean optics over the whole lifetime of the laser and a long lifetime of the laser.

In contrast to the present design, early HeNe lasers were not sealed by the mirrors but by a Brewster window at each end. Thus, they used an external resonator, mostly made of mirrors hold on invar rods. This older design is used today only in high-power HeNe lasers (> 35 mW), because such lasers need a very long cavity (> 1 m). Here, the external resonator allows a better stability of the mirror alignment, and the capillary (which suffers from bending due to their own weight) can be aligned too (Figs. 11.162, 11.163).

Resonator Design

The design goal of a HeNe resonator is mainly to achieve a Gaussian beam profile. The calculation of all beam parameters can be easily done by means of the *ABCD* matrix formalism [11.1639]. In this case, every optical element in the laser is described by a matrix, as described below.

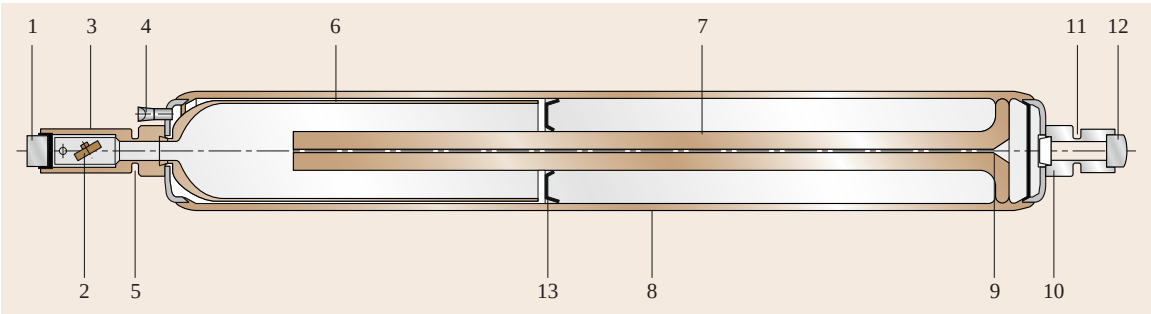

Fig. 11.161 Sectional view of a HeNe laser tube (LASOS Lasertechnik GmbH), see text for explanation

The matrix of a mirror with curvature r

$$M = \begin{pmatrix} 1 & 0 \\ -2/r & 1 \end{pmatrix} . \tag{11.142}$$

The matrix for the free-space propagation of distance s

$$S = \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix} . \tag{11.143}$$

Starting at the output mirror all single matrices for every element are multiplied for one complete round-trip (RT), resulting in the following calculation:

$$\mathrm{RT} = S\, M_2\, S\, M_1 = \begin{pmatrix} A & B \\ C & D \end{pmatrix} . \tag{11.144}$$

In a last step, the $1/\mathrm{e}^2$ beam radius (w) and the wave-front curvature (R) are calculated from this matrix:

The beam radius at the output mirror is

$$w = \sqrt{\frac{\lambda}{\pi} \frac{2|B|}{\sqrt{4-(A+D)^2}}} . \tag{11.145}$$

The wave-front curvature at the output mirror is

$$R = \frac{2B}{D-A} . \tag{11.146}$$

Using the well-known formalism for Gaussian beam propagation, the beam diameter can be calculated at any desired position.

The complex parameter q is defined as:

$$\frac{1}{q} = \frac{1}{R} - \mathrm{i}\frac{\lambda}{\pi w^2} . \tag{11.147}$$

The propagation of a Gaussian beam through an optical system described by the $ABCD$ matrix yields

$$q_{\mathrm{out}} = \frac{Aq_{\mathrm{in}} + B}{Cq_{\mathrm{in}} + D} . \tag{11.148}$$

The beam diameter at the position of the mode field aperture is important for the laser design (Fig. 11.164). The ratio between this aperture and the beam diameter has to be chosen in such a wa, that the losses for the TEM_{00} mode are low but high enough for the first higher-order transversal modes, e.g., TEM_{01}, in order to suppress the higher modes. This ratio depends on the laser gain and can be calculated theoretically. The practical experience for a common 633 nm laser leads to a ratio between the aperture diameter and beam radius of about 3.5 : 1. For high-power HeNe lasers, this value must be reduced, whereas for the low-gain 543 nm laser it has to be increased.

Fig. 11.162 Laser tube with fixed mirrors (LASOS Lasertechnik GmbH)

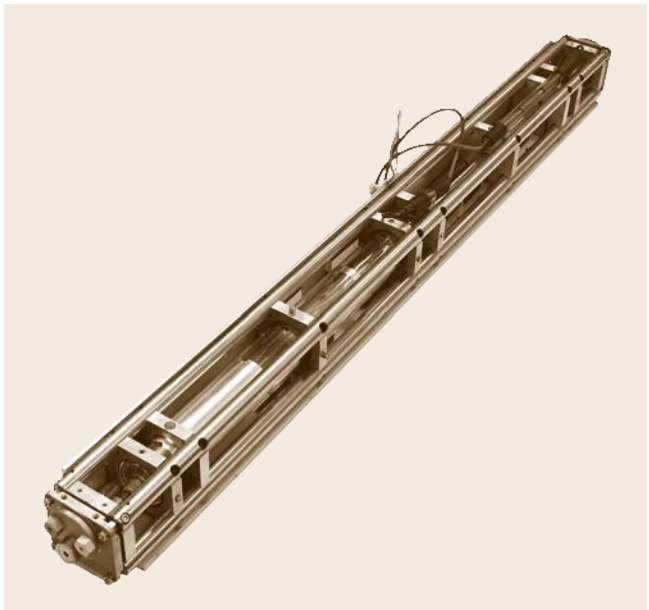

Fig. 11.163 35 mW laser tube with external resonator (LASOS Lasertechnik GmbH)

In practical designs the above formalism is used to balance the resonator design between the beam diameter, required by the application (the beam waist is normally located at the surface of the output mirror), and the laser power, which determines the laser length on one hand, and the available mirror curvatures as well the available aperture diameters and aperture positions on the other.

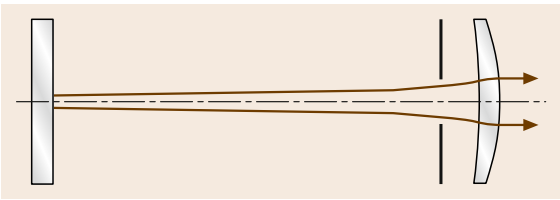

Fig. 11.164 Principle setup of a HeNe resonator with rear and output mirror and a mode-field aperture

Scaling Relations

Scaling relations are very useful for the practical design of new lasers. The most important scaling relations are described below. Firstly, the laser power P, which is proportional to the discharge length l (capillary)

$$\frac{P}{l} = \text{const.} \tag{11.149}$$

For this reason, today HeNe lasers with a power above 25 mW are very rare. These lasers are very long (> 1 m) and need sensitive and expensive external resonators. Thus, in this power region the costs for beam shaping of laser diodes (aspheric lens systems with prisms, cylindrical lenses and/or zoom telescopes) are comparable or lower than for a HeNe laser and the mechanical dimensions of the diode-lasers systems are much smaller (about 15 cm).

The product of the pressure p and capillary diameter d is constant

$$pd = \text{const.} \tag{11.150}$$

Following this equation, two systems with the same pd product have comparable discharge properties and the excitation of the upper laser levels is comparable in both cases if the same current is applied. This rule is very useful if a well-running laser must be customized in order to get more power or different beam diameter. If the new capillary diameter has been estimated using the formalism of Sect. 11.6.2 then the corresponding gas pressure for this new design can be calculated by means of (11.150).

The current–density scaling relation is less important because there is only a weak dependence on capillary diameter

$$j\sqrt[4]{d} = \text{const.} \tag{11.151}$$

The scaling of the small signal gain g_0 with capillary diameter d

$$g_0 d = \text{const.} \tag{11.152}$$

Equation (11.152) shows that a small capillary diameter d should be achieved in the design process because, with higher gain, losses can be higher too and it is possible to come closer to the theoretical maximum power.

Additionally two electrical relations [11.1640] should be noted: the current density j_K at the cathode

$$\frac{j_K}{p^2} = \text{const.} \tag{11.153}$$

and the ignition voltage U_I

$$U_I = f\left(\frac{pl}{T}\right) . \tag{11.154}$$

Equation (11.153) has the consequence that low-pressure laser tubes, like versions for 543 nm, need larger cathodes. Equation (11.154) shows that the voltage necessary to ignite the laser increases with pressure and length and decreases with temperature T.

Laser Line Selection

Today, the HeNe laser has been replaced in the infrared range by laser diodes, but its visible lines, especially those at 632.8, 594.1 and 543.3 nm, are widely used in scientific applications such as laser scanning microscopy. Because of this fact, we will only consider the visible range. Except for some educational lasers, all modern HeNe lasers operate at one wavelength only. The reason is that it is only possible by this approach to obtain the maximum power of each laser line and to reduce the optical noise. The operating wavelength is selected from the possible lasing lines by means of the laser mirrors. In the most common design the rear mirror has as high as possible a reflectivity ($> 99.9\%$) for the desired wavelength, and the output coupler will have ≈ 1–2% transmission at this line and $> 10\%$ at the other lines. So, the unwanted laser lines have losses greater than their gain and will not be amplified. Because of the low gain of the 543.3 nm line, lasers for this wavelength must have output mirrors with transmissions of about 0.05–0.15% (Fig. 11.165).

3.39 µm Suppression

From Table 11.45 it can be seen that the 3.39 µm line must be suppressed very carefully, because it has a gain that is some orders of magnitude higher than all visible lines. Insufficient suppression of this line causes power loss and power fluctuations at the desired lines. Therefore, both laser mirrors must have a reflectivity for this line below 0.5%. Another approach for the 3.39 µm suppression is to use the Zeeman effect. Applying an

inhomogeneous transversal magnetic field to the laser splits the laser levels into the Zeeman sublevels. The gain of the sublevels is the gain of the unsplit level divided by the number of sublevels, so the gain may fall below the losses and this line is suppressed. The frequency difference of the sublevels is the same for all laser lines. However, Doppler broadening of the laser lines depends on their frequencies.

The Doppler broadening of a laser line λ is given by

$$\partial\nu_{\mathrm{D}} = \frac{2}{\lambda}\sqrt{\frac{2kT\ln 2}{m}}\,, \qquad (11.155)$$

where k is Boltzmann's constant, T is the gas temperature and m is the mass of the Ne atom.

For visible wavelengths the frequency split caused by the Zeeman effect is lower than the Doppler-broadened line. Thus, the gain is not influenced by the Zeeman effect, whereas for the 3.39 µm line the Zeeman splitting is larger than the Doppler-broadened line and the gain decreases with the number of sublevels. This method is normally used in high-power 633 nm lasers (> 35 mW) or in the 543 nm laser.

Line Width and Coherence Length

The natural line width of a red HeNe laser is about 20 MHz [11.1636] but this line is broadened by two different processes. The first process is collision broadening, leading to a line width of about 500 MHz at typical pressures of 4–6 mbar [11.1636]. This line width is proportional to the gas pressure. The second process is Doppler broadening (11.155), which results in a width of 1–1.5 GHz for the visible laser lines.

A TEM_{00} laser usually runs at several longitudinal modes, which are spaced by

$$\Delta f = \frac{c}{2L}\,. \qquad (11.156)$$

Thus, the longer the resonator (mirror distance L), the more modes can oscillate simultaneously.

As can be seen in Fig. 11.166, the mode spacing is 257 MHz (seven modes) and the gain profile is about 1.5 GHz. A Lamb dip does not occur because the collision broadening is larger than the mode spacing [11.1636]. For interferometric purposes tubes that exhibit only one or two longitudinal modes are often used. The typical length of such a tube is about 140 mm with a power of 0.5–1.0 mW. Whereas the gain curve is fixed in frequency space, the longitudinal mode pattern shows a movement when the resonator length changes in the dimensions of the wavelength λ, which may result from small ambient-temperature

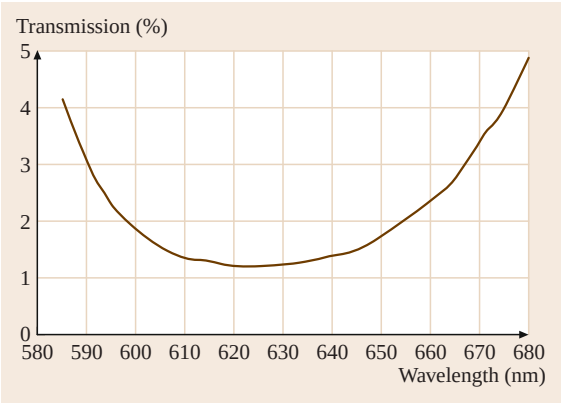

Fig. 11.165 Typical transmission curve of the output mirror for a 632.8 nm laser

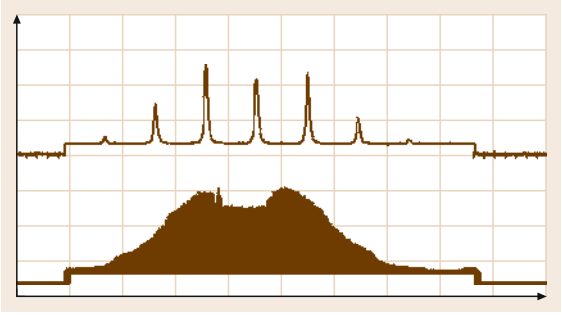

Fig. 11.166 Longitudinal modes (*upper curve*) and corresponding gain profile of a 584 mm-long 20 mW laser at 633 nm (LASOS: LGK 7665 P), measured with a scanning interferometer

fluctuations. Such a movement causes power fluctuations in the range of about 5% (depending on the laser length). Because in most applications only the sum power of all modes is used, it is possible to stabilize the laser power by increasing the number of modes under the gain profile. This can be done by two methods. The first is to increase the laser length and the second uses a 1 : 1 mixture of the neon isotopes ^{20}Ne and ^{22}Ne instead of natural Ne (90% ^{20}Ne and 10% ^{22}Ne). Because of the heavier nuclear core of the ^{22}Ne isotope the radiated light has a frequency about 800 MHz higher than the light from ^{20}Ne (isotopic shift, [11.1641, p. 333]). This means that the difference between these two lines is smaller than the Doppler broadening. Therefore, using a mixture of these two isotopes gives a broader gain curve. The isotopic mixture has no influence on other laser parameters such as the power or noise.

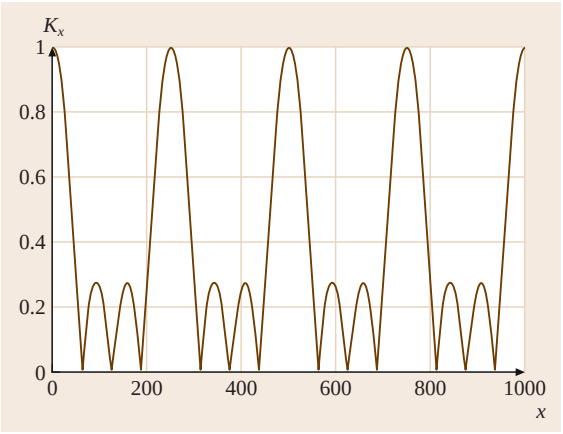

Fig. 11.167 Contrast ratio for the interference of two four-longitudinal-mode laser beams

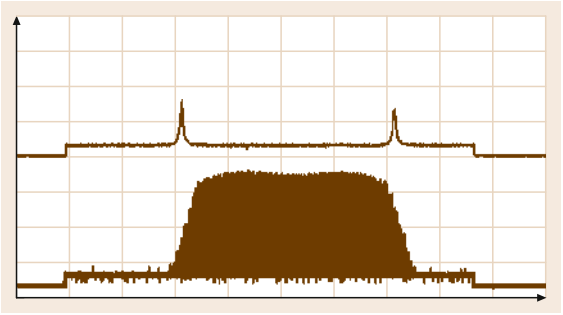

Fig. 11.168 Modes and gain profile of a 140 mm-long laser

One of the most exciting applications of the HeNe laser is interferometry. For this purpose, the coherence length of the laser is important. The coherence length can by calculated from the line width $\Delta\nu$ by

$$l_c = \frac{c}{\Delta\nu} .$$

The problem of a multimode laser is that it does not run at a single frequency but at several equidistant modes.

Figure 11.167 shows the calculation of the measured contrast ratio of a longitudinal multimode laser beam after a Michelson interferometer over the optical path difference. The beam was formed of four laser modes with equal intensity. This picture is overlayed by the decreasing contrast function of the single mode, but the coherence length of the single mode is in the range of kilometers and cannot be seen here. Whereas the interference can be observed over very long distances, the periodic structure makes it necessary to define the coherence length only in the region up to the first minimum. In the case of N longitudinal modes, this first minimum is located at the position

$$l_{\min} = \frac{2L}{N} . \qquad (11.157)$$

Thus, for the laser of Fig. 11.166 the coherence length is below 16 cm.

It should be mentioned that in a real laser the different modes have different intensities, but this only changes the amplitudes in Fig. 11.167 and leads to a nonzero intensity at the minima.

11.6.3 Stabilization

In order to obtain a larger coherence length, a common approach is it to use only one of the longitudinal modes. In order to select a single mode, the fact that in an unpolarized laser (without internal Brewster windows) neighboring modes have perpendicular polarization directions can be used. Hence, using a short unpolarized laser with only two modes, it is possible to select one mode by means of an external polarizer.

In some applications the frequency of this mode must be fixed. This can be achieved by controlling the length of the laser tube by means of a heater around the glass tube. One way is to select the two perpendicular modes using a polarizing beam splitter and measure the power difference between these two modes. By means of the heater, this signal should be held at zero. In this case (Fig. 11.168) both modes are located at the sharp flanks of the gain profile. Here, small frequency changes result in large power changes and exact control of the frequency is possible. This principle is much easier than stabilizing a laser diode, at least with an external resonator with a grating, and the frequency depends only on the atomic properties of the neon. This first approach to frequency stabilization is widely used in the field of mechanical engineering for measurement devices with an accuracy of about 1 nm. A detailed description of frequency stabilization is given in Sect. 11.14.

11.6.4 Manufacturing

Because the first HeNe lasers were built in the 1960s, today the manufacturing technology is a fully developed process, where the processes of cleaning, connecting and the vacuum processes are the key know-how of the manufactures.

After an initial cleaning process of the different components (Fig. 11.169), in a first step the metal

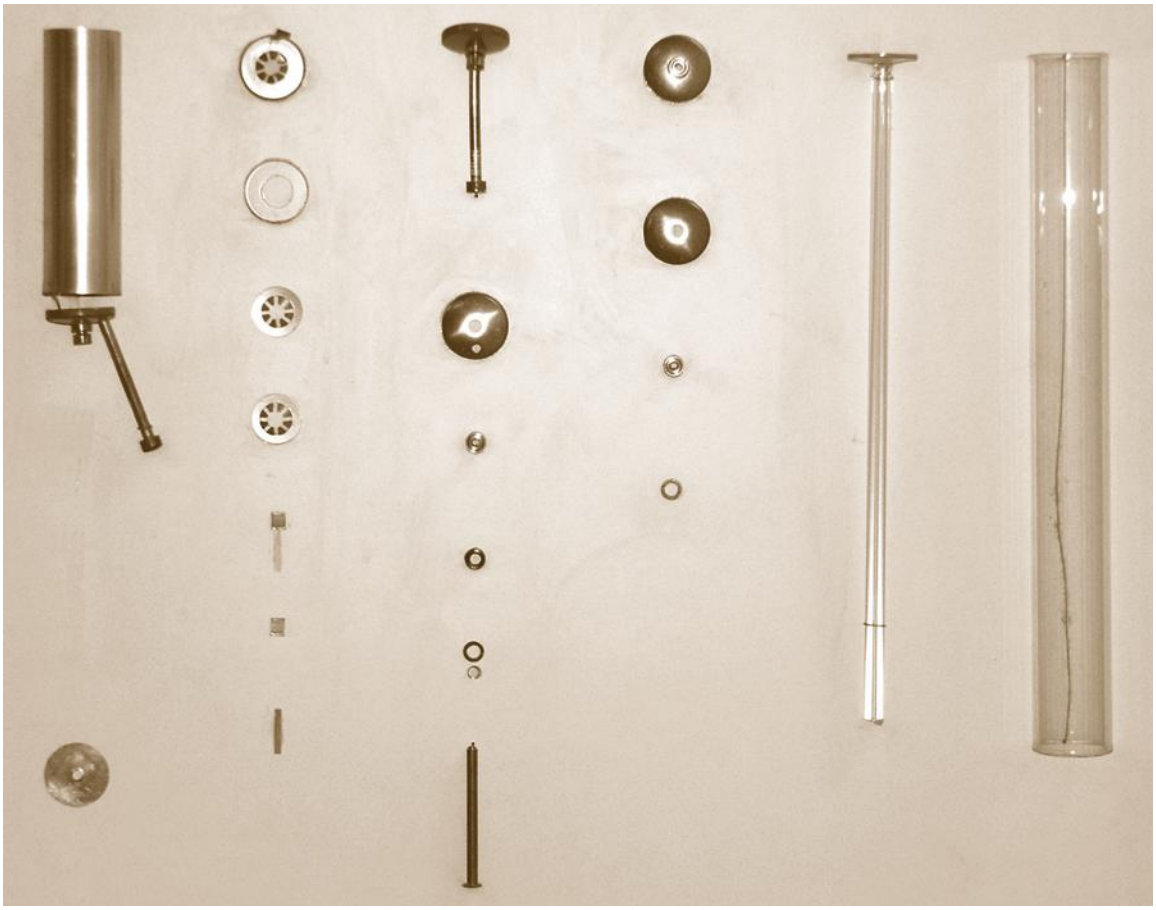

Fig. 11.169 Components of a laser tube

parts are soldered together in a high-temperature process (about 1000 °C). In the next step, the metal and glass parts are melted together at temperatures of about 800 °C. During this step, care must be taken that the capillary bore is at the position of the subsequent optical axis. In order to avoid mechanical stress, the different materials must be chosen in such a manner that the thermal expansion coefficients of the metal and glass parts are matched. The third step is soldering the mirrors to the mirror holders (at about 500 °C). After this preparation, the tubes are backed out under vacuum for many hours. Than, by means of an oxygen discharge, the inner surfaces of the tube are cleaned of residual organic traces. The oxygen discharge is also used to form an Al_2O_3 layer on the cathode surface, which is important for the lifetime of the tube. The next steps are filling the tube with the helium–neon gas mixture, carrying out a burn-in process and the final filling. In order to obtain laser emission, after these steps it is only necessary to align the mirrors. A pre-alignment may be done by means of external lasers, using the back reflection of the laser mirrors from the tube, which should be adjusted. The criteria for final alignment is maximization of the output power.

In order to get a robust product and/or because the long high-power tubes are very sensitive to air flow, the glass tube is usually connected to the ballast resistor and both are placed in an outer aluminium tube.

11.6.5 Applications

Most applications make use of the visible wavelengths of the HeNe laser. Typical applications are flow cytometry, confocal microscopy, DNA sequencing, sensing, haematology and photo-finishing. Last but not least the HeNe laser is a very popular teaching apparatus in ed-

ucation, school or studies. A variety of applications use fluorescence imaging and interferometry which are described in more detail below.

Fluorescence Imaging

Fluorescence imaging makes use of the different wavelengths to excite fluorescence of certain fluorophores. Particularly in biomedical applications this is one of the basic methods. Different fluorophores bind to specific cells and allow the detection of abnormal structures. The working principle is that each particular fluorophore is excited by a special wavelength, emitting light at another wavelength, which is detected by highly sensitive sensors. Using various of these markers allows one to distinguish, label or sort cells. This method is applied in basic research as well as in clinical diagnostics, where it helps to detect serious diseases such as leukaemia or acquired immune-deficiency syndrome (AIDS).

Since most of these methods were developed in a period when the only lasers sources available were gas lasers, the fluorescing substances were made especially for these wavelengths. Together with the common wavelengths of the Ar-ion laser they have become a kind of standard for this application, although a variety of other wavelengths and corresponding dyes are also used today. The emission lines of the HeNe lasers are found in nearly all commercial devices. Common applications are flow cytometry and confocal microscopy.

Interferometry

Interferometric methods are used for the precision measurement of various physical values. Examples are the position or speed of particles, distances, stress or vibration. The optical properties and the long coherence length of the HeNe laser make it ideally suited for this kind of application. The narrow line width of the laser allows its wavelength to be used as a measurement standard. For many interferometric applications the frequency of the emission line has to be stabilized to achieve the maximum measurement precision (Sect. 11.6.3).

11.7 Ultraviolet Lasers: Excimers, Fluorine (F_2), and Nitrogen (N_2)

In 1984, in the introduction to the world's first-ever book on excimer lasers *Rhodes* stated [11.1642, 1643]:

> *The development of excimer laser systems marked a significant turning point in the development of coherent sources. The progress of the last years has been largely predicated upon the combined knowledge of several disciplines including atomic and molecular physics, optical technology, and pulsed-power technology.*

This early statement was primarily associated with electron beam excitation of laser transitions of rare gases and rare-gas halogen mixtures. Present excimer lasers are, however, based on precisely controlled electrical discharges, and rely on a detailed knowledge of material chemistry to assure long service life of the discharge tubes. A cost-effective operation has, therefore, become possible, which is a prerequisite for industrial applications. Together with laser beam monitoring and control by electronic means, the multidisciplinary approach has made excimer lasers important tools for a large variety of industrial and medical applications.

For semantic reasons, the term *excimer* originally referred to excited dimers. Today it is used for all kinds of laser active media that are characterized by bound excited states and dissociative ground states, more generally named *exciplexes*.

This section is organized as follows. An overview of the unique properties of excimer lasers (Sect. 11.7.1) is followed by a guide to the physics and technology behind these laser systems, including beam characterization using wavefront diagnostics (Sect. 11.7.2). Section 11.7.3 focuses on the various techniques of material modification using excimer lasers and includes the use of fluorine (F_2)-laser radiation at 157 nm.

Promising applications of femtosecond excimer laser pulses as unusual sources of extremely high intensities in the UV spectral range are also considered. At the leading edge of current research, the chapter on ultra-high intensity applications deals with the consequences of the new ability to produce *hollow atoms* and their application for ultra-short wavelength x-ray generation. Indeed, studies conducted during the past three decades with short-pulse excimer laser technology, over an intensity range spanning $\approx 10^{14}$–$10^{20}\,\mathrm{W/cm^2}$, have demonstrated the existence of a zone of anomalous nonlinear radiative coupling that lies in the high intensity (I) – high frequency (ω) quadrant of the ($I-\omega$) interaction plane. This discussion includes data demonstrating

the recent observation of nonlinear coupling in the kiloelectronvolt x-ray range and concludes with a perspective on the future that predicts the experimental achievement of intensities approaching the Schwinger limit of $\approx 4.6 \times 10^{29}\,\mathrm{W/cm^2}$ with coherent x-rays. The achievement of intensities at this scale would enable the basic properties of physical space, including the fundamental character of the cosmological constant, to be explicitly examined experimentally.

The final Sect. 11.7.5 presents the new radiation sources at 13.5 nm for the next-generation lithography. Radiation sources in the extreme UV (EUV) can be realized by both laser and discharge pumping and are expected to transform present microlithography into nanolithography.

Since the field of UV lasers is very large and has recently been covered in a review book [11.1644], this section just summarizes the various possibilities and requests the reader to browse in [11.1642–1644], and in primary publications if more details are required.

11.7.1 The Unique Properties of Excimer Laser Radiation

The most impressive property of excimer laser radiation is its large variety of emission wavelengths, which cover the entire ultraviolet spectral region (Fig. 11.170). The shorter the wavelength, the higher the resolution that can be achieved in microprojection and imaging, which in turn opens a wide field of applications. Concurrent with the short wavelength is the high quantum energy. Short-wavelength photons are strongly absorbed by most materials and they can supply sufficient quantum energy to induce photochemical reactions and cause molecules to dissociate. Together with the high peak power available in a laser pulse, the bond-breaking capability of excimer laser radiation allows ablative evaporation, which opens the door to microprocessing of many materials, ranging from soft biological tissue to hard diamond.

The pulse duration is an important parameter. Typical excimer lasers emit pulses in the range of a few nanoseconds so that material processing can be frequently performed *on the fly*, i. e., it can be applied to a continuous flow of components to be processed. In addition, due to the naturally broad linewidth, excimer lasers can be tailored to supply pulses in the femtosecond range with extremely high peak power. This allows one to generate a plasma that consists of electrons and *hollow* atoms, i. e., inner-shell ionized atoms that recombine via highly energetic transitions, thereby

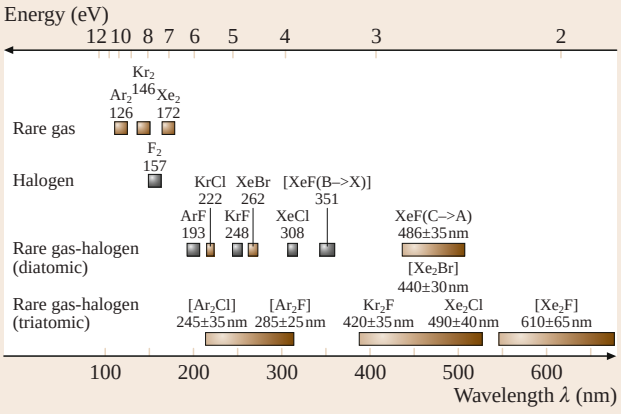

Fig. 11.170 Wavelength (*lower scale*) and corresponding photon energy (*upper scale*) of the various excimer transitions. The *solid symbols* indicate commercially important wavelengths

delivering radiation in the extreme ultraviolet or weak x-ray region. This is surely one of the most advanced and promising applications.

Finally, excimer lasers are scalable to high pulse energies in the Joule range, to high repetition rates of a few kHz, to high average powers up to 1 kW, so that they can be conveniently adapted to their specific industrial task. Compared to these facts, their drawbacks are the fairly broad linewidths, the low degree of coherence and the noncontinuity of the radiation. However, the latter characteristics are of minor importance considering the strengths discussed above. This leaves some room for other lasers that might *conquer* the UV range by frequency conversion until more powerful semiconductor emitters may partly fill the gap. The low degree of coherence may be utilized for speckle-free imaging, and the broad linewidth, which enables ultrashort pulses, may be narrowed by some frequency selecting means in the resonator setup. However, the beam, which somehow resembles the *emission of a lighthouse* (large divergence), requires some harnessing by beam shaping optics.

Figure 11.170 summarizes the data on wavelength and quantum energy of rare-gas halide lasers, together with those of the fluorine laser and some other diatomic and triatomic species. The F_2 laser is actually not an excimer laser but can be excited almost in the same way. These UV sources are most important for the wide field of applications outlined in the next sections. The *exotic* types such as KrBr, rare-gas dimers and other dimers, as well as trimers are discussed in some detail in [11.1642–1644].

11.7.2 Technology of Current Excimer Lasers and the N_2 Laser

We start with the fundamentals of excimer lasers and the fluorine laser. Due to its role as a *forefather* of all gaseous UV lasers, the (molecular) nitrogen laser (N_2 laser) will be considered as well. Finally, the technology of discharge-pumped excimer lasers will be briefly outlined.

Excimer Transitions: Unusual Four-Level Laser Systems

Excimer lasers derive their emission from molecules that are generated *a priori* in an electronically excited state, which decays by emission of (laser) radiation into a repulsive or loosely bound ground state out of which the molecule dissociates. In usual test-tube chemistry the rare gases are *noble* or inert, i. e., avoid chemical binding, although special noble-gas compounds do exist also in the electronic ground state. The most important molecules for commercially available excimer lasers are ArF^*, KrF^*, $XeCl^*$, and XeF^*, where the asterisk refers to electronic excitation.

The dissociative electronic ground state is responsible for the four-level character of these systems. Generally, four-level laser systems can be operated in continuous manner. However, this is not possible with rare-gas halide excimer lasers because of physical and technical restrictions. A fundamental restriction is the important role that spontaneous emission plays with respect to the stimulated emission in the ultraviolet spectral region. The ratio of the Einstein coefficient A, which is responsible for spontaneous emission, and that responsible for the stimulated emission in the same transition B is proportional to the third power of the transition frequency ν [11.1651]:

$$\frac{A}{B} = \frac{2h\nu^3}{c^2} \,.$$

Hence stimulated emission can only compete with spontaneous emission if the radiation intensity within the transition $I(\nu)$ is so large that the product $B \cdot I(\nu)$ exceeds A, that is, if the system is pumped extremely hard. Electrical power densities of some 100 MW/l must be deposited in the gas volume. In the early days, this excitation density was achieved by using energetic electron beams [11.1642, 1643]; nowadays short-pulse transverse electrical discharges are used. An extension of the pulse duration beyond about 1 μs is hampered by discharge instabilities caused by arcing. The detrimental reaction products and heat must be removed before the next shot so that rapid exchange of the laser gas is required.

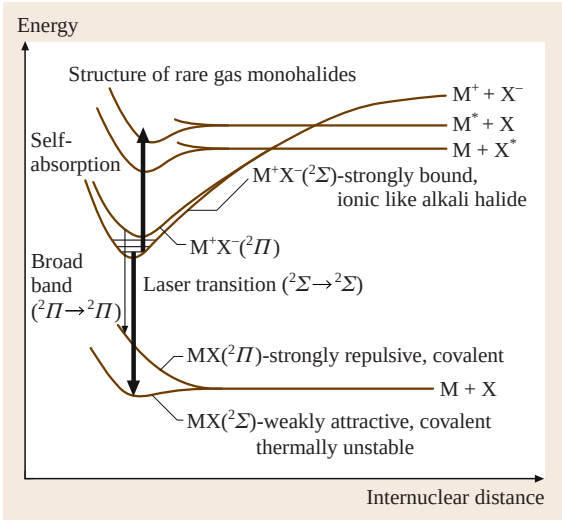

Fig. 11.171 Typical potential energy diagram of a rare-gas halide molecule. M stands for the rare gas, X for the halogen atom (after [11.1645–1650])

After the first experimental demonstration of a bound-free laser system at liquid Xe_2 [11.1652], a large number of other excimer or exciplex molecules were successfully investigated, homonuclear as well as heteronuclear ones [11.1642, 1643], but mostly did not gain importance for application. The door to the systems listed in Fig. 11.170 was opened in an avalanche manner in 1975 [11.1645–1650]. Their efficiency, the wavelengths, and, after some technical effort, the ease of handling the laser gases was convincing. The gases are primarily the discharge carrier which is the buffer gas (mostly helium), and, to a much lower extent, the reactants which are the laser gases.

Molecular Potentials and Reaction Kinetics

Rare-gas halide systems are characterized by two electronic ground states, correlating with the electronic ground states of the rare gas and halogen atoms, which combine to a molecular Σ and a Π state, arising from the p-hole of the halogen atom (Fig. 11.171, [11.1645–1650]). Whereas the Π state is strongly repulsive, the Σ state shows a minimum, mostly with a depth of a few hundred cm^{-1} only, so that thermal energy lets the molecule dissociate within a few picoseconds. The first electronically excited states correlate with the positive rare gas and negative halogen ions, and hence show a deep minimum. The higher states correlate with the

electronic excitations of the neutrals, their potentials are shallower, as typical for covalent binding. This general scheme holds for rare gas halides, except XeF where the potential of the ground state reaches a depth of 1065 cm^{-1} according to [11.1645–1650].

In buffer-gas supported electrical discharges, the excited and ionic species are formed as shown for the KrF* case in Fig. 11.172. The formation of the excited rare-gas halide molecule follows both a *neutral* channel, a chemical exchange reaction, and an *ionic* recombination channel, stabilized by third-body collisions with the buffer gas atoms. Hence the formation of exciplexes is favored at high pressure, i. e., pressure of a few bars. The buffer gas also provides fast relaxation to the lowest vibrational level within the electronically excited state, followed by a radiative transition to the ground state within a few nanoseconds.

The laser transitions couple with the continuum states above the ground state, showing a homogeneously broadened non-Lorentzian lineshape [11.1656]. Hence, excimer lasers can be tuned within a certain bandwidth range if frequency selective optics are introduced (see the tuning ranges in Fig. 11.170). The homogeneous line broadening turns out to be favorable for the amplification of short pulses.

In more detail, many more excited states that correlate to the excited atomic states exist and are being populated. However, their buffer-gas-induced relaxation feeds the population of the lowest electronically excited state. An overview of the reaction kinetics of both pure rare gases and rare-gas atoms with halogens and the underlying rate constants is given in [11.1657].

The *fluorine laser* is based on bound–bound transitions. With 157 nm it shows the shortest wavelength of all homonuclear halogen lasers [11.1658]. From the two p-holes of the F atoms, three levels belonging to ground electronic configuration are obtained for the F_2 molecule; two of them are bound so that the stable molecule can be directly electronically excited in an electrical discharge. In addition, excitation transfer from the electronically excited He* and excited F* atoms, and ionic recombination of F^+ and F^- ions because fluorine atoms have a large electron affinity during interaction with a He atom, lead to the population of the upper $^3\Pi$ laser level that decays to the weakly bound lower $^3\Pi$ level. The F_2 laser transitions can be excited in discharges like those in rare-gas halide lasers. Therefore, the F_2 laser is frequently mentioned among the commercial excimer lasers – in particular with respect to its short wavelength. Femtosecond operation of the F_2 laser has been described in [11.1659].

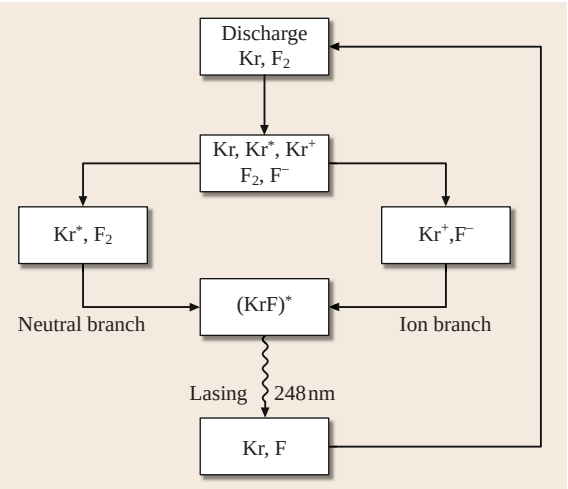

Fig. 11.172 Dominant reaction paths for the generation of KrF* (after [11.1653])

Figure 11.173 shows details of the F_2 laser emission together with a *line-selected* spectrum of only 1.034 pm halfwidth (FWHM) according to [11.1644].

Technical Design Principles of Excimer Lasers

From the physical preconditions described in the two preceding sections it follows that an electrical energy of high density, in the order of 10^{-2} J/cm^3 [11.1660], must be discharged homogeneously into the laser gas (Fig. 11.174a) on a time scale of a few nanoseconds so that a high-pressure (up to 0.5 MPa) glow discharge can be maintained for as long as possible.

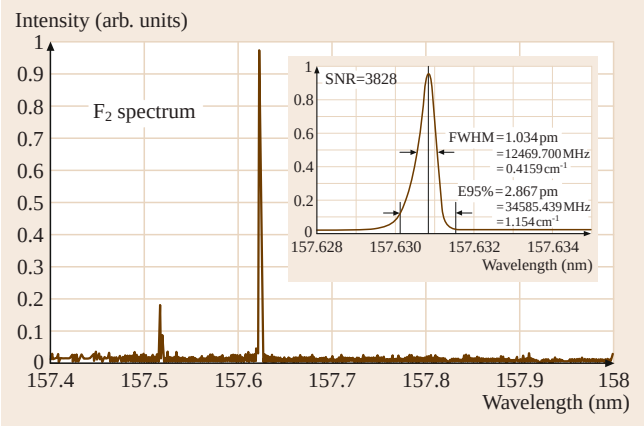

Fig. 11.173 Emission spectrum of the fluorine laser (after [11.1654, 1655]). *Inset* shows spectral details of the stronger transition after *line-selection* (after [11.1644, p. 97])

Table 11.46 Preionization techniques applied in excimer laser discharges

	Preionization of the laser gas by UV radiation emitted from spark discharges between pin electrodes mounted in a row parallel to the laser channel. Sparks are being ignited some 10 ns before the main discharge starts so that at least 10^8 electrons/cm^3 are created as a seed for the main discharge
	A possible modification of a): spark preionization through one of the electrodes designed as a screen or mesh electrode
	Dielectric(alumina)-surface-guided spark discharge for preionization. Because the discharge spreads, erosion of the pins is reduced considerably. Thus the lifetime of the laser gas is increased, and the laser tube can be operated up to 10 billion shots. This design is mostly used in high-average-power excimer lasers
	Surface corona discharges on a dielectric sheet emit UV with high spatial uniformity. Consuming a lower amount of energy as compared to sparks, they supply an electron density sufficient for a narrow discharge volume as used in high-repetition-rate excimer lasers, and provide increased discharge electrode lifetime
	Knife-edge-released discharges creeping on a dielectric surface (similar to the well-known Lichtenberg discharges) cover a large area, thus can be conveniently applied for the preionization of large-aperture excimer lasers. The knife edge is connected to the ground electrode of the main discharge

The electrical charge comes from a storage capacitor or, more effectively, a low-impedance pulse-forming line. For a homogeneous ignition, an efficient preionization is required. Preionization by ultraviolet radiation has prevailed over x-rays. Table 11.46 summarizes the different methods of UV preionization. Glow discharges, especially in halogen-containing gases, tend to transform into an arc or sparking discharge due to electron capture by the halogens so that laser emission breaks down. Hence, considerable efforts have been made to stabilize the glow discharge [11.1661, 1662]. In order to supply the charge sufficiently fast, favorable use is made of magnetic pulse compression (Fig. 11.174b,c). The energy switches, formerly thyratrons, are mostly thyristors, gate-turn-off (GTO) thyristors, or insulator gate bipolar transistors (IGBT).

To guarantee a long laser tube lifetime, the choice of electrode material is very important. Considerable material research has taken place and has led to different materials for fluorine and chlorine rare-gas lasers. Even different materials for either the cathode or the

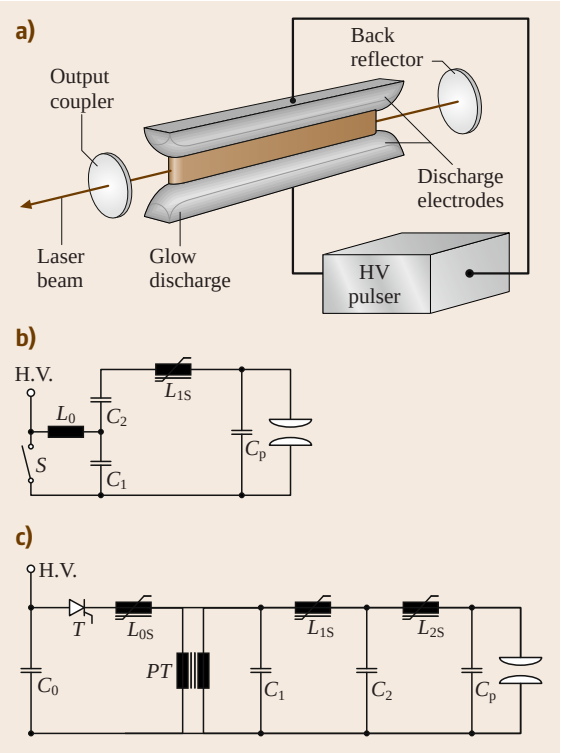

Fig. 11.174 **(a)** Schematic layout of an excimer laser together with gas discharge and laser resonator, **(b–c)** Excitation circuits employing magnetic pulse compression. **(b)** *L–C* inversion circuit with single-stage pulse compression, **(c)** thyristor-switched circuit using double-stage pulse compression (after [11.1660])

anode, or over the profile of one electrode have been used [11.1660]. Rapid transverse gas circulation provides cooling and supply of fresh laser gas for every shot. In order to achieve a stable laser output power, halogen gas consumption is compensated by processor-controlled gas injections so that the laser tube can be operated with a single main fill typically for about 1 billion pulses.

Excimer laser resonators (Fig. 11.174a) mostly consist simply of plane windows made of CaF_2, allowing high outcoupling in the range 50–92%. For special applications, unstable resonators or resonators with frequency-selective optics are employed, as well as oscillator-amplifier systems.

The number of technical papers on the technology and construction of excimer lasers and their applications has become numerous. Excimer laser parameters are scalable to a considerable extent. Special excimer lasers have been developed by putting in the foreground either high single-pulse energy (up to 10 J), or high repetition rate (6 kHz), or medium or high average power (up to 1 kW). The efficiencies, calculated from the ratio of laser output energy to stored electrical energy, are typically a few percent (< 5%). Since meanwhile digital inter-publisher retrieval has become possible, nearly every combination of the above can be electronically traced back, in part over the last three decades. As an example, Table 11.47 shows data specified for a XeCl excimer laser designed for industrial applications.

Beam Characterization and Homogenization of Excimer Lasers

Many applications of excimer lasers, like for example semiconductor microlithography or eye surgery, strongly rely on the stability and the precise control over the characteristics of the emitted radiation, such as pulse energy, beam width, divergence, pointing stability, uniformity, etc. While output energy and power can be monitored with standard tools used also for other high power lasers, recording of spatial beam profiles and directional distributions (wavefronts) requires specific instrumentation adapted to the output characteristics of excimer lasers. Besides sensitivity for the various emission wavelengths in the deep UV spectral range, such diagnostics systems must also possess detector apertures adapted to the large near-field beam cross-section, and, most importantly, guarantee long-term stability of the employed optics and sensors under pulsed high-power UV irradiation. Due to substantial improvements in this field achieved in recent years, evaluation of relevant excimer beam propagation parameters is now possible from camera-based profile and wavefront measurements in accordance with current ISO standards.

Table 11.47 Data from a XeCl excimer laser for industrial use. (Type: Steel 2000, Coherent Lambda Physik 2005)

Maximum stabilized energy (mJ)	Maximum average power (W)	Maximum repetition rate (Hz)	Pulse duration (ns)	FWHM beam dimensions V × H (mm)	Divergence V × H (mrad)	Beam point stability V × H (mrad)

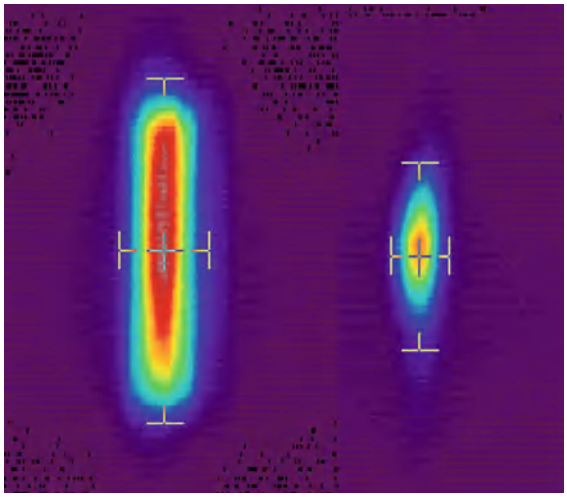

Fig. 11.175 Near-field (*left*) and far-field profile (*right*) of an ArF laser (193 nm) recorded simultaneously with a camera-based measurement system. The evaluated second moment beam widths in horizontal and vertical directions are indicated

A corresponding beam profiling system has been developed at Laser-Laboratorium Göttingen and optimized in cooperation with industrial partners. This device allows monitoring of both near-field and far-field profiles at the excimer laser wavelengths 351, 308, 248, 193, and 157 nm [11.1663]. While the near-field profile is imaged onto the detector, the far-field beam is focused using a lens of long focal length in order to minimize errors caused by spherical aberration. Near-field and far-field distributions are simultaneously recorded side by side using of a UV camera with large active area. UV sensitivity of this camera is achieved by use of a highly linear, uniform and radiation resistant quantum converter screen, followed by a demagnifying projection of the fluorescence onto a CCD camera chip.

As an example, Fig. 11.175 shows the near-field (NF) and the far-field (FF) recorded for an ArF excimer laser (Novaline, Lambda Physik), indicating rather smooth and symmetric profiles. From these two-dimensional energy density distributions ($H_{NF}(x, y)$ and $H_{FF}(x, y)$) beam parameters can be evaluated according to the ISO standards (Table 11.48, [11.1664–1667]).

Figure 11.176 shows the NF profile of a standard KrF laser with a stable resonator. Beam widths in horizontal and vertical directions were computed using both the second moment and moving slit evaluation method, indicating a deviation of less than 1%.

Homogenized Excimer Laser Beams. The majority of excimer laser applications, especially in the semiconductor industry and the production of TFT flat panel displays, strongly depend on the use of homogenized profiles, i. e., top-hat distributions with steep edges and

Table 11.48 Relevant beam parameters of excimer lasers and evaluation procedures according to ISO standards. $H_{NF}(x, y)$ and $H_{FF}(x, y)$ denote the near-field (NF) and far-field (FF) energy density distributions, respectively

Beam parameter		Evaluation	ISO standard
Near-field profile			
Centroid	(x_c, y_c)	1st moment of $H_{NF}(x, y)$	ISO 11146 [11.1644]
Beam positional stability (x, y)	$\Delta_x = 2s_x$	Standard deviation of centroid Distribution of consecutive pulses	ISO 11670 [11.1651]
Beam width (x, y)	$d_{\sigma,x} = 4\sigma_x$ $d_{sx} = x_2^{1/e^2} - x_1^{1/e^2}$	2nd moment of $H_{NF}(x, y)$ or: moving slit evaluation	ISO 11146
Effective irradiation area	$A_{eff}(\eta)$	Integration over beam areas with energy density $H_{NF}(x, y)$ above threshold η	ISO 13694 [11.1652]
Edge steepness	$s = (A_{10\%} - A_{90\%})/A_{10\%}$	Normalized difference of eff. integration areas	ISO 13694
Plateau uniformity	$U_p = \Delta H_{NF}/H_{max}$	Peak width of histogram curve	ISO 13694
Far-field profile			
Divergence (x, y)	$\Theta = d/f$	Beam width in far-field	ISO 11146
Beam directional stability (x, y)	$\delta\alpha_x = 2s_x/f$	Standard dev. of centroid distribution of far-field profiles	ISO 11670
Wavefront	$w(x, y)$	Hartmann–Shack measurement	ISO 15367 [11.1645–1650]
Spatial coherence	l_c	Young's double slit experiment	–

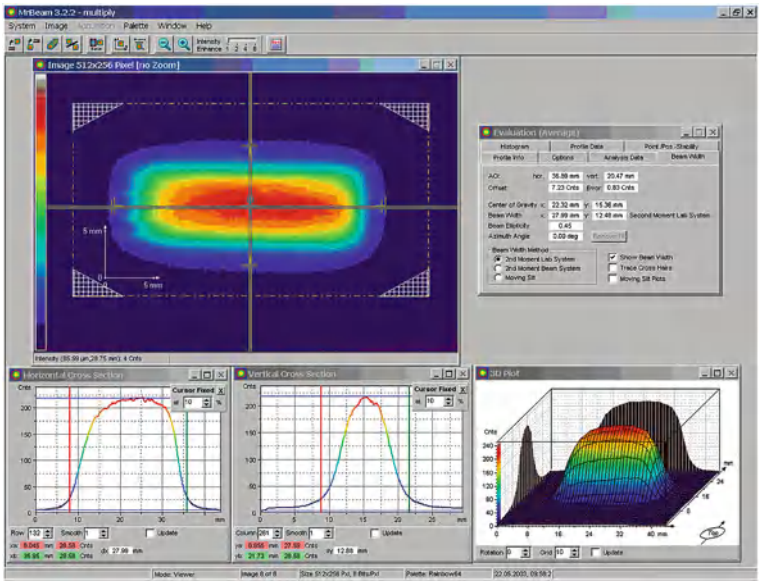

Fig. 11.176 Near-field profile of excimer laser measured at 248 nm. Second moment beam widths ($d_{\sigma,s,x} = 27.5$ mm, $d_\sigma = 11.8$ mm) are indicated

high uniformity in the plateau region. Examples can also be found in laser-based material processing in microelectronics, or medical applications such as corneal reshaping. In all these cases, only a narrow process window with respect to the laser energy density is tolerable. Various techniques for homogenization of excimer laser radiation are employed, which all mix fractions of the original beam in order to smooth out intensity spikes. Due to the low spatial coherence of excimer lasers this can be achieved with high quality, avoiding disturbing interference patterns from the homogenization optics.

Figure 11.177 displays the profile of a KrF laser after planarization with a simple fly's eye lens homogenizer [11.1668], consisting of two crossed arrays of cylindrical lenslets that split the incident laser beam into partial rays. A spherical lens provides an effective integration of the beam into a flat-top beam profile (Fig. 11.177a), which can be used for high quality material structuring based on mask projection (Fig. 11.177b).

Edge steepness and plateau uniformity of such homogenized profiles can be characterized unambiguously according to ISO standard 13694 [11.1668]. The corresponding definitions take into account the entire 2-D distribution rather than single cross sections; thus, they may be applied to flat-topped profiles of arbitrarily shaped footprints.

Brief Recollection of the N_2 UV Laser

The molecular nitrogen laser, already realized in 1963 with emission in the near infrared [11.1669] and shortly

later between 300–400 nm with the strongest line at 337 nm [11.1670] (this was described in detail in 1965 [11.1671, 1672]) – quickly became the workhorse of laser spectroscopy. Its predominant use was, and still is, optical pumping of pulsed dye lasers throughout the near UV, the visible, and near infrared spectrum. In addition, it serves as an excitation source in photochemistry and biological research. The lasing is achieved in high-voltage (10–20 kV) high-speed (a few ns) transverse gas discharges in a broad pressure range from some 10 mbar up to atmospheric pressure (TEA laser), in pure nitrogen and also, with lower efficiency, in air. The 337 nm transition is the most intense of the vibronic transitions (0–0) between the $C^3\Pi_u$ and the $B^3\Pi_g$ state. Since the B state is long-living (about 10 μs) with respect to the C state (about 10 ns), the laser action is quickly self-terminated.

The pumping is achieved from the X state by direct electronic excitation of the C-state, which happens to occur with a larger cross section than that for the B-state, so that population inversion can be obtained if the discharge current rises much faster than radiative increase of population of the B-state. To emit pulse energies in the mJ range, N_2 lasers must be equipped with low-impedance discharge circuits as, for example, can be realized by embedding the laser channel into a Blumlein transmission line that enables a rise time of a few nanoseconds. Since the gain is very large, the emission may be stimulated predominantly in one direction when the excitation wave is made to reach the discharge channel synchronous to the light propagation; in this way a 10 : 1 ratio in favor of one direction was achieved [11.1673], and fairly short lasers with considerable peak output power (1.2 MW) became possible [11.1674]. Transmission line circuits have been thoroughly analyzed in [11.1675]. A pulse energy of 20 mJ has been realized using a fast circuit with magnetic pulse compression [11.1676]. On the other hand, just for demonstration purposes, a nitrogen laser can be easily realized by adjusting two electrodes on a glass sheet and supplying the electrodes with a spark-gap-switched high voltage source. A *home-built* nitrogen laser, using standard ignition transformers, spark gaps, refrigerator circulating pumps, and some dielectrics and aluminium foil or copper-layered circuit boards, is precisely described on the web [11.1677].

Historically speaking, N_2 lasers as well as homonuclear excimer lasers and metastable mercury compounds were already proposed in 1960 by *Houtermans* [11.1678]; much earlier than the first ruby laser had been realized!

11.7.3 Applications

Physically, the applications of excimer lasers can be grouped according to benefits:

1. Short wavelength
2. High quantum energy
3. High pulse energy density obtained by focusing
4. The extreme peak power when the pulse energy is compressed into ultrashort pulses.

Property 1 allows exposing and patterning sub-100 nm-structures in photoresists for semiconductor lithography. Property 2 allows photochemical near-surface modifications like color change as used for marking of plastics, and index-of-refraction change used for the generation of fiber Bragg gratings. Property 3 allows melting of thin silicon films, used to induce large-grain crystallization in the production line of TFT displays. Properties 1–3 enable microstructuring by material ablation including biological tissue, and property 4 opens the door for the generation of x-rays of extreme brilliance. Besides these technical applications, excimer laser radiation is still widely used for scientific purposes, such as optical pumping of dye lasers. Here, we briefly refer to a few technical applications.

Excimer Lasers in the Electronics Industry

Actual lithography for the generation of semiconductor circuits has been based on excimer laser light sources for more than a decade now, and will prevail for a couple of years. Thus, this is the economically most important application of these lasers. Because the diffraction-limited minimum (half pitch) that is resolvable in optical projection is given by $k_1 \cdot \lambda/\mathrm{NA}$, every effort is made to decrease the wavelength λ for the illumination together with the process factor k_1, and to increase the numerical aperture (NA) of the projection system. After extensive use of 248 nm lasers, now 193 nm illumination is the state-of-the-art, and increasing NA by using immersion optics has turned out to be a highly successful method to arrive considerably below the diffraction limit. In the International Technology Roadmap for Semiconductors (ITRS) 2005 (Figs. 11.178, 11.179) the 45 nm half pitch for DRAMs in production is scheduled for 2010, to be achieved with 193 nm immersion technology. Fluorine lasers (157 nm) are no longer under consideration since immersion fluids with an index of refraction higher than that of pure water are being investigated. These could extend the use of 193 nm down to 30 nm half pitch [11.1679].

For lasers to be used in lithography, there are considerable requirements with respect to linewidth, wavelength and pulse-to-pulse stability, and the lifetime of the laser tube and all the optics [11.1643]. Dual-chamber systems distribute the task of narrowband generation in the oscillator and power generation in the amplifier tube; the latter can be designed as a regenerative ring amplifier [11.1643]. Recently, a 60 W system operating at 193 nm was introduced (Fig. 11.180 [11.1680]) with the benefit of improved energy stability of the 6 kHz pulses, so that the expo-

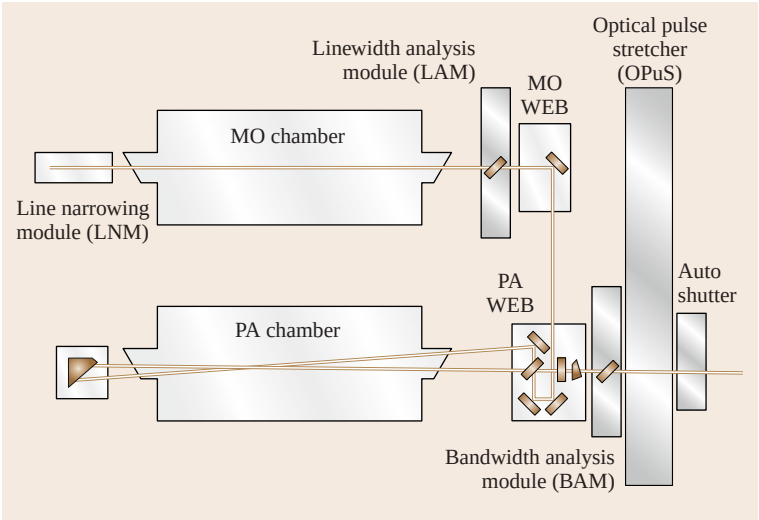

Fig. 11.180 Schematic of a MOPA (master oscillator power amplifier) excimer laser system to be used in semiconductor lithography (after [11.1681], courtesy of Cymer Inc.)

sure dose of the resist can be precisely controlled. This system aims at 45 nm half-pitch production.

Transistors in thin films are the key elements to controlling the individual pixels in displays. To increase the mobility of the electrons, large silicon crystal grains are produced by applying excimer laser radiation for the melting and controlled recrystallization, the beam being scanned line-shaped across the surface [11.1682, 1683]. This process, summarized as excimer laser annealing (ELA), is performed by applying 308 nm radiation that is strongly absorbed by silicon so that thin films on glass can be molten without damage to the substrate [11.1684]. In this way, large-area TFT displays can be manufactured. Even doping imperfections due to incomplete annealing near source/drain junctions can be eliminated by oblique-incidence ELA [11.1685].

Further excimer laser applications that are well-established in electronics are printed circuit board (PCB) via drilling [11.1686], wire stripping, and wire marking [11.1644]. A rather new technology is the lift-off method to de-bond, for example, an electronic GaN LED from its sapphire substrate, which is used for crystal growth, by shining the laser through the substrate, thereby ejecting the LED from its heat sink electrical interconnect [11.1687]. For future optical coupling of PCBs, the attempts to integrate optical mirrors manufactured by ablation should be mentioned [11.1688, 1689].

Processing of Optical, Ceramic, Polymeric, and Biological Materials

Ablation is surely the best-known application of excimer lasers: drilling and microstructuring of glass, quartz, even diamond, ceramics and polymers [11.1690] allows highly precise contouring with high reproducibility. This subject is covered in Chapters 11–14, and 16 in [11.1644] and includes also the ophthalmological application including the LASIK method [11.1644, 1690]. Nonablative processing of glass and polymers allows one to generate fiber Bragg gratings in optical waveguides by changing the index of refraction [11.1691, 1692]. Microstructuring will also play a role in the upcoming technology of organic light emitting devices (OLEDs) [11.1693].

11.7.4 Femtosecond Excimer Laser Pulses

Direct generation of ultrashort pulses in excimer modules is not feasible because excimers cannot be excited continuously, which is necessary for mode locking. On the other hand, excimers (especially ArF and KrF) are well suited for the amplification of ultrashort UV pulses. The reason is that the gaseous amplifying media exhibit low nonlinearities, high damage threshold, and good scalability, combined with high gain [11.1694]. The available bandwidth of excimer amplifiers support pulse durations of 100–200 fs limited by the actual gain narrowing. These properties facilitate very high output energies and thus very high peak powers with excellent focusability. Another fundamental advantage of UV laser sources is their short wavelength, which allows much tighter focusing than in case of IR radiation (focal area $\propto \lambda^2$). Therefore, femtosecond excimer systems are well suited for the generation of intensities in excess of $10^{19}\,\mathrm{W/cm^2}$ [11.1695].

A state-of-the-art ultrafast UV laser system consists of a commercial Ti:sapphire seed laser generating ≈ 140 fs pulses at 745.5 nm, a frequency tripling unit (THG) to convert the wavelength to the UV, and a special large-aperture dual-channel KrF excimer amplifier to boost the pulse energy to ≈ 60 mJ. Additionally, relay imaging of the THG crystal to the output windows of the subsequent amplifier stages provides excellent beam quality. A spatial filter implemented between the discharge tubes provides very efficient ASE (amplified spontaneous emission) suppression. With such a laser system a few tens of millijoules with pulses on the 100 fs level can be generated at 248 nm (Fig. 11.181).

In order to overcome the limitation on the achievable minimal pulse duration posed by the limited gain bandwidth of excimers, spectral broadening methods can be applied to the amplified UV pulses. For this purpose the most common technique utilizes self-phase modulation during pulse propagation through a noble gas filled hollow-core fiber [11.1696], which is well established for IR pulses. When adapting this method to UV pulses, long (> 2 m) hollow fibers with large inner diameters must be used in a pressure gradient scheme and the focusing/recollimating optics must be placed in the gas chamber for optimal performance (Fig. 11.182) [11.1696].

In this arrangement a novel, stretched flexible fiber assembly is used whose length can be freely scaled up to several meters while maintaining ideal waveguide properties [11.1697]. Applying this method to the laser system shown in Fig. 11.181, a compressed pulse duration of 24 fs (Fig. 11.183) with pulse energies as high as 0.2 mJ was achieved [11.1696]. These are by far the most energetic sub-50 fs pulses generated so far in the DUV spectral range.

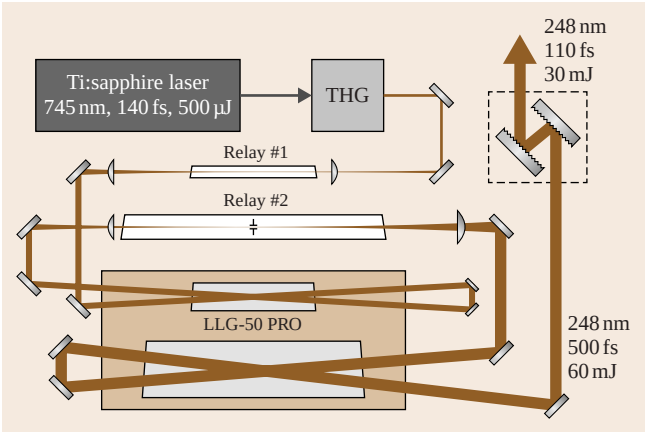

Fig. 11.181 High-energy ultrafast UV laser system

Materials Processing with Femtosecond Excimer Laser Pulses

Nanoscale fabrication of materials is more and more in demand in scientific and industrial applications. The general trend to reduce the size of optomechanical devices and the growing need for assemblies with feature sizes below one micron generate new challenges for laser fabrication techniques.

Short-pulse lasers with picosecond and femtosecond pulse duration offer material processing capabilities with highly decreased damaged area around the irradiated spot, and consequently smaller feature sizes. If the short pulse duration is combined with a short wavelength, unprecedented results can be achieved due to the dependence of the spatial resolution on the wavelength. Thus UV femtosecond laser systems provide superior material processing quality.

The application of various irradiation strategies allows the generation of complex 2-D and 3-D structures with feature sizes down to ≈ 200 nm or lower on all materials including metals, semiconductors, and dielectrics.

Special emphasis is put on rapid prototyping of *periodic* nanostructures. Various optical schemes have been introduced to create a great variety of surface textures. Strictly periodic structures can be obtained by combining diffractive optical masks with reflective imaging/focusing systems, enabling well controlled multiple-beam interference. Furthermore, for the generation of arbitrary quasi or nonperiodic patterns, special designs of diffracting optical elements (DOEs) have been developed. With all these techniques a modulated

intensity profile is projected onto the workpiece with a laser fluence high enough for direct material removal.

A so-called phase-controlled multiple-beam interference technique [11.1698] uses a multitude (at least two) of gratings to split an incoming beam into a number of beams via diffraction. By varying the separation of the elements, the optical path length between the beams and hence their phase difference can be changed (Fig. 11.184a). After superposition of some or all of these partial beams (e.g., by an objective), a big variety of textures can be obtained as a result of multiple-beam interference (Fig. 11.184b).

The use of a grating interferometer in combination with cylindrical focusing allows the direct ablation of large area submicron grating structures on solid surfaces [11.1699]. In this case a line focus provides the necessary fluence for material removal. When scanning this focal line across the sample area, the grating interferometer assembly ensures that the coherence properties of the generated interference pattern are preserved, resulting in a large area coherent grating structure (Fig. 11.185).

DOEs are known to be able to redistribute the laser energy in a virtually arbitrary spatial pattern by only manipulating the phase of light. By delivering sufficient intensity to a target sample, direct laser patterning can be accomplished. Among many other applications, this can give rise to the creation of special surface functionalities. DOEs can be optimized, e.g., for the generation of a two-dimensional pattern of intensity maxima, each carrying enough power to drill holes in, e.g., a stainless steel mold. After replication of this pattern by, e.g., injection molding in appropriate materials, an array of surface bumps is obtained, giving rise to a super-hydrophobic surface functionality (Fig. 11.186) [11.1700].

Progress in High-Intensity Studies with Femtosecond Excimer Laser Pulses

Studies conducted during the past three decades with short-pulse excimer laser technology, over an intensity range spanning $\approx 10^{14}$–$10^{20}\,\mathrm{W/cm^2}$, have demonstrated the existence of a zone of anomalous nonlinear radiative coupling that lies in the high intensity (I)–high frequency (ω) quadrant of the (I–ω) interaction plane. This discussion includes data demonstrating the recent observation of nonlinear coupling in the kiloelectronvolt x-ray range and concludes with an outlook to the future that predicts the experimental achievement of intensities approaching the Schwinger limit of $\approx 4.6\times10^{29}\,\mathrm{W/cm^2}$ with coherent x-rays.

Intensity–Frequency Interaction Landscape: Experimentally Determined Zone of Anomalous Coupling. Due to a long sequence of experimental studies [11.1701–1719], it has been possible to establish a zone of anomalous electromagnetic coupling that stands in contrast to a corresponding region of conventional interaction. These two regions are presented in the intensity (I) – quantum energy ($\hbar\omega$) plane illustrated in Fig. 11.187. The lower boundary of the intensity for the anomalous coupling shown in Fig. 11.187 is given approximately by $I \cong 10^{15}$–$10^{16}\,\mathrm{W/cm^2}$, a range corresponding to an electric field slightly less than one atomic unit ($e/a_0^2 \cong 5.14\times10^9\,\mathrm{V/cm}$). The corresponding lower limit in the frequency is $\hbar\omega \cong 5\,\mathrm{eV}$, a value slightly less than one half of a Rydberg. Therefore, as a rough measure, the region of anomalous interaction is bounded by the characteristic values of electric field strength (intensity) and frequency (energy) associated with the hydrogen atom, the paramount fundamental atomic entity.

Key supplementary data are also shown in Fig. 11.187. They include:

1. The line
$$\frac{eE}{m\omega c} = 1 \qquad (11.158)$$
that defines the peak electric field E for the onset of relativistic motions for elections with mass m and charge e driven at angular frequency ω.
2. The vacuum pair creation limit, the upper value bounding the achievable intensity that is associated with ultrarelativistic electron/positron cascades [11.1720].
3. The intensity $I \cong 4.6\times10^{29}\,\mathrm{W/cm^2}$ corresponding to the Schwinger–Heisenberg limit [11.1721, 1722].

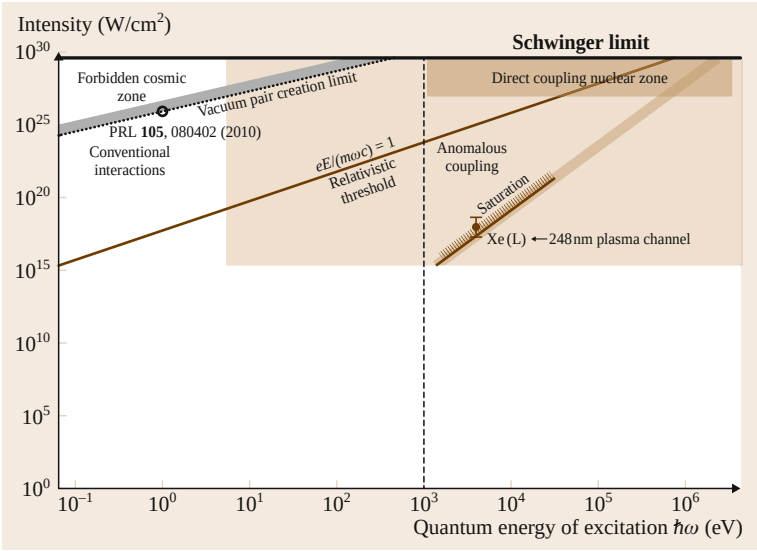

Fig. 11.187 Intensity-quantum energy interaction plane. Experimental data define a region of anomalous coupling that is designated by the *light brown shading*

4. The intensity point characterizing saturated amplification of the Xe(L) hollow atom system [11.1711–1724].

The quadrant of Fig. 11.187 that corresponds to the zone of anomalous coupling that is estimated to be free of the cosmic e^+/e^- cascade intensity limit [11.1720] is highlighted in Fig. 11.188. The lower boundaries are given roughly by

$$\hbar\omega > 1\,\mathrm{keV} \qquad (11.159)$$

and

$$I > 10^{15}\,\mathrm{W/cm^2}\,. \qquad (11.160)$$

This figure also designates a zone for intensities $I > 10^{27}\,\mathrm{W/cm^2}$ that is projected as a region in which nuclear reactions will be abundantly observed [11.1723, 1724].

Evidence for Nonlinear Coupling in the X-Ray Range. Simultaneous single-pulse x-ray pinhole images recording Xe(M) and Xe(L) emission, respectively, at ≈ 1 and ≈ 4.5 keV from 248 nm channels produced in a xenon cluster medium, give evidence for a strong nonlinear coupling of the Xe(M) radiation to unexcited clusters. The outcome of the strong Xe(M) production is the clear observation of both (11.158) subsequent spatially overlapping Xe(L) emission in the $\lambda \approx 2.8$ Å range and (11.159) heavily modified anomalous propagation of the Xe(M) radiation. The propagation, as shown in

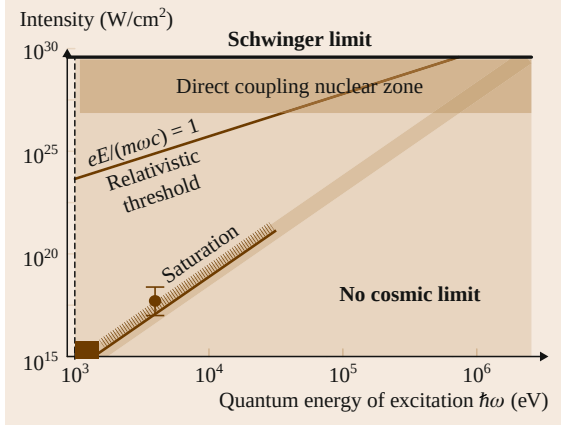

Fig. 11.188 Zone of anomalous interaction presented in Fig. 11.187 that is free of the cascade limit for intensities up to the Schwinger/Heisenberg value. The *small dark zone* indicated in the *lower left corner* refers to the Xe(M) experiments

Fig. 11.189, manifestly illustrates the phenomena self-focusing of the Xe(M) radiation. The Xe(L) signal presented in Fig. 11.190 reveals a spatially broad zone of Xe(L) emission well matching the area of Xe(M) emission, a fact that shows that this more energetic radiation is excited directly by the strong Xe(M) radiation. Specifically, the overall nonlinear absorptive process observed is

$$n\gamma(\mathrm{M}) \rightarrow \mathrm{Xe}^*(\mathrm{L}) \rightarrow \gamma(\mathrm{L})\,, \qquad (11.161)$$

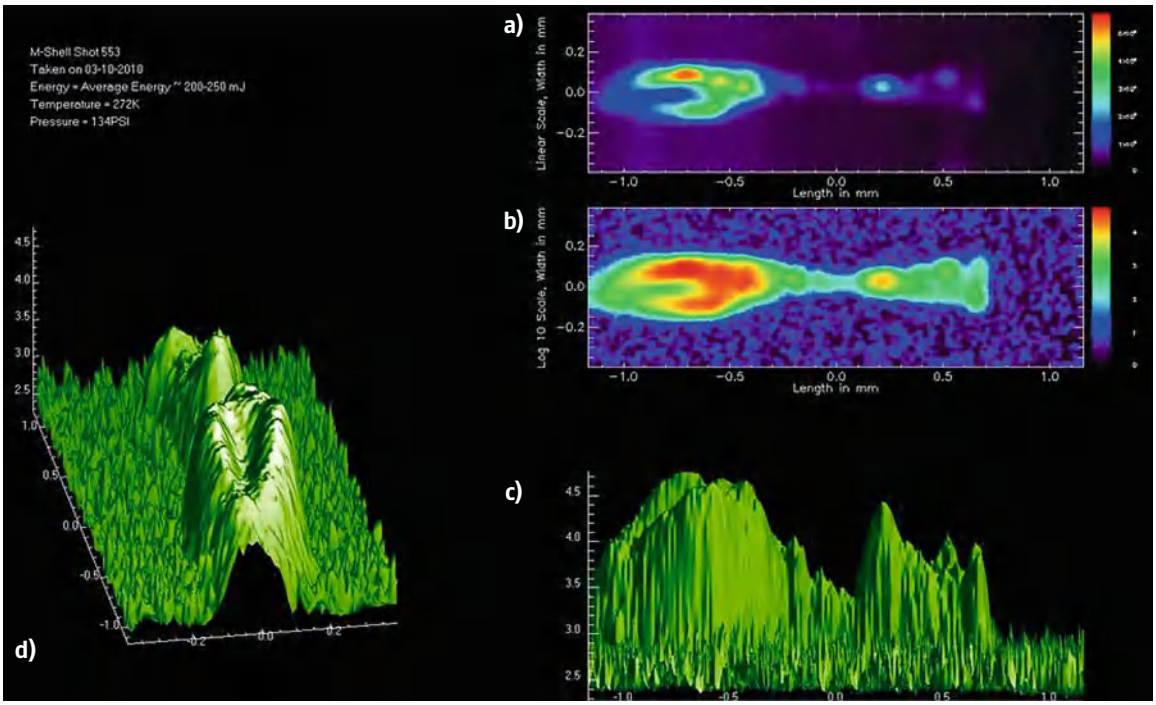

Fig. 11.189a–d Transverse image of Xe(M) radiation from the 248 nm channel region; the direction of the 248 nm propagation is *right* to *left*. **(a)** Linear scale of observed emission. **(b)** Log scale of observed emission. **(c)** Panel **(b)** presented as a pixel array. **(d)** Isometric view of panel **(c)** clearly illustrating the focusing collapse of the central zone as the Xe(M) beam propagates; downward in the image corresponds to increased distance of propagation, from *right* to *left* corresponding to panels **(a–c)**. Data from 10 March 2010, #553, Xe(M)

in which the minimum value of n is 5, based on the energies of the states involved. We note that, on the basis of the known threshold intensity of $\approx 2\times10^{17}\,\mathrm{W/cm^2}$ for the production of Xe(L) emission by 248 nm irradiation of xenon clusters [11.1725], the 248 nm power used in this experiment could not produce this required intensity over the large spatial scale of $\approx 400\,\mu\mathrm{m}$ in breadth observed for the Xe(L) signal.

The two observed nonlinear couplings, one dispersive and the other absorptive, as illustrated in Figs. 11.189 and 11.190, can be explained by the nonlinear Kramers–Krönig relation [11.1726]; the governing statement is

$$\Delta n(\omega;\zeta) = \frac{c}{\pi} P \int_0^\infty \frac{\Delta\alpha(\omega';\zeta)}{\omega'^2-\omega^2}\,\mathrm{d}\omega' \,. \qquad (11.162)$$

The direct comparison illustrated by the twin observations shown in Figs. 11.189 and 11.190 simply express both sides of (11.162). Estimates of the maximum intensity of the Xe(M) x-ray emission shown in Fig. 11.189 give values in the $\approx 10^{14}$–$10^{16}\,\mathrm{W/cm^2}$ region. This range of intensity falls in the anomalous interaction zone described above and is shown in Fig. 11.188 as the dark zone. The overall lesson is that, if the frequency is sufficiently high, an intensity of $\approx 10^{15}\,\mathrm{W/cm^2}$, or equivalent, possesses a radiative electric field E in the range

$$E \geq \frac{e}{5a_0^2} \,, \qquad (11.163)$$

the wave is sufficiently strong that the chief outcome is the induction of very strong nonlinear behavior.

Photon-Staging and the Schwinger Limit. The ability to produce stable self-channeled propagation of intense pulses of radiation in an underdense plasma is a well established phenomenon at quantum energies below $\approx 5\,\mathrm{eV}$ [11.1711, 1712, 1727–1735]. The observation [11.1712–1714, 1736–1739] of strongly saturated amplification on Xe(L) hollow atom transitions in the multikilovolt spectral region ($\approx 4400\,\mathrm{eV}$) at $\lambda_x \approx 2.71$–$2.93\,\mathrm{Å}$, with a peak spectral bright-

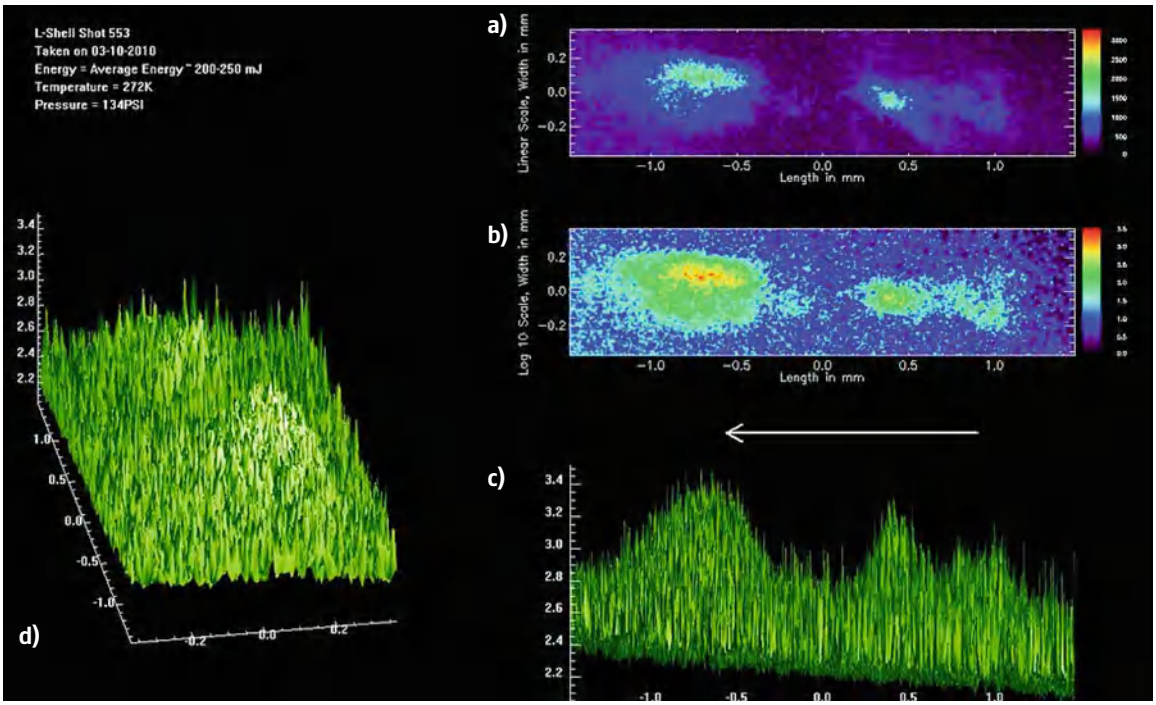

Fig. 11.190a–d Transverse images of Xe(L) radiation from the 248 nm channel that correspond spatially to the images shown in Fig. 11.189. The key finding is the large broad (≈ 400 μm) zone of Xe(L) emission presented in panel **(b)** that matches the pattern of Xe(M) emission illustrated in Fig. 11.189b. Data from 10 March 2010, #553, Xe(L)

ness of $\approx 10^{31}$–10^{32} photons $\cdot\, s^{-1} \cdot mm^{-2} \cdot mr^{-2}$(0.1% bandwidth)$^{-1}$, demonstrates the importance of the controlled compression of power ($\approx 10^{20}$ W/cm^3) enabled by the dynamic formation of these channels. Indeed, as an immediate consequence of this amplification, the availability of a high power source of coherent x-rays introduces the possibility of extending the generation of these highly confined stable modes of deeply penetrating propagation to x-ray wavelengths in materials at solid density. If such channels can be produced with multikilovolt x-rays in high-Z solids, the production of power densities on the order of $\approx 10^{30}$ W/cm^3 are projected [11.1723, 1724]. This value is sufficiently high that (a) copious electron/positron pair production and nuclear excitation are predicted and (b) the extension of coherent amplification to quantum energies approaching the MeV region can be reconsidered [11.1740] in an entirely new perspective.

The key concept for the production of ultrahigh intensities with x-rays is *photon staging*. Simply stated, this is the channeling process outlined in Fig. 11.191 elevated in both frequency ω and electron density n_e. The governing scalings are illustrated in Fig. 11.191;

- $\hbar\omega = 5\,\text{eV}\ (248\,\text{nm}) \longrightarrow \hbar\omega_x \cong 4500\,\text{eV}\ (2.8\,\text{Å})$
- $n_e \cong 10^{21}\,\text{cm}^{-3} \longrightarrow n_e \approx 10^{24}$–$10^{25}\,\text{cm}^{-3}$ (Solid)

Critical power scaling

$$P_{crit} = (m_{e,0}^2 c^5/e^2) \int_0^\infty g_0^2(\rho)\rho\,d\rho\,(\omega/\omega_{p,0})^2$$
$$\cong 1.6198 \times 10^{10}\,(\omega/\omega_{p,0})^2\,\text{W}$$

Outcome

$\omega \longrightarrow 10^3\omega$

$n_e \longrightarrow (10^3$–$10^4)\,n_e$

- $P_{crit} \cong 1\,\text{PW}\ (2.8\,\text{Å}) \longrightarrow 10\,\text{mJ in} \approx 10\,\text{as}$

Fig. 11.191 *Photon staging*, channel formation in solids with x-rays. Enormously enhanced power compression is the leading outcome

basically, it is the channeling of x-rays in solids, a phenomenon that raises the critical power P_{crit} to values in the range of ≈ 0.1–1 PW. We will see that since the plasma density is $n_e \approx 10^{24}$–10^{25} cm^{-3}, the corresponding channel diameters are compressed to ≈ 100 Å.

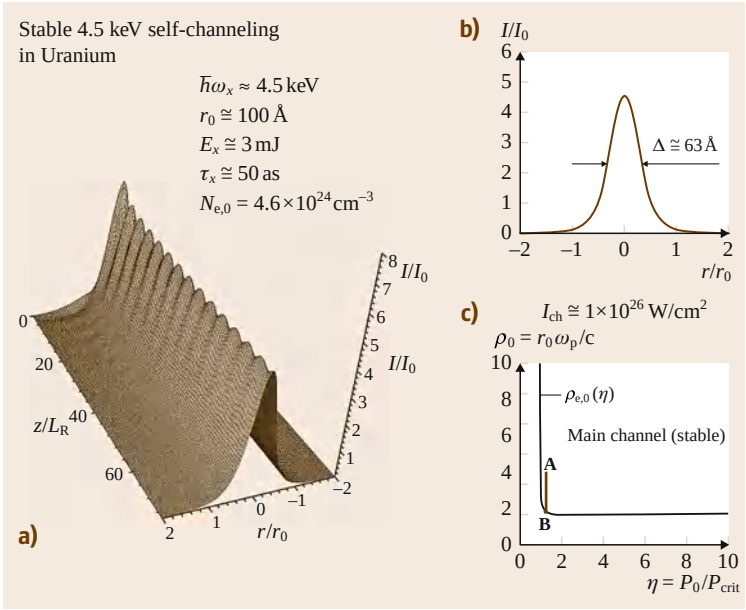

Fig. 11.192 **(a)** Computed evolution in solid U of the incident beam, designated by point A in panel **(b)**, to the eigenmode $\rho_{e,o}(\eta)$, denoted by point B in panel **(b)**. A pulse energy $E_x \cong 3$ mJ and a pulse width $\tau_x \cong 50$ as are assumed for this calculation. The parameter r_0 designates the radius of the incident pulse. The incident power P_0 is ≈ 60 TW and the medium is assumed to be fully ionized with an electron density $N_{e,0} = 4.6\times10^{24}$ cm^{-3}. The critical power for these conditions is $P_{crit} \cong 47$ TW giving $\eta \cong 1.78$. The pulse evolves to point B in a distance of approximately 60 Rayleigh ranges ($Z/L_R \cong 60$). For these conditions, the Rayleigh range corresponds to $L_R \cong 0.25\,\mu$m. **(b)** Stability map corresponding to the relativistic/charge-displacement mechanism [11.1728, 1732]. The incident pulse, point A, evolves in the zone of stability to point B on the eigenmode $\rho_{e,o}(\eta)$. **(c)** The transverse profile of the channeled x-ray pulse at point B gives the characteristic width of the channel $\Delta \cong 63$ Å. This value yields a corresponding propagating intensity $I_{ch} \approx 1.0\times10^{26}$ W/cm^2

At the wavelength $\lambda_x \approx 2.9$ Å, for which the critical electron density is $n_{crit} = 1.33\times10^{28}$ cm^{-3}, all fully ionized condensed matter is underdense, including uranium. The key requirement [11.1727, 1728] for the production of a channel in the underdense regime is the generation of a peak power P_0 exceeding the critical power P_{crit} necessary for the development of the confined propagation with the relativistic/charge-displacement mechanism. This critical power P_{crit} represented in Fig. 11.191 is given by

$$P_{crit} = \left(m_{e,0}^2 c^5/e^2\right)\int_0^\infty g_0^2(\rho)\rho\,d\rho(\omega/\omega_{p,0})^2$$
$$= 1.6198\times10^{10}(\omega/\omega_{p,0})^2\ \text{W}\,. \qquad (11.164)$$

In (11.164), $m_{e,0}$, c, and e have their standard identifications, $g_0(\rho)$ is the Townes mode [11.1737] representing the lowest eigenmode for cubic Kerr self-focusing, and ω, $\omega_{p,0} = \left(4\pi e^2 N_{e,0}/m_{e,0}\right)^{1/2}$ denote the angular frequency corresponding to the propagating radiation and the angular frequency of the unperturbed plasma at electron density $N_{e,0}$. The stability of the propagation is assured by the existence of a robust eigenmode [11.1727, 1728, 1732]. For the case of $\lambda_x \cong 2.9$ Å and fully ionized uranium, (11.164) gives $P_{crit} \cong 47$ TW. With a pulse length $\tau_x \approx 50$ as, a value that is well within the projected performance [11.1725, 1741, 1742] of the Xe(L) system, the critical power corresponding to uranium can be achieved with a pulse energy as small as $E_x \approx 3.0$ mJ, as shown in Fig. 11.192. A stable pulse configuration is formed on the eigenmode with a characteristic diameter $\Delta \cong 63$ Å and a propagating intensity $I_{ch} \approx 1\times10^{26}$ W/cm^2.

The power scaling properties of these channels are summarized in Fig. 11.193. Detailed calculations of the propagation of Xe(L) radiation in uranium channels shows that a power of ≈ 300 PW is sufficient to reach

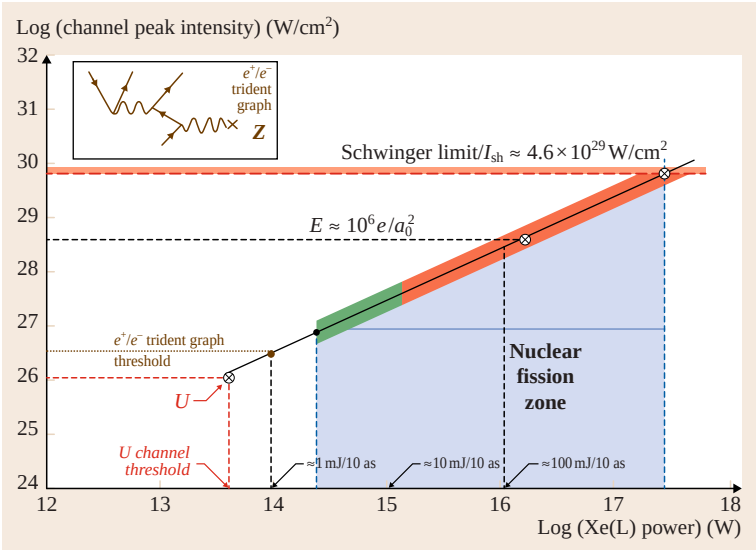

Fig. 11.193 Projected power compression in solid-state channels. A value of Xe (L) power of ≈ 300 PW in a U channel is indicated as sufficient to reach an intensity corresponding to the Schwinger limit of $\approx 4.6\times10^{29}$ W/cm^2

the Schwinger limit of $\approx 4.6\times10^{29}$ W/cm^2. It can be shown that the total energy required for the 248 nm driver technology is ≈ 1.5 J, a value that can be attained with the utilization of KrF* technology at its present level of development.

We conclude that an intensity of the magnitude of the Schwinger limit can be attained and that the basic physical scaling of coherent x-ray sources greatly favors the use of x-rays. This achievement will test the basic character of the concept of space, one of the fundamental pillars of theoretical physics.

In summary, it has been shown that the organized study of high-intensity interactions with ultraviolet excimer lasers on atoms, molecules, and plasmas over the last 20 years culminated in the ability to produce new forms of matter that are both highly excited and highly ordered [11.1706, 1723, 1736]. A leading consequence is the capacity to achieve saturated x-ray amplification in the multikilovolt regime to peak brightness figures sufficient for the implementation of new modalities of microimaging [11.1712]. Basically, the amplification proceeds through the creation of a highly ordered excited state [11.1723, 1727] that is comprised of four mutually coupled components; namely, atomic (ionic) matter, plasma electrons, and two coherent radiative fields, specifically, the ultraviolet and x-ray waves. The chief consequence is energy flow conducted through a radiation dominated interaction that is confined to a small phase space volume. Based on experimental results that establish the power scaling of the Xe(L) system, the achievement of an intensity approaching the Schwinger limit is presently feasible.

11.7.5 Outlook: Radiation in the EUV

The roadmap of the semiconductor industry (Fig. 11.178) shows in which way computer chips with critical dimensions of 32 nm and below are planned to be manufactured; light sources with emission in the extreme ultraviolet (EUV) at 13.5 nm wavelength will be used. EUV lithography is considered as the next generation lithography (NGL) to be established after reaching the physical limits of ultraviolet (immersion) lithography based on ArF excimer lasers.

13.5 nm Technology

EUV with 13.5 nm wavelength has been selected for future semiconductor lithography technology. After the establishment of this technology in the industrial environment through EUV microexposure tools in 2003, those tools are still under operation for technology development and feasibility studies (Fig. 11.194).

The next tool generation on the alpha level was installed in 2007 at four different sites world wide (Fig. 11.195). Those tools were provided from the scanner manufacturers Nikon and ASML. The source technology in all tools is based on gas discharge produced plasmas, and two target materials were used, xenon and tin [11.1743, 1744].

One of the biggest challenges concerning the introduction of EUV lithography is the development of

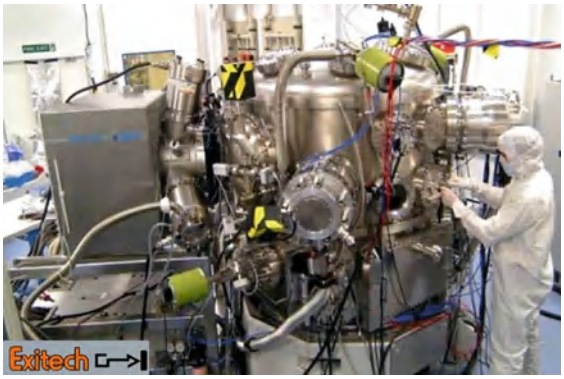

Fig. 11.194 EUV microexposure tool from Exitech with an integrated EUV source from XTREME Technologies (*left*)

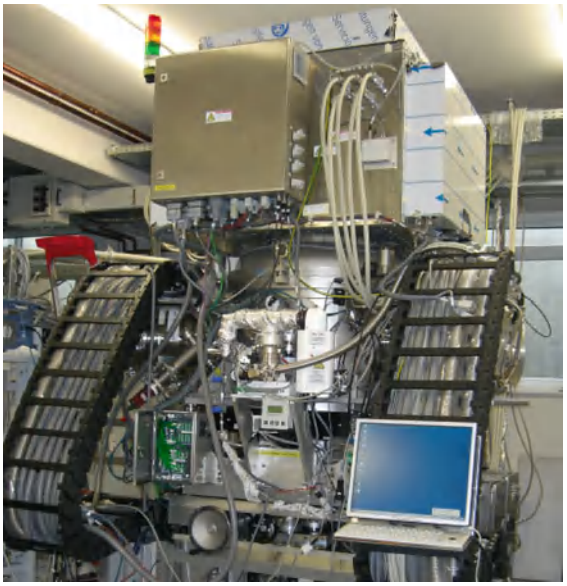

Fig. 11.195 EUV sources on alpha level are integrated into lithography tools at four different sites worldwide

high-power EUV sources at a reasonable cost. Making the operation of the photolithography manufacturing tools economically viable requires a source with several 100 W power at the 13.5 nm exposure wavelength measured in the so called intermediate focus behind the first collector optics. In addition, the optical design of the collector optics sets limits to the source size, i. e., an emission volume of a few cubic millimeters. Only the combination of both the high power and small emission volume will enable high optical efficiency and, therefore, high wafer throughput. The goal is the development and manufacturing of these high-power EUV

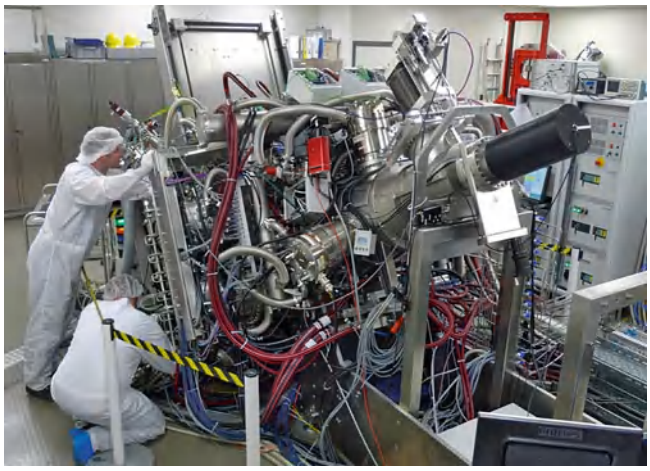

Fig. 11.196 Beta tool source collector module (SoCoMo) before integration into a scanner

sources as well as their integration into the optical system of the photolithography tool. Whereas sources for the microexposure tool deliver usable EUV power below 1 W, alpha tool sources provide up to 10 W. Sources for beta tools are already able to produce more than 30 W EUV power at intermediate focus (Fig. 11.196).

Plasmas are known as efficient emitters of 13.5 nm EUV radiation presuming that their temperature reaches about 200 000 °C, i. e., approximately 35 times higher than at the surface of the sun. Plasmas can be generated either by an electrical discharge or by means of pulsed laser excitation. Both methods are able to generate small plasma volumes fulfilling the technical requirements of photolithography [11.1745, 1746]. The spatial homogeneously emitted radiation from such plasmas is pulsed with lengths in the nanosecond range (typically). The distribution of the wavelength spectrum is narrow from elements with low atomic numbers and broad from elements with high atomic numbers. In addition, the radiation is almost fully incoherent as from a thermal Planck emitter.

Presently the highest EUV power is achieved in so-called *pinch plasma* sources. However, the heat load on the configuration of the static electrodes can lead to fast erosion and even melting of the surfaces, thereby limiting the power scaling through increasing repetition rates. Alternative technologies with moving electrodes have been investigated and finally a potential solution with rotating disc electrodes (RDE) has been found. A new excitation scheme has been applied to this technology at Xtreme Technologies resulting in a world record (170 mJ/2πsr) of the achieved EUV

pulse energy [11.1747]. This effect resulted in a reasonable repetition rate to fulfill the power requirements of high volume manufacturing tools. Further development efforts will be directed towards combining the power scaling capability with the reliability goals of this concept.

11.8 Dye Lasers

11.8.1 Overview

Laser action from dye molecules was first observed in 1966 by *Sorokin* and *Lankard* [11.1748], and then by *Schäfer* et al. [11.1749]. The distinctive feature of dyes as lasing media is their broad emission with a typical bandwidth of 50–60 nm. Compared to the gas and solid-state lasers of the 1960s, dye lasers easily excelled both in terms of broad spectral coverage and in versatility of output performance (viz. high per-pulse energy output, long or short pulse operation, flashlamp, or laser pumping). Researchers quickly recognized the wavelength tuning capability of dye lasers, which is probably one of the most important operation characteristics in view of applications. In the following years, literally hundreds of organic dyes with emission spectra from the near ultraviolet to the near infrared (300–1200 nm) have been made to lase. Continuous-wave (CW) or ultrashort pulse (femtoseconds) operation of dye laser was also demonstrated. With their broad spectral coverage and narrow linewidth tunability, dye lasers have been the workhorse in scientific laboratories for applications ranging from fundamental physics to clinical medicine. In this regard, liquid dye lasers continue to be quite attractive for various important applications such as atomic vapor laser isotope separation (AVLIS) [11.1750–1752] and laser guide stars at large terrestrial telescopes [11.1753]. This is despite the fact that many, particularly in popular magazines, predicted the demise of the dye laser back in the early 1990s. Apparently, that attitude was fueled by anecdotal stories of dye laser incidents during operation. The reality is that with good engineering and proper laboratory practices, dye lasers are superb and reliable sources of tunable coherent emission. An excellent example of operational reliability was provided by the multi-kW (average power) copper-vapor laser-pumped dye laser system built for AVLIS applications at Lawrence Livermore [11.1750]. Indeed, all-stainless-steel and Teflon dye flow systems can readily provide sealed systems impervious to practitioner error. A flashlamp-pumped dye laser system, using such flow engineering, was constructed in an all-invar structure providing very stable narrow linewidth oscillation, at $\Delta\nu \approx 300$ MHz, and nearly diffraction limited laser beams [11.1754]. This ruggedized narrow-linewidth dye laser was tested using vehicular displacement over a rugged terrain, passing the test with flying colors. Despite the introduction of solid-state tunable laser systems, today there are many loyal practitioners of liquid dye lasers and these lasers continue to be developed and improved [11.1755]. This loyalty is a tribute to the efficient emission of visible laser tunable radiation, the versatile output performance of these liquid lasers, and the simplicity of the technology involved in constructing a liquid dye laser. In this regard, almost any research lab can put together the necessary elements to build a pulsed liquid dye laser. There are, of course, numerous commercial user-friendly and powerful liquid dye lasers available. Here, we give a short description of the characteristics of liquid dye lasers and then discuss several types that are commonly found in research laboratories for photophysical, photochemical, and spectroscopy applications. Next, this review focuses on solid-state dye lasers.

11.8.2 General Description

Dyes are organic compounds that contain conjugate double bonds. The presence of the conjugate double bonds renders these compounds optically active. There are over 200 laser dyes that can, in principle, provide spectral coverage from 320–1200 nm [11.1756]. The tuning range of each dye is 40–60 nm. When used sequentially, continuous tunable laser action can be obtained from the near ultraviolet to the near infrared. Typically a strongly absorbing and strongly emitting dye is dissolved in a suitable solvent (such as ethanol, methanol, ethanediol, or ethanol-water mixtures) at concentrations of 10^{-3}–10^{-4} molar to serve as the gain medium. A flashlamp or a laser is used as the pump. Powerful coaxial flashlamp-pumped rhodamine 6G dye lasers can deliver laser energy up to 400 J per pulse [11.1757]. Average output powers of up to 1.2 kW in burst mode have been obtained in a flashlamp-pumped dye laser by *Morton* and *Dragoo* [11.1758]. On the other hand, copper vapor laser pumped dye

laser systems, for AVLIS, have demonstrated 2.5 kW *average power* at a pulse repetition frequency of 13.3 kHz [11.1750]. Additional lasers used as excitation sources of dye lasers include, excimer, nitrogen, or frequency-multiplied Nd:YAG lasers. A saturable absorber (another dye) is used to passively mode-lock the dye laser to generate pulses of about 200 fs without dispersive elements and down to tens of fs with dispersive optical elements [11.1759]. For applications that require single-longitudinal-mode laser output, CW operation of dye lasers is achieved by using a modified flow system to remove the long-lived triplet state of the dye molecule. The linewidth of a free-running jet-stream CW dye laser can be as low as 2 MHz [11.1760]. In the following sections, we discuss several common dye laser arrangements.

11.8.3 Flashlamp-Pumped Dye Lasers

A flashlamp was the pump source for Maiman's ruby laser. Today's flashlamps are still used to pump liquid and solid-state lasers. Linear flashlamps are often the choice for laser pumping and usually consist of a tubular quartz envelope sealed by tungsten electrodes at both ends. The tube is often filled with a heavy rare gas (e.g., xenon or krypton) for high electrical-to-optical conversion efficiency. Still much of the electrical power ends up as heat, which requires a cooling system for its removal. Often, an elliptical reflector is used to focus the output from the flashlamp into the dye cell. For optimum coupling of the light from the flashlamp into the dye, the dye cell must be placed close to the lamp. Coaxial lamps have emitting surfaces that completely surround the flowing dye. Figure 11.197 shows a coaxial flashlamp-pumped dye laser, a structure commonly employed in many commercial dye as well as solid-state lasers. The dye cell is set at the center of the coaxial, cylindrically shaped xenon flashlamp for optimal pumping. Two broadband mirrors provide the optical feedback. Such a flashlamp-pumped dye laser typically produces a broadband emission (about 10 nm linewidth) centered at the peak of the gain profile with a pulse duration of 1–2 μs. The output energy is about 100 mJ for typical commercial flashlamp-pump dye lasers. Figure 11.198 shows the super-invar structure of the ruggedized narrow-linewidth, $\Delta\nu \approx 300$ MHz (that is, $\Delta\lambda \approx 0.00035$ nm at $\lambda \approx 590$ nm), flashlamp-pumped dye laser mentioned earlier [11.1754]. The multiple-prism grating configuration used to induce narrow-linewidth lasing is visible at one end of the cavity. An authoritative review of flashlamp-pumped dye lasers is given by *Everett* [11.1761].

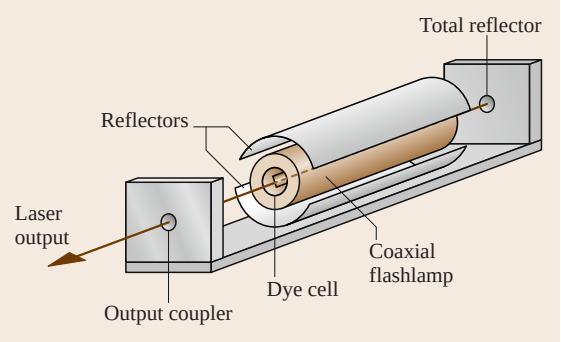

Fig. 11.197 Schematics of a coaxial flashlamp-pumped dye laser

11.8.4 Narrow-Linewidth High-Power Tunable Dye Lasers

By incorporating wavelength-selective elements inside the resonator cavity, dye laser output can be tuned at will. Excimer, nitrogen, copper-vapor, frequency-multiplied Nd:YAG, or diode lasers are used to pump dye lasers. Excimer, nitrogen, and frequency-multiplied Nd:YAG lasers all provide high peak pump power (peak power of several MW) at various wavelengths, making them highly suitable for pumping dye lasers. Dye lasers pumped by high-power UV-visible lasers exhibit such high gain that the loss introduced by the additional wavelength-selective elements inside the resonator cavity can be easily overcome. Either prisms, diffraction gratings, or multiple-prism grating arrangements can

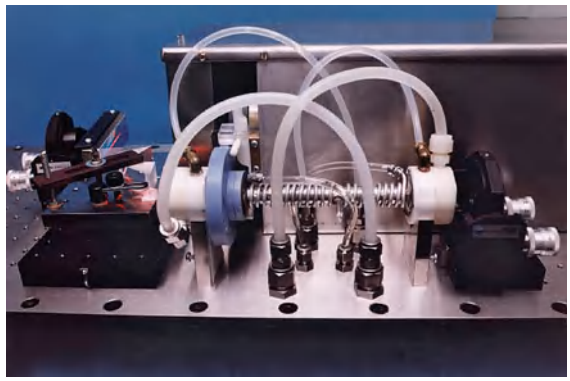

Fig. 11.198 Photograph of the ruggedized coaxial flashlamp-pumped narrow-linewidth multiple-prism grating dye laser oscillator engineered in an all-invar structure. The excitation flashlamp is coaxial (after [11.1754])

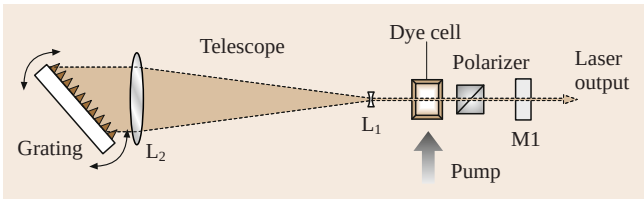

Fig. 11.199 Schematics of a Hänsch-type cavity dye laser. A telescopic lens is used to improve the spectral resolving power of the grating

be used for wavelength selection. Figure 11.199 shows a variant of the telescopic grating resonator originally used by *Hänsch* [11.1762] for the generation of narrow-linewidth laser output. A nitrogen laser provided the pumping. The use of the telescopic expander increases the number of grooves illuminated by the laser light and reduces the light intensity on the grating, preventing damage to the coating on the grating surface. The linewidth of an optimized telescopic-grating cavity dye laser can be as narrow as 0.003 nm [11.1762]. To further reduce the linewidth an intracavity etalon (e.g., a coated optical flat or air-spaced Fabry–Pérot cavity) is introduced between the telescope and the grating. Other alternatives to attain tunable narrow-linewidth emission include the grazing-incidence grating cavities of *Shohan* et al. [11.1763], or *Littman* and *Metcalf* [11.1764], and the multiple-prism near gazing-incidence grating oscillators introduced by *Duarte* and *Piper* [11.1765, 1766] (Fig. 11.200). These dispersive oscillator configurations yield laser linewidths as narrow as $\Delta\lambda \approx 0.0007$ nm [11.1766] and became the configuration of choice in the field of efficient copper-vapor laser pumped narrow-linewidth dye lasers [11.1767]. Eventually the various narrow-linewidth oscillator configurations mentioned here became key advances in the development of tunable narrow-linewidth lasers in general and were later adopted in gas lasers [11.1768], solid-state lasers [11.1769], and diode lasers [11.1770]. A detailed review of telescopic, grazing-incidence, and multiple-prism grating laser oscillators is given in [11.1771].

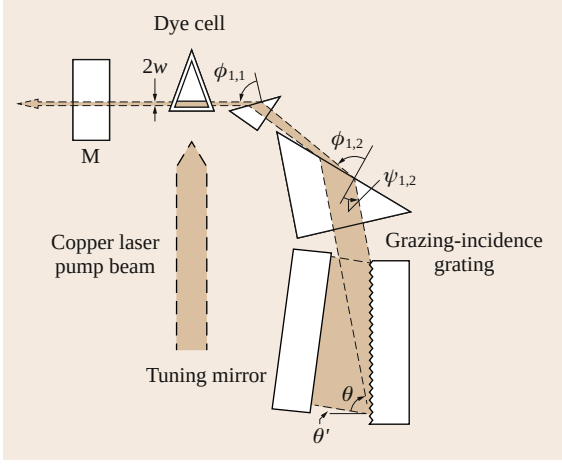

Fig. 11.200 Schematics of the multiple-prism near grazing-incidence, narrow-linewidth dye laser oscillator (after *Duarte* and *Piper* [11.1765, 1766])

Narrow-linewidth high-power tunable dye lasers exist in various forms and usually they involve oscillator-amplifier systems. One particular system is that described by *Dupre* [11.1772] that uses a *Duarte–Piper* type oscillator followed by two amplification stages. In a low repetition mode this laser yields pulses with more than 3.5 mJ per pulse, for a 5 ns (FWHM) pulse duration, which translates to approximately 700 kW per pulse. The laser linewidth reported by *Dupre* [11.1772] was $\Delta\nu \approx 650$ MHz. A second class of oscillator-amplifier system, that operates at a high-pulse repetition frequency (≈ 13.2 kHz), also uses a prismatic narrow-linewidth oscillator and several (3–4) stages of amplification [11.1750]. This system yields laser linewidths in the 500 MHz–5 GHz range at average powers approaching 2.5 kW [11.1750].

At this stage, it is relevant to mention that both laser efficiency and dye lifetime are greatly improved by using excitation lasers whose emission wavelength match the main absorption spectral region of the dye molecules. For example, for the copper-laser pumped multiple-prism grating oscillators *Duarte* and *Piper* [11.1766] report laser efficiencies in the 4–5% range, for $\Delta\nu \approx 650$ MHz at $\lambda \approx 575$ nm (that is $\Delta\lambda \approx 0.0007$ nm), an efficiency which is fairly optimum for dispersive narrow-linewidth oscillators. In the case of copper-laser pumped oscillator-amplifier systems, emitting in the same spectral region, the efficiency can be greater than 50% [11.1750].

11.8.5 Colliding-Pulse Mode-Locked Dye Lasers

The broad emission band of a dye can be used effectively to generate ultrashort laser pulses, since the theoretical limit of the ultrashort-pulse duration supported by the gain medium is proportional to the inverse of the gain bandwidth. As the emission bandwidth of many laser dyes is 40–60 nm, pulse durations down to tens of fs can be produced. The development of passive

mode-locking is essential for the successful demonstration of femtosecond pulse generation in dye lasers. In passive mode-locking, a saturable (nonlinear) absorber (an absorbing dye) with an absorption that matches the emission wavelength of the lasing dye is placed inside the resonator cavity. Ideally, the leading and trailing edges of the optical pulse are removed by the absorber whilst the peak of the pulse, unaffected by the absorber, experiences amplification. The efficiency of the absorber increases considerably if two oppositely traveling pulses interact or collide in the saturable absorber at the same time (colliding-pulse mode locking). This is a result of the two coherent pulses interfering constructively, leading to the reduction of power required for the saturation of the absorber. The colliding-pulse mode-locking configuration can be realized in either a linear or ring cavity. Because of the ease of alignment, the ring cavity is often preferred. Using this type of cavity *Fork* et al. demonstrated the emission of pulses shorter than 100 fs [11.1773]. Figure 11.201 shows a ring laser configuration, including a single-prism pulse compressor, similar to that introduced by *Dietel* et al. [11.1774] to demonstrate laser pulses shorter than 60 fs. Subsequently, *Fork* et al. [11.1775] introduced a four-prism pulse compressor that became rather popular. The multiple-prism dispersion theory applicable to prismatic pulse compression was introduced by *Duarte* [11.1776]. Both the laser dye (e.g., rhodamine 6 G) and the absorbing dye (e.g., DODCI) are in the form of a flowing jet, and a CW argon-ion laser serves as the pump. The radii of curvature of the mirrors must be carefully chosen so that the spot size in the absorber is smaller than that in the gain medium to assure pulse-forming stability.

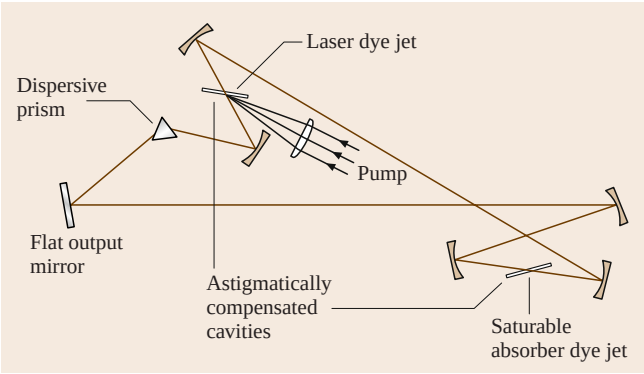

Fig. 11.201 Schematic of a colliding-pulse dye laser, including prismatic pulse compression [11.1774], for ultrashort-pulse generation

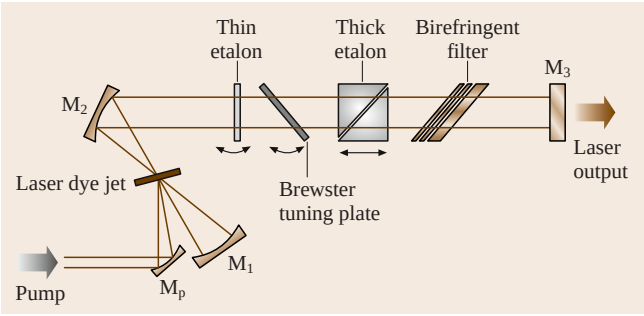

Fig. 11.202 Schematic of a linear-cavity CW dye laser for single-mode operation

11.8.6 Tunable Continuous-Wave Dye Lasers

The linewidth of well-designed tunable pulsed dye lasers with intracavity dispersive element for narrow-linewidth operation are of the order of 300–700 MHz. In contrast, due to inherent advantages, a continuous-wave dye laser is capable of delivering laser output with linewidths as narrow as tens of kHz. The high resolving power is ideal for fine spectroscopy. Such high performance is facilitated by sophisticated designs and high-power pump sources (such as a CW argon-ion laser with 10–20 W output power). Additional excitation lasers for CW dye lasers are Kr-ion lasers and diode lasers. Continuous-wave dye lasers have much lower gain than their pulsed counter parts. The loss reduction becomes critical and the removal of the long-lived triplet state is crucial for the stable operation of the laser. A flowing jet is used to induce rapid circulation of the dye. Since the gain profile of most dyes may be regarded as homogeneously broadened, one might expect single longitudinal-mode output from a simple grating or prism-cavity CW dye laser. However, single longitudinal-mode operation may not be possible in such linear-cavity dye lasers without intracavity frequency-selecting elements because spatial hole burning can give rise to gain saturation by the standing wave. Multimode output then results. Additional frequency-selecting elements such as an etalon must be inserted inside the cavity for single-mode operation increasing losses and lowering output power. Figure 11.202 shows a linear (standing-wave) cavity arrangement for a CW dye laser end-pumped by an argon-ion laser for single-mode operation. The dye jet flows perpendicularly to the page. The etalons assure narrow-linewidth output. The birefringent filters are for wavelength tuning. A ring-cavity supports the propagation of traveling waves and thus is ideal for single-mode

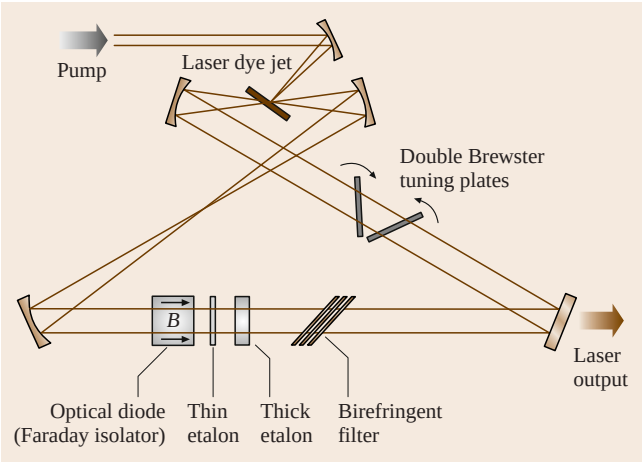

Fig. 11.203 Schematic of a ring-cavity CW dye laser for single-mode operation. Note the use of an optical diode to assure unidirectional propagation of the traveling wave

operation. Figure 11.203 shows a tunable single-mode ring laser supporting single-mode operation. The optical diode (a Faraday isolator) ensures unidirectional traveling waves, thus avoiding spatial hole burning. An authoritative and extensive review on CW dye lasers is given by *Hollberg* [11.1777].

11.8.7 Advanced Solid-State Dye Lasers

The contribution of liquid dye lasers to the advance of laser technology, particularly to ultrafast laser technology and the many applications of tunable lasers, cannot be overstated. Interested readers should consult monographs such as *Dye Lasers* by *Schäfer* [11.1778] or *Dye Laser Principles* by *Duarte* and *Hillman* [11.1779] and references therein for more detailed information on the range of applications of dye lasers. The excellent output performance (as mentioned in the last paragraph) notwithstanding, support for dye lasers declined among some users. Regardless of the merit, the liquid form of the gain medium was often criticized, albeit this very feature is what enables dye lasers to yield reliable kW average powers [11.1750, 1758]. As it turned out in the early 1990s, the position of dye lasers as the leading tunable laser was challenged by tunable crystalline solid state lasers (most notably the Ti^{3+}:Al_2O_3 or titanium: sapphire laser) [11.1780], optical parametric oscillators (OPO) [11.1781], and external cavity semiconductor, or external cavity diode, lasers [11.1782, 1783]. Here it should be noted that all these sources have their own strengths and weaknesses (in regard to power characteristics, energy characteristics, spectral region, optical ruggedness, configurational simplicity, etc.) and that it is often the application itself that selects a preferred particular source. In this regard, a perspective of *complementarity* [11.1784], rather than a posture of competition, is the rational and practical approach to this subject and is what is largely observed at present. Nevertheless, the rush toward the solid-state, in the early 1990s, revived the interest in *solid-state* dye lasers.

Challenges and Opportunities

Solid-state dye lasers (SSDL) incorporating the dye molecules in solid matrices appear to be able to combine the cost-effectiveness of liquid dye lasers and the convenience of inorganic solid-state lasers. However, in order for SSDL to be a serious competitor to inorganic solid-state lasers in various fields of applications, the issue of photodegradation must be neutralized.

Good progress has been made in SSDL performance [11.1785] and in the synthesis of photostable dyes. The recently synthesized perylene family [11.1786] and the pyrromethene family [11.1787] of laser dyes have been shown to outperform rhodamine-6G in efficiency, tunability and photostability. Equally important to the development of SSDL are the solid-state matrices that serve as host materials where there has also been impressive progress. In the 1980s *Avnir* et al. [11.1788] and *Gromov* et al. [11.1789] demonstrated dye-doped sol-gel materials and dye-doped polymeric materials, respectively, as promising laser media. Both sol-gel materials and polymeric materials were shown to have good chemical stability and wide optical transparency for use as host materials for laser dyes. The pace of research activity has increased considerably since then. In the sections to follow, we bring the reader up to date with recent developments in solid-state dye lasers. The state of the art of solid-state dye lasers based on pure and hybrid sol-gel materials and on advanced polymers is covered in the next section. Widely used solid-state dye lasers may be polymeric [11.1790] or sol-gel [11.1791] waveguide lasers using a distributed feedback configuration. These compact lasers produce tunable narrow-linewidth output and appear to be readily integrable into planar optical circuits. This is covered in the penultimate section. Finally the topic of tunable upconverted DFB dye lasers is presented.

Solid-State Dye Lasers Based on a Polymer Host

In 1967, 1 year after the demonstration of the first liquid dye lasers, *Soffer* and *McFarland* observed

lasing in rhodamine-doped poly(methyl methacrylate) (PMMA) [11.1792]. The first polymeric hosts suffered from large thermal coefficients, stress birefringence, optical inhomogeneity, and chemical reactivity with laser dyes. The most serious problem of dye-doped polymers is the tendency of aggregation of dye molecules, which effectively quenches fluorescence. As a result, the performance of the initial solid-state dye lasers was less than satisfactory. The properties of PMMA can, however, be improved by purification of the monomer, by introducing alcohol additives [11.1788] and can be modified through copolymerization with a low molecular-weight polymer [11.1793]. The result is an improved polymer: modified poly(methyl methacrylate) (MPMMA) with excellent optical homogeneity and chemical stability suitable for use as a solid-state dye laser host [11.1794]. Broadband emission laser efficiency for rhodamine-doped MPMMA was reported by *Maslyukov* et al. [11.1795] to be as high as 60% under laser excitation at 532 nm. Work on the development of new polymeric hosts has been very active. *King* and coworkers showed that the photostability of solid-state dye lasers can be enhanced by deoxygenation of the host [11.1796] and the addition of a triplet-state quencher [11.1797]. Following the idea that photodegradation of dye molecules can be reduced by increasing the rigidity and hence the rate of heat dissipation of the host matrix, *Costela* et al. [11.1798] prepared pyrromethene dye-doped copolymers of methyl methacrylate (MMA) and different methacrylic and acrylic crosslinking polymers. The combined use of a photostable dye and new polymeric hosts results in SSDLs that boost the lifetime exceeding 10^6 shots at a repetition rate of a few Hz when pumped at 532 nm. Narrow-linewidth oscillation, with a laser linewidth of $\Delta\nu \approx 1.12$ GHz ($\Delta\lambda \approx 0.0013$ nm at $\lambda \approx 580$ nm), was achieved for the first time in solid-state dye lasers by using a dye-doped MPMMA in a multiple-prism grating resonator cavity [11.1794].

Subsequently, using a rhodamine-doped MPMMA gain medium, in an optimized multiple-prism grating laser oscillator *Duarte* [11.1785] demonstrated single-longitudinal-mode laser oscillation at linewidths as narrow as $\Delta\nu \approx 350$ MHz ($\Delta\lambda \approx 0.0004$ nm at $\lambda \approx 590$ nm), in near-Gaussian temporal pulses $\Delta t \approx 3$ ns (FWHM), which indicates a performance near the limit allowed by *Heisenberg's uncertainty principle*. The optical efficiency of this optimized oscillator configuration (shown in Fig. 11.204) is quoted at 5% with a peak laser power in the kW regime. This remains the best reported laser performance in the field of tunable narrow-linewidth solid-state organic lasers.

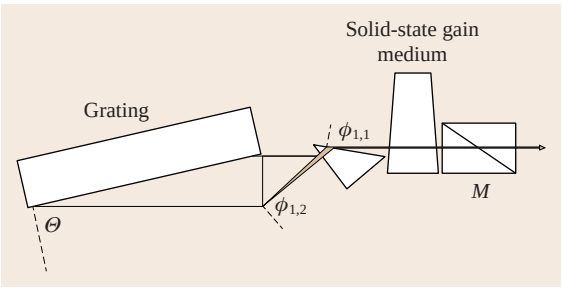

Fig. 11.204 Schematics of the optimized narrow-linewidth, multiple-prism grating, solid-state tunable laser oscillator (after *Duarte* [11.1785])

Solid-State Dye Lasers Based on Organic-Inorganic Matrices

The organic-inorganic gain media include the dye-doped sol-gels, organically modified silicates, and organic-inorganic nanomaterials. The sol-gel method is a low-temperature glass-making technique that enables the introduction of organic dyes into inorganic glasses. Porous glass can be obtained via the sol-gel route by hydrolysis and polycondensation of metal alkoxides [11.1799]. Initial studies of sol-gel silica doped with organic dyes indicated that sol-gel materials held good promise as SSDL host materials because of their wide transparency range and the apparently excellent optical and thermal properties of silica [11.1788]. An added advantage is the high concentration without aggregation and the photostability of a dye when trapped in sol-gel silica, as a result of the isolation of dye molecules in the silica cage. Soon tunable laser action from sulforhodamine-doped sol-gel silica was demonstrated [11.1800]. Lasing and fluorescence properties of a large number of dyes in sol-gel silica that cover the spectral range from the near ultraviolet to the near infrared were fabricated and examined [11.1801]. Several variants of sol-gel materials have been used as solid-state dye-laser host materials with varying degree of success. The first sol-gel material used in dye-laser experiments was, in fact, a glassy gel obtained by the gelation of a solution and is sometimes called a xerogel [11.1802]. Xerogel derived from inorganic precursors is mechanically fragile and optically lossy due to the presence of numerous pores. The use of organically modified precursors or organic modifiers during the sol-gel process results in organically modified silicates (ORMOSILs) that show

improved mechanical strength and much reduced optical loss [11.1794, 1796]. The combined use of the improved sol-gel materials as host and the deoxygenation procedures during sample preparation has lead to sol-gel dye lasers with lifetime exceeding one million shots [11.1803].

One of the attractions of sol-gel materials is the potential that such glassy materials can have properties similar to glasses made via the traditional high-temperature approach. Another attraction is the ability of sol-gel materials to trap both organic and inorganic dopants while showing exceptional chemical stability. Whilst very few polymeric dye lasers work in the blue to near-UV range due to problems related to attenuation and photostability under UV excitation, several UV laser dyes have been doped into sol-gel materials [11.1805, 1806]. Laser action with output wavelengths as short as 340 nm have been observed [11.1806].

An additional class of solid-state organic-inorganic gain media is the dye-doped polymer-nanoparticle matrices introduced by *Duarte* and *James* [11.1807]. This approach uses uniform distributions of SiO_2 nanoparticles (of about 10–12 nm in size) in PMMA to improve the $\partial n/\partial t$ of the dye-doped organic-inorganic matrix so as to reduce beam divergence with the added advantage of improved conversion efficiencies. These authors [11.1807] report laser efficiencies of 63% in a grating-tuned compact resonator yielding a laser beam with a near TEM_{00} profile. The laser beam divergence was measured to be $\Delta\theta \approx 1.9$ mrad, which corresponds to ≈ 1.3 times the diffraction limit. Other advances in organic-inorganic nanomaterials, as gain media for solid-state dye lasers, include the class of matrices introduced by *Sastre* et al. [11.1808]. These dye-doped polyhedral oligomeric silsesquioxane (POSS) polymeric matrices provide excellent photostability and laser efficiencies up to 60% when using the pyrromethene 567 dye [11.1808].

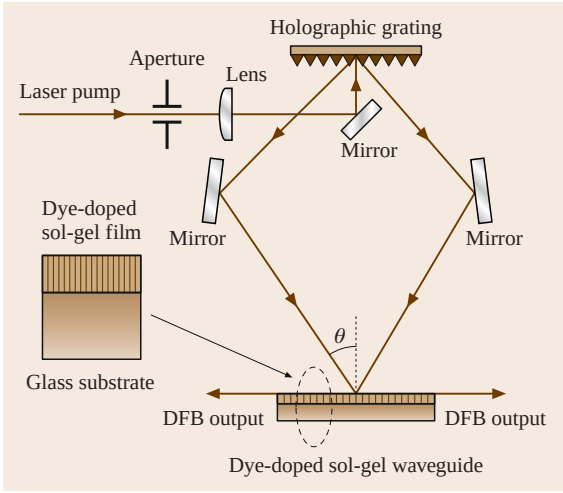

Fig. 11.205 Experimental arrangement of a sol-gel DFB waveguide dye laser

Distributed Feedback Waveguide Dye Lasers

Distributed feedback (DFB) lasers are compact tunable laser sources that produce narrow-linewidth output. The first DFB laser was, in fact, a *quasi*-solid-state dye laser (dye-doped gelatin film), but it did not operate as a waveguide laser because of the high film thickness [11.1809]. Proper solid-state DFB dye lasers were introduced using dye-doped PMMA [11.1810] and dye-doped sol-gel silica [11.1811] gain media. In other developments, the majority of DFB laser work has concentrated on semiconductor lasers that have been of obvious industrial significance. Recently, there has been a renewal of interest in organic DFB lasers, particularly those based on waveguide structures. This renewal in interest was caused in part by the application of conjugated polymers as luminescent materials [11.1804, 1812] and the subsequent conjugated polymer laser experiments [11.1813, 1814]. Dye-doped polymeric materials or sol-gel materials can be prepared in a planar waveguide structure by simply using spin-coating or dip-coating. Sol-gel materials have the additional advantage of a larger range of refractive index variation [11.1815, 1816], which allows integrated optics application on a large number of polymer or glass substrates. The DFB configuration seems ideally suited for laser output generation in these waveguide structures. Polymeric [11.1817] and sol-gel [11.1791] DFB waveguide dye lasers with tunable narrow-linewidth output have indeed been demonstrated.

Figure 11.205 shows the typical setup for the generation of a sol-gel DFB waveguide dye laser. The

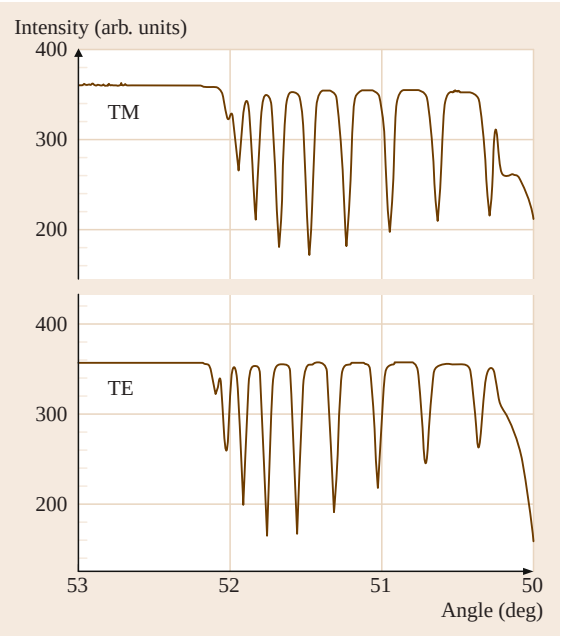

Fig. 11.207 Scans of TE TM waveguide modes for a sol-gel titania-zirconia organically modified silicate waveguide of thickness 6.7 μm and a refractive index of 1.56 on a glass substrate using a prism coupler

dynamic grating responsible for the lasing effect was produced by crossed beams, which also served as the pump. Tuning was done by varying the incident angle of the beams and hence the grating period. The periodic perturbation necessary for DFB lasing can also be produced by permanent morphological modulation of the substrate surface. One of the interesting features of DFB waveguide dye lasers is the possibility of the production of tunable multiple-wavelength output. *Oki* et al. [11.1818, 1819] fabricated a multistriped plastic waveguide laser array that could generate multiple output wavelengths in the range 575–945 nm (Fig. 11.206). Another approach to obtain multiple output wavelengths is to take advantage of waveguide structures that support multiple propagation modes [11.1820]. Figure 11.207 shows the scan traces of a prism coupler for a titania-zirconia organically modified silicate waveguide on a glass substrate [11.1821]. The titania-zirconia organically modified silicate film has a thickness of 6.7 μm and a refractive index of 1.56. Eight TE modes and eight TM modes were observed. The action of the crossed beams produced DFB laser output with wavelengths that obey the Bragg condition, $\lambda_L = \eta\lambda_p/M \sin\theta$, where η is the refractive index of the gain medium at λ_L, λ_p is the pump-laser wavelength, and M is the Bragg reflection order. For DFB laser action in waveguides, η takes on the values of the effective indices for TE_i modes or TM_i modes (i. e., i varies from 0–7 for a 6.7 μm film). Figure 11.208 shows a typical DFB laser output spectrum with a polarizer that blocks the TM modes [11.1821]. Without the polarizer all eight pairs of TE/TM modes could be observed. It was found that the crossing s-polarized beam generated purely TE modes, whilst pairs of TE/TM modes were produced when p-polarized beams were used. Furthermore, the separation between the modes and the number of modes can be controlled by varying the waveguide parameters such as the index difference and guiding-film thickness. Simultaneous tuning of multiple output modes was also achieved (Fig. 11.209). Such compact tunable multiple-wavelength lasers should find wide applications from analytical spectroscopy to optical communications.

Watanabe et al. [11.1822] have used SiO_2 nanoparticles in a dye-doped PMMA/HEMA film to configure a distributed-feedback waveguide laser yielding linewidths of $\Delta\lambda \approx 0.1$ nm at conversion efficiencies of $\approx 38\%$ at $\lambda \approx 590$ nm. Other distributed-feedback waveguide experiments have demonstrated blue emission, in the 410–440 nm range, with laser linewidths of $\Delta\lambda \approx 0.1$ nm at 8.2% efficiencies [11.1823].

Distributed Feedback Laser Action by Polarization Modulation

The original DFB laser theory describes the laser action caused by periodic perturbation of gain or refractive index [11.1809, 1824], both of which could

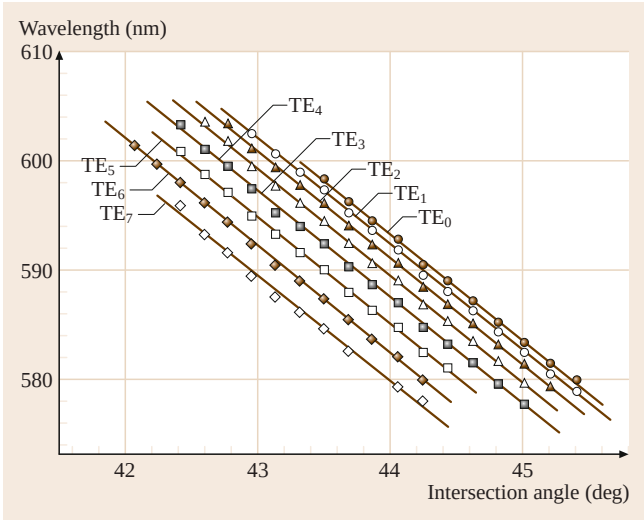

Fig. 11.209 Wavelength tuning of a multiple wavelength sol-gel DFB waveguide dye laser. The conditions of the waveguide are the same as in Fig. 11.207

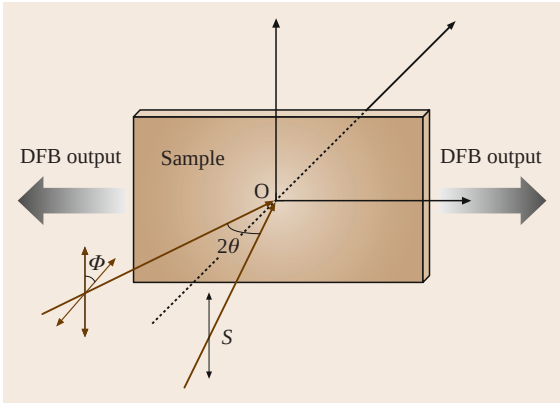

Fig. 11.210 Schematics for polarization modulation DFB laser experiments

be generated by intensity modulation. A schematic of a typical crossing beam experiment is illustrated in Fig. 11.210. The two beams are shown to have their polarization directions at an angle Φ. The crossing beams must both be s-polarized ($\Phi = 0°$) for the formation of an intensity interference pattern (intensity modulation). The intensity interference pattern in the gain medium produces a concentration grating of excited-state atoms/molecules that will provide the periodic change in gain or refractive index necessary for DFB laser action. The crossing of an s-polarized beam with a p-polarized beam ($\Phi = 90°$), however, does not produce an intensity interference pattern. Instead, it produces a periodic change of the polarization (polarization modulation) of the resultant field that changes from linear polarization to elliptical polarization to circular polarization and then back to elliptical polarization after one period. The grating that results from polarization modulation is a polarization grating.

Figure 11.211 shows the DFB laser emission spectra of rhodamoine 6G-doped zirconia waveguides as Φ changes from 0° to 90° for $\theta \approx 44°$ [11.1821]. The pump energy used was 10 μJ. The situation at $\Phi = 0°$ corresponds to the case of pure intensity modulation. The variation of Φ changes the amplitude of the s-polarized component of the beam. As Φ increases, the effectiveness of intensity modulation weakens as the disparity in amplitude of the s-polarized components of the two crossing beams grows, resulting in a low degree of modulation in the transient intensity grating. At $\Phi = 60°$, the amplitude of the electric field of the s-polarized component is 1/2 of the companion beam. The effect of intensity modulation is already so weakened that a substantial ASE (attenuated spontaneous emission) background (ratio of the DFB output intensity to the ASE intensity of 10 : 3) appears in the emission spectrum. At $\Phi = 90°$, DFB lasing is completely extinguished since the s-polarized component of one of the beams has zero amplitude. The pump energy is then gradually raised to about 30 μJ. DFB lasing reappears at 30 μJ, but this time the feedback mechanism is provided by polarization modulation. The distinguishing feature of DFB lasing induced by the polarization modulation is the appearance of a pair of TE_0/TM_0 output modes, whereas only the TE_0 mode is observed in the case of intensity modulation.

Experiments on polarization modulation have revealed that DFB lasing can also be induced in liquid dye solution. The pump threshold is drastically reduced by increasing θ. For θ larger than 75°, as is the case for DFB lasing of liquid oxazine dye near 800 nm under the first-order Bragg condition, the threshold pump energy for DFB lasing by polarization modulation is the same as that by intensity modulation.

Two-Photon-Pumped Solid-State Dye Lasers

Compact visible lasers by direct upconversion of infrared light are versatile light sources that hold promise for many applications in optoelectronics. Many dyes (e.g., R6G, DCM) have been known to emit weakly in the visible when pumped in the near infrared. Indeed, broadband laser emission in the visible

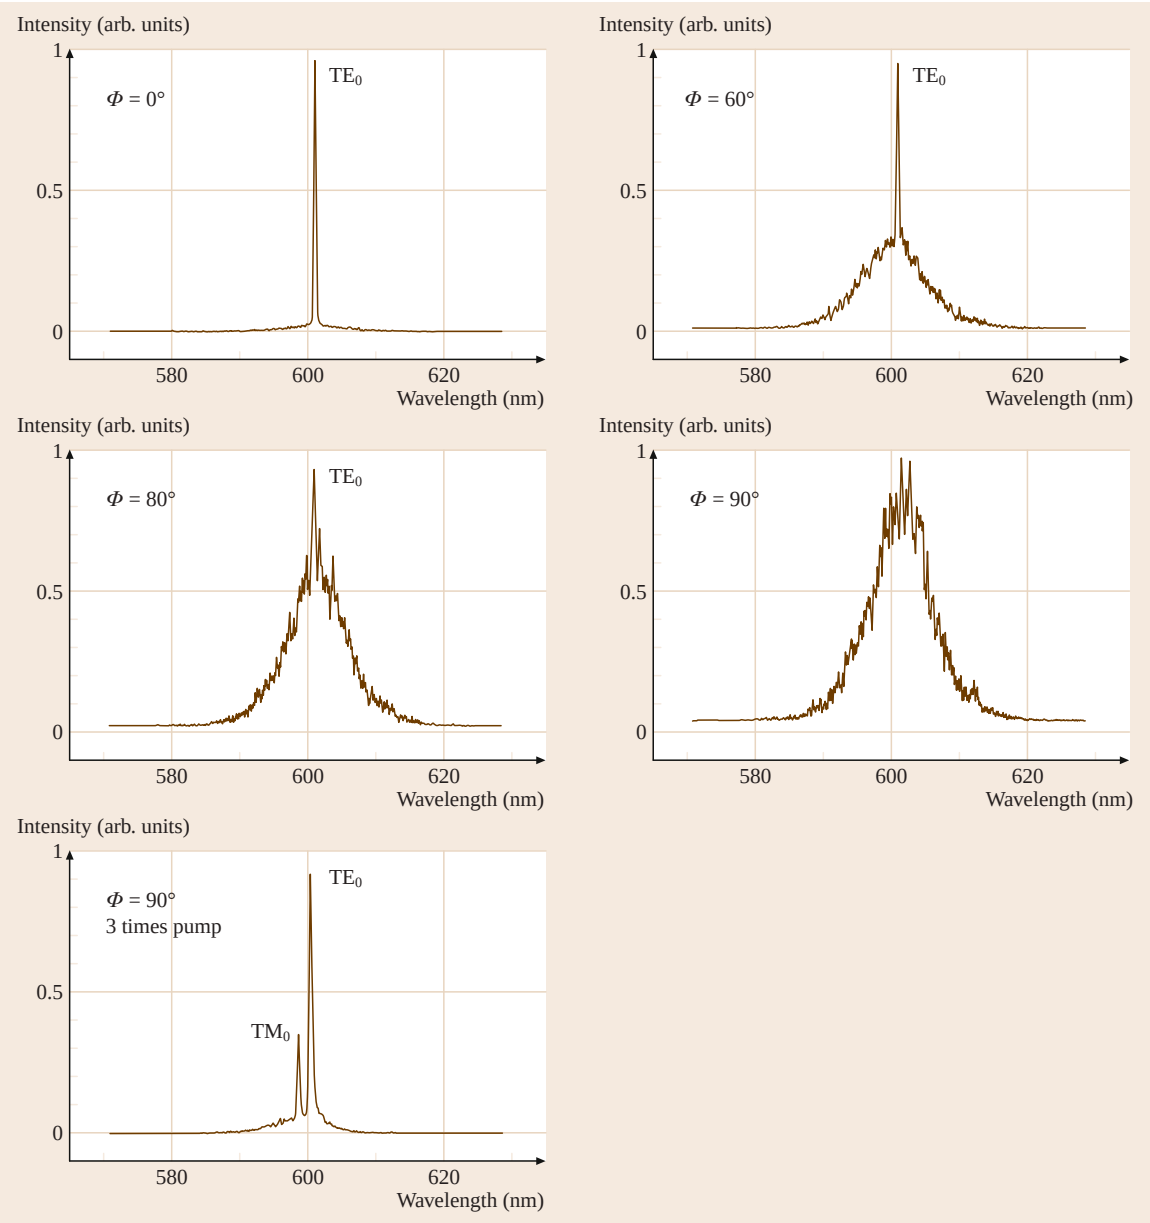

Fig. 11.211 Output emission spectra of sol-gel DFB waveguide dye lasers as Φ varies

was observed in two-photon pumped polymer waveguide and fiber [11.1825, 1826]. A number of dyes with large two-photon pump upconverted absorption cross section were synthesized recently. In particular, a styryl pyridinium dye: *trans*-4-[*p*-(*N*-hydroxyethyl-*N*-methylamino) styryl]-*N*-methylpyridinium *p*-toluene sulfonate (abbreviated as HMASPS) that shows strong emission in the red [11.1827] was doped in sol-gel zirconia thin films on a glass substrate [11.1828]. Figure 11.212 shows the absorption, two-photon-pumped fluorescence, and ASE spectra from the HMASPS thin-film waveguides. A strong emission peak centered at 620 nm is seen. Using two crossing 1.06 μm beams as the pump, DFB lasing was observed in the red with

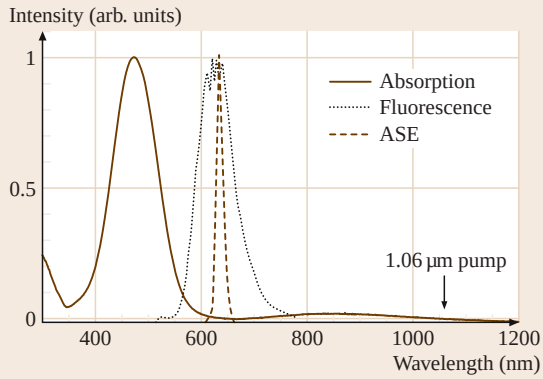

Fig. 11.212 Absorption, two-photon-pumped fluorescence and ASE spectra for an HMASPS-doped zirconia waveguide

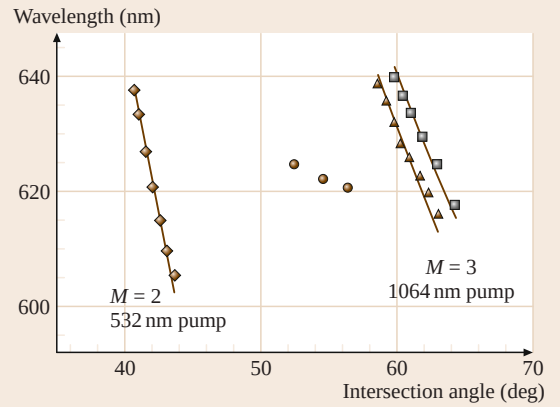

Fig. 11.213 Tuning curves for DFB lasing in HMASPS-doped zirconia waveguides

a linewidth of 45 GHz. Subsequent experiments demonstrated tuning by varying the intersection angle of the two 1.06 μm crossing beams [11.1828]. Figure 11.213 shows the tuning curves for second ($M = 2$) and third ($M = 3$) Bragg orders. A tuning range of 25–30 nm was observed.

11.8.8 Further Developments

Although dye lasers are now only *one of many* lasers in the class of *tunable lasers*, they continue to offer unique advantages: they emit efficiently right in the visible spectrum, their gain media are inexpensive, and they require very little manufacturing infrastructure. The published literature on liquid dye lasers shows that these sources of coherent radiation offer enormous operational versatility. Liquid dye lasers can deliver very large pulsed energies, or very high average powers. They can lase CW, or they can emit in the femtosecond domain, depending on the operational mode selected and engineering configuration adopted. Also, well engineered liquid dye lasers have demonstrated exquisite tunable narrow-linewidth performance and dependable operational characteristics [11.1750, 1754, 1766]. In the high-energy and high average-power domains, tunable liquid dye lasers are inherently advantageous in the critical area of heat removal. In this regard, the introduction of efficient, highly-stable, water soluble laser dye molecules might bring a whole new interest into these pioneering sources of tunable coherent emission. The efficient highly-soluble coumarin tetramethyl dyes [11.1829, 1830] might hold some clues in this regard.

Considerable progress has been achieved in the area of solid-state dye lasers, and although better stability for the gain media is always desirable it might well be argued that these gain media are ready for deployment in well-designed laser configurations offering inexpensive, and optically rugged, alternatives for laser spectroscopy and medical applications.

Within a decade of the discovery of the dye laser [11.1748, 1749] researchers became interested in the possibility of direct electronic excitation of laser dye molecules [11.1831, 1832]. Although there has been no explicit claim of a conventional electrically-pumped dye laser device, coherent emission has been observed from pulsed electrically-excited dye-doped interferometric emitters [11.1833]. More explicitly, coherent emission, from an electrically-excited laser dye-doped organic semiconductor submicrocavity confined within an interferometric configuration, has been observed and characterized [11.1833]. This pulsed emission is highly directional within a nearly diffraction-limited beam [11.1833, 1834]. Further, this emission exhibits high-visibility interferograms, with $V \approx 0.9$ [11.1833, 1834], a feature that is associated with laser emission [11.1835–1837]. Miniature coherent interferometric emitters, comprising dye-doped organic diode microcavities [11.1835], could find a number of applications in medicine and metrology.

11.9 Optical Parametric Oscillators

Optical parametric oscillators (OPO) are based on nonlinear frequency conversion of laser radiation into two coherent light waves with lower frequencies, called the signal and idler waves. Optical parametric oscillators are powerful devices for the efficient generation of widely tunable coherent light. The tunability and the high output power define the optical parametric oscillator as an attractive source in many applications, including high-resolution spectroscopy, environmental monitoring, medical research, process control, remote sensing, and precision frequency measurements. The intense research in OPOs has resulted in reliable OPO systems, which are commercially available.

The first optical nonlinear conversion experiment was demonstrated soon after the invention of the laser by the observation of second-harmonic generation of ruby laser radiation in a quartz crystal [11.1838]. This first result initiated intense experimental and theoretical investigations to increase the conversion efficiency and the available wavelength range. In the following years the physics of the nonlinear frequency conversion was theoretically well understood and all important methods of maximizing the conversion efficiency were elaborated, including quasi-phase matching [11.1839, 1840], birefringence phase matching in crystals [11.1841, 1842], and the requirement for optimum focusing [11.1843]. The first optical parametric oscillator was proposed in 1962 by *Kroll* [11.1844] and realized in 1965 by *Giordmaine* and *Miller* [11.1845], followed by detailed theoretical and experimental investigations [11.1846–1848]. Several review articles display a survey about the state-of-the-art of optical parametric oscillation until the mid 1980s [11.1849–1852].

However, despite these initial efforts, the success of OPOs as a versatile tunable light source fell short of expectations for almost a decade. At that time the reasons were unsuitable birefringence of the crystals to permit phase matching, low transparency and damage thresholds, difficulties in growing large homogenous crystals, and the lack of reliable laser sources with good spatial and spectral properties, which are important for efficient frequency conversion.

This situation changed due to significant advances in crystal growth techniques in the mid 1980s for both laser-active and nonlinear crystals [11.1853, 1854], leading to a renaissance of solid-state lasers. The availability of reliable pump sources with high spatial and spectral coherence (in continuous and pulsed operation mode), low-loss optical components and the appearance of new or optimized nonlinear materials (BBO, LiB_3O_5 (LBO), $KTiOPO_4$ (KTP), $KNbO_3$) started a new OPO evolution. Meanwhile a new generation of conversion media have appeared with periodically structured ferroelectric (e.g., $LiNbO_3$, $LiTaO_3$, $KNbO_3$, KTP) orientation patterned (GaAs) or epitaxially grown (GaAs) materials for quasi-phase matching. Together with the development of diode-pumped all-solid-state lasers, and in particular high-brightness diode-laser systems, new perspectives have been opened towards modern, compact, efficient, powerful, and tunable OPO systems.

11.9.1 Optical Parametric Amplification

The theoretical treatment of optical parametric amplification and generation was presented in the early 1960s [11.1855, 1856] and can be found in many textbooks and review articles [11.1849–1851, 1857–1859]. Therefore, this section will provide only a brief description of the difference frequency generation (DFG), optical parametric amplification, and the most important equations. The interaction of intense laser fields with a dielectric material induces nonlinear susceptibilities and causes the polarization of the medium to develop new frequency components not present in the incident radiation field.

The lowest-order nonlinear susceptibility $\chi^{(2)}$ is responsible for three-wave mixing processes such as second-harmonic generation (SHG), sum and difference-frequency mixing (SFG, DFG), optical rectification, optical parametric amplification (OPA), and optical parametric generation (OPG). Optical parametric generation with a feedback resonator for at least one of the waves is called optical parametric oscillation (OPO).

The relation between the electric field $\boldsymbol{E}$ and the polarization density $\boldsymbol{P}$ in the medium is given for a second-order susceptibility as

$$\boldsymbol{P} = \varepsilon_0(\boldsymbol{\chi}^{(1)}\boldsymbol{E} + \boldsymbol{\chi}^{(2)}\boldsymbol{E}\boldsymbol{E})$$
$$\boldsymbol{P} = \boldsymbol{P}_\mathrm{l} + \boldsymbol{P}_\mathrm{nl}\,, \qquad (11.165)$$

with ε_0 the vacuum permittivity and the susceptibility $\chi^{(k)}$, which are tensors of the rank k for an anisotropic medium. Because $\boldsymbol{\chi}^{(2)}$ is zero in centrosymmetric systems three-wave mixing is only possible in nonisotropic media. Generally, the $\boldsymbol{\chi}^{(2)}$ tensor possesses 27 elements, but many of the components vanish under certain symmetry conditions. The tensor can be reduced even to

a scalar if the interacting waves are linearly polarized and monochromatic for a fixed crystal orientation. In this case, the effective nonlinearity is denoted by a coefficient $\chi^{(2)}_{\mathrm{eff}}$. In the literature [11.1859] second-order susceptibility is often expressed by a coefficient d defined by $d := \chi^{(2)}/2$.

The dynamics of optical parametric generation or three wave-mixing processes in general can be described by a set of nonlinear coupled differential equations for the field amplitudes of the optical waves interacting with the nonlinear medium.

Considering the basic wave equation derived from Maxwell's equations for nonmagnetic dielectric media where $\boldsymbol{P}_{\mathrm{nl}}$ is regarded as a source,

$$\nabla^2 \boldsymbol{E} = \mu_0 \varepsilon \frac{\mathrm{d}^2}{\mathrm{d}t^2} \boldsymbol{E} + \mu_0 \frac{\mathrm{d}^2}{\mathrm{d}t^2} \boldsymbol{P}_{\mathrm{nl}} \tag{11.166}$$

result into the *coupled wave equations*

$$\frac{\partial E_1(z)}{\partial z} = \mathrm{i}\kappa_1 E_3(z) E_2^*(z) \mathrm{e}^{\mathrm{i}\Delta k z} , \tag{11.167}$$

$$\frac{\partial E_2(z)}{\partial z} = \mathrm{i}\kappa_2 E_3(z) E_1^*(z) \mathrm{e}^{\mathrm{i}\Delta k z} , \tag{11.168}$$

$$\frac{\partial E_3(z)}{\partial z} = \mathrm{i}\kappa_3 E_1(z) E_2(z) \mathrm{e}^{-\mathrm{i}\Delta k z} , \tag{11.169}$$

with the coefficients $\kappa_{\mathrm{i}} = \omega_{\mathrm{i}} d_{\mathrm{eff}}/n_{\mathrm{i}} c_0$ $(i = 1, 2, 3)$, d_{eff} the nonlinear coefficient, z the propagation direction and

$$\Delta k = k_3 - k_2 - k_1 \tag{11.170}$$

the phase mismatch.

This set of equations represents the interaction of three plane waves in a $\chi^{(2)}$ nonlinear dielectric. They have been solved exactly by *Armstrong* et al. [11.1839] for various input conditions. Depending on the initial conditions for the three complex amplitudes, these equations describe the various types of three wave-mixing processes generated by the single-pass propagation of the electromagnetic field through the crystal, such as second-harmonic generation, sum- and difference-frequency mixing and parametric amplification. Of particular interest in this case is the solution for DFG. Let us consider two waves with the frequencies ω_3 and ω_1 passing a loss less nonlinear medium. Within the medium these waves interact and generate the difference frequency $\omega_2 = \omega_3 - \omega_1$. For phase matched interaction $(\Delta k = 0)$ the wave with ω_2 is generated and ω_1 is amplified and vice versa, due to $\omega_1 = \omega_3 - \omega_2$. Therefore, this effect can be used to amplify coherent radiation even in spectral regions where no amplifiers are available (e.g., laser materials). This process is called optical parametric amplification. The injected wave, which shall be amplified, is called the *signal wave* $(\omega_1 = \omega_{\mathrm{s}})$. The second wave, which is generated and in most cases not used, is called the *idler wave* $(\omega_2 = \omega_{\mathrm{i}})$. The wave with the highest frequency ω_3, which is converted to signal and idler wave, is called *pump wave* $(\omega_3 = \omega_{\mathrm{p}})$. If only the pump wave is injected no signal or idler wave is generated or amplified in the model based on classical optics. However, experimentally it is observed that radiation is generated starting from quantum noise, which is called optical parametric fluorescence. If the optical parametric fluorescence is generated and amplified to macroscopic intensities this is called optical parametric generation. This pure quantum mechanical effect was first proposed and studied in 1961 by *Louisell* et al. [11.1860]. A quantum-mechanical model [11.1861] and semiclassical descriptions of the optical parametric fluorescence can be found in the literature [11.1857, 1858, 1862]. In this case, the definition of a signal wave is no longer useful, since no signal is injected. Therefore, the signal and idler wave are defined by $\omega_{\mathrm{s}} > \omega_{\mathrm{i}}$ for this type of nonlinear processes.

Introducing the definition for the intensity $I = 1/2\varepsilon_0 nc|E|^2$ the coupled field equations lead to the Manley–Rowe equation [11.1863], which is equivalent to photon conservation,

$$\frac{\mathrm{d}I_{\mathrm{s}}}{\omega_{\mathrm{s}}\,\mathrm{d}z} = \frac{\mathrm{d}I_{\mathrm{i}}}{\omega_{\mathrm{i}}\,\mathrm{d}z} = -\frac{\mathrm{d}I_{\mathrm{p}}}{\omega_{\mathrm{p}}\,\mathrm{d}z} . \tag{11.171}$$

The conversion of every pump photon generates a pair of signal and corresponding idler photons. In this sense the relation $\omega_{\mathrm{p}} = \omega_{\mathrm{s}} + \omega_{\mathrm{i}}$ corresponds to energy conservation and $\Delta k = k_{\mathrm{p}} - k_{\mathrm{s}} - k_{\mathrm{i}} = 0$ to the conservation of momentum of the parametric process.

Neglecting pump field depletion $(\mathrm{d}E_{\mathrm{p}}/\mathrm{d}z = 0)$ and assuming the presence of only the pump and signal field $(E_{\mathrm{p}} \neq 0,\ E_{\mathrm{s}} \neq 0,\ E_{\mathrm{i}} = 0)$ in the beginning of the parametric process the coupled wave equations can be solved analytically [11.1850, 1851]. The single-pass fractional gain in signal intensity is obtained as

$$G_{\mathrm{s}}(l) = \frac{I_{\mathrm{s}}(z = l)}{I_{\mathrm{s}}(z = 0)} - 1 = \Gamma^2 l^2 \frac{\sinh^2 gl}{(gl)^2} , \tag{11.172}$$

where l is the length of the nonlinear medium, g the total gain factor

$$g = \sqrt{\Gamma^2 - \left(\frac{\Delta k}{2}\right)^2} , \tag{11.173}$$

and Γ the parametric gain factor

$$\Gamma^2 = \frac{2\omega_s\omega_i|d_{\text{eff}}|^2 I_p}{n_p n_s n_i \varepsilon_0 c^3} . \tag{11.174}$$

The material-dependent part of the gain coefficient $|d_{\text{eff}}|^2/(n_p n_s n_i)$ is called the figure of merit (FOM) and classifies the nonlinear quality of the conversion medium. In the high-gain limit the single-pass gain becomes

$$G_s = \left[1 + \left(\frac{\Delta k}{2g}\right)^2\right] \sinh^2 gl , \tag{11.175}$$

which reduces to

$$G_s(l) \approx \tfrac{1}{4} e^{2\Gamma l} \tag{11.176}$$

when $\Delta k < g$. In the low-gain limit where $\Gamma^2 l^2 < (\Delta k/2)^2$ the gain of a parametric amplifier is

$$G_s(l) = \Gamma^2 l^2 \frac{\sin^2\left\{\left[\left(\frac{\Delta k}{2}\right)^2 - \Gamma^2\right]^{\frac{1}{2}} l\right\}}{\left[\left(\frac{\Delta k}{2}\right)^2 - \Gamma^2\right] l} . \tag{11.177}$$

Considering perfect phase matching $\Delta k = 0$, the single-pass signal gain in the low-gain limit approximates to

$$G_s(l) \approx \Gamma^2 l^2 \propto d_{\text{eff}}^2 l^2; . \tag{11.178}$$

It can be seen that the magnitude of the parametric gain depends on the intensity of the incoming field, as well as on the material parameters such as the nonlinear coefficient, the refractive index, and the interaction length. However, the main condition for an efficient parametric amplification is the phase-matching condition. As shown in Fig. 11.214 the parametric gain reaches a maximum for $\Delta k = 0$, and decreases symmetrically to zero for $|\Delta kl| = \pi$.

The gain bandwidth is defined by

$$\left|\left(\tfrac{1}{2}\Delta k^2\right) - \Gamma^2\right|^{1/2} l = \pi , \tag{11.179}$$

which reduces for low gain to

$$\tfrac{1}{2}\Delta kl = \pi . \tag{11.180}$$

The gain bandwidth increases with higher gain, but until reaching $\Gamma^2 l^2 \cong \pi$ the bandwidth broadening is small.

11.9.2 Phase Matching

From Fig. 11.214 it is obvious that optical parametric amplification is only achieved if the phase-matching condition is fulfilled

$$\Delta\boldsymbol{k} = \boldsymbol{k}_p - \boldsymbol{k}_s - \boldsymbol{k}_i = 0; . \tag{11.181}$$

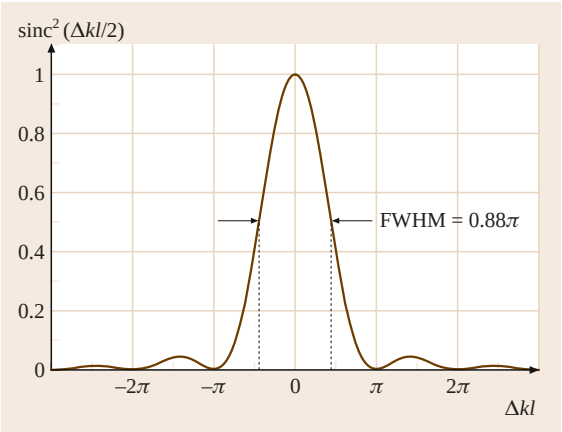

Fig. 11.214 Parametric gain of a nonlinear crystal of length l as a function of the phase mismatch Δkl. The gain is maximum by optimum phase matching $\Delta kl = 0$. The full width at half-maximum (FHWM) of the gain function is 0.88π

This equation can be expressed for $\Delta\boldsymbol{k} = 0$ as:

$$n_p(\omega_p)\cdot\omega_p = n_s(\omega_s)\cdot\omega_s + n_i(\omega_i)\cdot\omega_i \tag{11.182}$$

using the definition of the wave vector. In the case where $\Delta k \neq 0$ and the phase matching condition is not fulfilled the optical fields of the three frequencies differ in phase velocity, and the relative phase of the interactive waves varies along the medium, due to the different refraction indices. A measure of the phase mismatch is the coherence length $L_c = \pi/|\Delta\boldsymbol{k}|$, which defines the distance over which the relative phase of the interacting waves shifts by π. The propagation beyond the coherence length, which is typically several μm, leads to back-conversion from the generated waves into the pump wave. The oscillating behavior for not phase-matched interaction (NPM) of the generated intensity depending on the interaction length is shown in Fig. 11.215 (*solid brown curve*).

Equation (11.182) only depends on the wavelengths and the refractive indices of the nonlinear medium for the three waves. So the wavelengths for which efficient conversion is possible are determined by the dispersion of the nonlinear medium. Thus a crucial question for efficient nonlinear optics is to find a material and a propagation direction through this material with a suitable dispersion. This is, in fact, a problem of the linear optics. Mainly two different techniques are used to realize a phase-matched conversion process: birefringence phase matching (BPM) and quasi-phase matching (QPM).

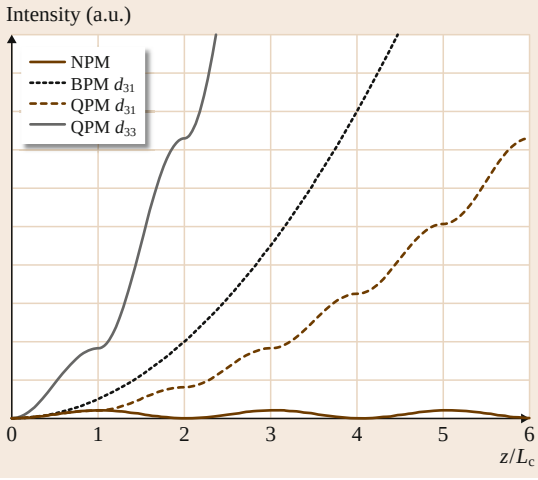

Fig. 11.215 Output intensity as a function of the propagation length in $LiNbO_3$. NPM: nonphase-matched process with no significant total conversion intensity. BPM: birefringence phase matching using the nonlinear coefficient d_{31}. The intensity increases quadratically with z, with a slope given by $d^2_{\text{eff,BPM}}$. QPM d_{31}: quasi-phase-matched process using d_{31}. Intensity increases quadratically with z on average, with a slope given by $d^2_{\text{eff,QPM}}$. QPM d_{33}: quasi-phase-matched process using d_{33}, which is only usable for QPM processes since all waves are polarized in the same direction. Intensity increases quadratically with z on average, with a slope given by $d^2_{33,\text{QPM}} \gg d^2_{31,\text{QPM}}$

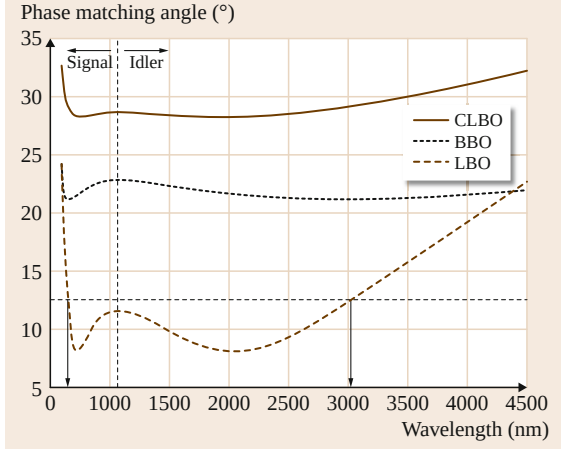

Fig. 11.216 Phase-matching angle in dependency on the wavelength for a 532 nm pumped OPO in different materials

Birefringence Phase Matching

This method uses the dependence of the refractive index on the propagation direction and polarization of electromagnetic waves in birefringent crystals. In order to discuss this technique in more detail, it is instructive to briefly recall the basics of wave propagation in birefringent crystals. In uniaxial crystals the waves are distinguished as ordinary (o) and extraordinary (e) waves, depending on their polarization direction. The refractive index of the ordinary wave is independent of the propagation direction, whereas the refractive index of the extraordinary wave depends on the polar angle between the optical axis and the propagation direction. To achieve phase matching the polarization of the high-frequency pump wave should be selected so that the index of refraction is smallest. The phase-matching condition (11.182) can be realized by choosing an appropriate angle between propagation direction and optical axis. This is illustrated in Fig. 11.216 for different materials in the case of a 532 nm pumped OPO. For a fixed phase matching angle two wavelengths can be identified (signal and idler wave) for which phase matching is obtained. These waves simultaneously fulfill the frequency-matching condition ($\omega_p = \omega_s + \omega_i$). For example, for a 532 nm pumped LBO OPO the 640 nm signal wave and the 3024 nm idler wave are phase matched at an angle of 12.5°. If the phase matching angle is reduced even two pairs of wavelengths (each fulfilling the frequency-matching condition) are phase matched in LBO, due to the retracing behavior of the dispersion.

Finally, this opens a sensitive way to select and tune the center wavelength, which is phase matched and hence amplified.

The birefringent phase-matching process is called type I phase matching (Table 11.49) when both generated waves have the same polarization perpendicular to the polarization of the pump wave, for example (e–oo). For type II phase matching the polarization of the generated waves are oriented perpendicular to each other (e–oe). Figure 11.217 shows the phase-matching angle for different wavelength and phase-matching schemes in BBO, for instance. An analytical solution of the phase matching angle is only possible for type I phase matching in uniaxial crystals, the other processes must be

Table 11.49 Naming of phase-matching schemes for OPOs

	Pump	Signal	Idler

solved numerically [11.1854]. The analysis in biaxial crystals is more complicated and has only numerical solutions; only in their principle planes can the formalism be reduced to the uniaxial conditions (Table 11.50, [11.1864, 1865]). A consequence of angular birefringence phase matching is the spatial walk-off generated by the birefringence, which reduces the interaction length of the optical waves.

Besides the angular phase matching the indices of refraction can be matched by changing the crystals' temperature (temperature phase matching). Combined with a propagation direction perpendicular to the principal axis this method is called noncritical phase matching (NCPM) and results in the absence of spatial walk-off and less angular sensitivity, which is important in applications with tight focusing.

The vector equation of the phase matching condition can be realized in a noncollinear or a collinear way. In contrast to collinear phase matching is the noncollinear phase matching a vector phase matching. Figure 11.218 shows the noncollinear angle included by the wave vectors. With the choice of a suitable noncollinear angle the angular acceptance is enlarged or the Poynting vector walk-off can be compensated. The conditions for the walk-off compensation are shown in Fig. 11.218a; the Poynting vectors of the ordinary signal and the extraordinary pump wave are parallel. Such walk-off compensation is of advantage for nanosecond OPOs reaching higher conversion efficiencies [11.1866] and necessary for critical-phase-matched

Table 11.50 Refraction indices of ordinary and extraordinary waves for uniaxial and biaxial crystals in the principal planes

Crystal	Extraordinary wave (e)	Ordinary wave (o)
Uniaxial	$n_e(\Theta) = n_o n_e / \sqrt{n_e^2 \cos^2\Theta + n_o^2 \sin^2}$	$n_o(\Theta) = n_o$
Biaxial, xy-plane	$n_e^{xy}(\Phi) = n_x n_y / \sqrt{n_x^2 \cos^2\Phi + n_y^2 \sin^2\Phi}$	$n_o(\Phi) = n_z$
Biaxial, xz-plane	$n_e^{xz}(\Theta) = n_x n_z / \sqrt{n_x^2 \cos^2\Theta + n_z^2 \sin^2\Theta}$	$n_o(\Theta) = n_y$
Biaxial, yz-plane	$n_e^{yz}(\Theta) = n_y n_z / \sqrt{n_y^2 \cos^2\Theta + n_z^2 \sin^2\Theta}$	$n_o(\Theta) = n_x$

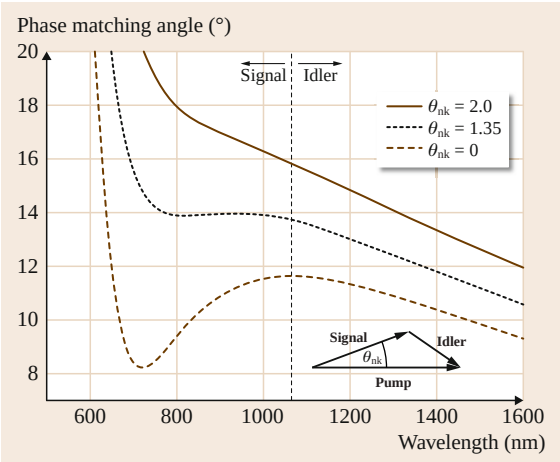

Fig. 11.219 Noncollinear phase matching in a 532 nm pumped LBO OPO for three different angles between the propagation directions of pump and signal radiation

OPOs pumped by ultrashort pulses because of the small beam radii [11.1867, 1868]. The diagram of tangential phase matching is shown in Fig. 11.218b. This special case of noncollinear phase matching produces a significant enlarged angular acceptance for the extraordinary pump wave. Figure 11.219 shows calculated curves for noncollinear phase matching in a 532 nm pumped LBO OPO. Three different angles between the propagation directions of pump and signal radiations are considered. For an angle of $\theta_{nk} = 1.35°$ between pump and signal radiation and a phase matching angle of $\approx 14°$ wavelengths in an approximately 200 nm wide range between 800 and 1000 nm are phase-matched. In addition, group-velocity matching for ultrashort pulses is realized via noncollinear phase matching [11.1869].

Quasi-Phase Matching

While for BPM true phase matching is obtain throughout the whole crystal, quasi-phase matching (QPM) uses a periodic phase correction. Here the relative phase between the three waves is corrected using a periodic change in the sign of the nonlinear susceptibility (*dotted brown curve* in Fig. 11.215) before the back conversion starts. Although the technique of QPM was proposed even before birefringence phase matching [11.1839], difficulties in fabrication of the periodic structure in the range of the coherence length (typically 1–100 μm) have prevented its realization for a long time. Recent advances in the fabrication of structured ferroelectrics (PPLN, PPLT, PPKTP, etc.) [11.1870–1872] or the epitactical growth of GaAs [11.1873] have meanwhile established this technique for efficient frequency conversion applications.

Since the phase of the waves is not truly matched throughout the whole crystal but periodically adjusted, the effective nonlinear coefficient of QPM

$$d_{\text{eff,QPM}} = \frac{2}{\pi m} d_{\text{eff}} \qquad (11.183)$$

is lower compared to BPM. Where m denotes the order of QPM. However, QPM offers two major advantages over birefringence phase matching. First, the polarization of the interacting waves can be equal for all waves. Thus, for instance, d_{33} can be used, which is the highest nonlinear coefficient in lithium niobate (*solid black curve* in Fig. 11.215), for instance. This reduces the pump threshold and increases the conversion efficiency. The second advantage is that quasi-phase matching of any combination of pump, signal, and idler wavelength can be realized in such materials via adjusting the periodic structure. In addition, QPM provides design flexibility of nonlinear conversion devices by engineered domain structures. Applications with novel configurations such as chirped gratings for pulse compression [11.1874], fan-out gratings for broad tunability [11.1875], quasi-periodic structures for simultaneous operation of two three-wave-mixing processes [11.1876], and two-dimensional gratings for multiple direction phase-matching processes [11.1877] have been demonstrated. Figure 11.220 shows a sketch of the typical QPM crystal structures for the different configurations.

Phase Mismatch and Acceptance Bandwidths

The center wavelength for which phase matching is obtained can be adjusted by the phase matching angle, the temperature (BPM), or the periodic structure in QPM materials, as discussed in the previous section. However, to date, it has not been discussed how sensitively the wavelengths of the signal and idler wave respond on these parameters. This is a crucial question for experiments, since these depend on several parameters such as the divergence and bandwidth of the pump radiation, the bandwidth of the generated radiation, and an inhomogeneous temperature distribution. This should be illustrated by two examples: ultrashort pulses require a certain bandwidth. For efficient frequency conversion this bandwidth must be completely maintained during the conversion. Otherwise the pulse duration is changed. Therefore, the sensitivity of the nonlinear conversion on small wavelength shifts around the center wave-

length should be small and thus the spectral acceptance large. Real world experiments mostly work with focussed beams in order to enhance the power density and the conversion efficiency. However, focused beams consist of different components with different angles. So the sensitivity on the phase-matching angle should be low in order to convert all parts of the focussed beam. The tolerances of the nonlinear material concerning to these perturbations are expressed by the acceptance bandwidths. They are defined by the FWHM of the parametric gain width (Fig. 11.214) and developed in Taylor series of Δk:

- Angular acceptance
$$\Delta\delta = 0.886\pi l^{-1}(\partial\Delta k/\partial\delta)^{-1} . \quad (11.184)$$
- Gain bandwidth
$$\Delta\omega_s = 0.886\pi l^{-1}(\partial\Delta k/\partial\omega_s)^{-1} . \quad (11.185)$$
- Spectral acceptance
$$\Delta\omega_p = 0.886\pi l^{-1}(\partial\Delta k/\partial\omega_p)^{-1} . \quad (11.186)$$
- Temperature acceptance
$$\Delta T = 0.886\pi l^{-1}(\partial\Delta k/\partial T)^{-1} . \quad (11.187)$$

11.9.3 Optical Parametric Oscillators

An optical parametric oscillator (OPO) consists of three basic components, namely the pump source, the gain medium, and the feedback resonator. This is very similar to the setup of a laser. However, in a laser the pump energy is absorbed and stored in the gain medium. Later the stored energy is used to amplify the resonant wave. In contrast to this behavior in an OPO the gain is produced by an optical parametric effect and no energy is stored in the gain medium. This requires that the pump wave and the amplified wave pass simultaneously through the medium.

For a qualitative description of the operation principle we consider the most basic OPO setup, as shown schematically in Fig. 11.221.

An intense coherent light field produced by a laser beam propagates through an optically nonlinear crystal with the frequency ω_p. The crystal is placed inside an optical resonator, which resonates for reasons of simplicity with one wave, for example the signal wave. As the nonlinear crystal provides a sufficient nonlinearity, parametric generation takes place and a pump photon is converted into a signal and idler photon fulfilling photon-wise energy conservation $\omega_p = \omega_s + \omega_i$. The resonator feeds the signal wave back into the crystal

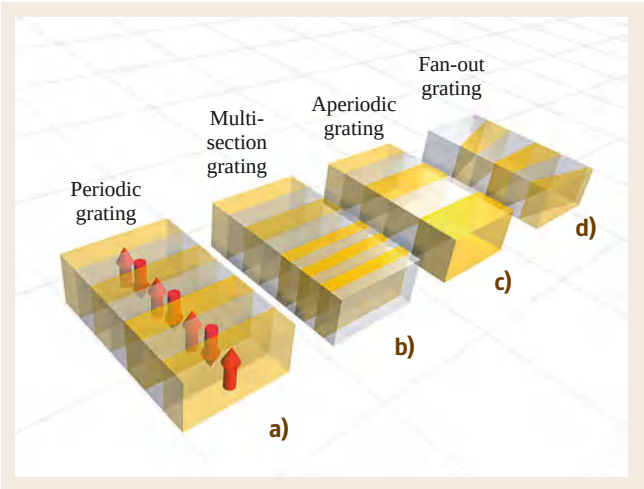

Fig. 11.220a–d Scheme of QPM structures. **(a)** Standard frequency conversion, **(b)** quasi-periodic or cascaded structures for simultaneous operation of two three-wave-mixing processes, **(c)** chirped gratings for pulse compression, **(d)** fan-out grating for broad tunability

where it is further amplified through the power transfer from the pump wave, as expressed in (11.171). Optical parametric oscillation starts, when the increased signal intensity surpasses threshold this means that the amplified signal wave compensates for the round-trip losses in the resonator (due to mirror transmission, absorption, scattering, and diffraction). Reaching this distinct pump intensity, the threshold pump intensity, a significant portion of the pump intensity is converted into signal and idler intensity. This power transfer from the pump to the generated waves reduces the (spatially averaged) pump intensity inside the nonlinear crystal and thus the signal gain. This effect is called gain saturation. Finally, this leads to steady-state operation of the OPO, where the signal power generated inside the crystal exactly balances the resonator losses for the signal wave.

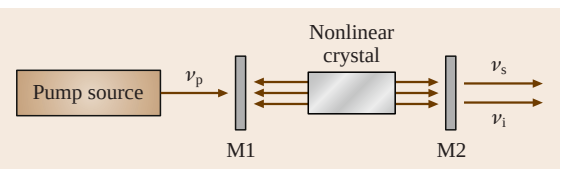

Fig. 11.221 Schematic setup of an OPO. An optical wave with frequency ν_p from the pump source is converted into two output waves with frequencies ν_s and ν_i via three-wave interaction in a nonlinear crystal. M1 and M2 are mirrors of a feedback resonator

As any pair of signal and idler photons can be generated from the initially random vacuum field fluctuations in steady-state operation, the signal and idler frequency pair that has the minimum threshold pump intensity is generated. Thus, the generated frequencies, and with them the ratio of the signal and idler frequency, are determined by the frequency dependence of the parametric gain in the crystal and the frequency dependence of the resonator losses.

A detailed description of the behavior of optical parametric oscillators has been published in several reviews [11.1849–1851]. The physics of OPOs is discussed more fundamentally in a number of textbooks on nonlinear optics [11.1857–1859].

Due to parametric interaction of the three waves, the duration of the interaction is crucial for the description. Therefore, optical parametric oscillators are mostly classified into three groups in the literature, depending on the temporal characteristic of their pump laser:

1. Continuous-wave optical parametric oscillators
2. Nanosecond pulsed optical parametric oscillators
3. Synchronously pumped picosecond or femtosecond optical parametric oscillators.

This distinction is not only a practical classification but is important for the theoretical description and the basic performance, such as pump intensity at threshold, conversion efficiency, and spectral performance.

11.9.4 Design and Performance of Optical Parametric Oscillators

The performance of an optical parametric system concerning:

- Signal and idler wavelength
- Tunability
- Bandwidth
- Output power
- Spectral and spatial coherence
- Beam quality

is directly related to key elements of the OPO's architecture, which are pump source, nonlinear material, and feedback resonator. In general, the physics of the optical parametric process imposes several requirements of potential OPO components. A simultaneous optimization of all OPO features cannot be done fairly because of material limitations and physical conflicts. Therefore, a general description of an optimized OPO design is not possible and the device configuration is always a compromise depending on the requirements of the specific application.

Together with the selection of the nonlinear material, the choice of the pump laser depends on the required wavelength range and time resolution for a given application. Obviously, the pump laser must be powerful enough to drive the OPO well above threshold and guarantee stable OPO operation. Since good spatial and spectral beam quality reduces the threshold, preferred pump sources will be high-power lasers of several watts, which also provide an excellent spatial beam quality, and good power and frequency stability. If the available pump power is restricted, low beam divergence is of particular importance to allow focusing into the nonlinear crystal. The deviations in spectral and spatial coherence tolerated by the parametric frequency conversion are determined by the acceptance bandwidths of the nonlinear material. Wavelength tunability of the pump laser offers an additional attractive feature: tuning of the OPO via the pump wavelength.

The selection of the nonlinear material depends on the nonlinear parametric process, the experimental design, and the properties of the pump source. Fundamentally, the nonlinear crystal should be distinguished by a broad transparency range, a high optical-damage threshold, and large effective nonlinearity. An important parameter is the birefringence of the crystal that must be high enough to maintain phase matching. However, this effect should not be too large because another consequence of birefringence is spatial walk-off, which reduces the interacting length of the coupled fields. Large spectral and angular acceptance bandwidths are advantageous because real laser systems show finite bandwidths and divergence and in ultrashort optical parametric oscillation, the temporal walk-off and group-velocity dispersion between pump, signal and idler wave should be low. For stable operation of OPO systems with high energies the thermo-mechanical and thermo-optical stability of the crystal should be sufficient. Finally, the crystals should be available in appropriate dimensions and excellent optical homogeneity.

The design of the feedback resonator is strongly connected to the output characteristic of the pump source. If the available pump power is restricted the OPO design may need to be modified for lower threshold, which might however restrict the tuning capabilities of the OPO. Three types of feedback resonators are distinguished, depending on the number of resonating waves. The singly resonant OPO (SRO) has highly reflecting mirrors at the signal or the idler wave. In

principle, this configuration is of particular advantage because it should provide continuous wavelength tunability. The disadvantage of these systems are their high pump power at threshold, which exceeds several watts [11.1878, 1879]. Therefore SRO devices are mainly found for pulsed OPO configurations.

Doubly resonant OPO configurations (DRO) where both signal and idler waves are resonated have received much attention, because the pump power at threshold is reduced by one to three orders of magnitude. However, such DRO OPOs do not provide mode-hop-free tunability and often suffer from frequency and power instabilities [11.1883, 1884]. Continuous wavelength tuning requires active stabilization techniques [11.1880, 1885].

The doubly resonant configuration where pump and signal (or idler) waves are resonated is called pump-enhanced SRO (PESRO). Such devices are very attractive because they provide a compromise between the low pump power at threshold of DROs and the wide tunability of SROs when the length of the OPO is carefully locked to a frequency-stabilized pump laser [11.1886]. In addition, a continuous tunability is possible with a pump-enhanced SRO, by using a resonator internal beam splitter to separate the pump spatially from the resonated OPO wave [11.1887]. These waves are then resonated on two separate cavity end mirrors (dual cavity) for independent control of the resonated OPO wave and the length of the pump cavity.

Triply resonant OPOs (TRO) suffer from the combined problems of both types of DROs, and consequently they provide less tunability in comparison to SRO and DRO, but they are remarkable because of their low threshold pump power in the range of several mW or below [11.1888, 1889].

Continuous-Wave Optical Parametric Oscillators

Continuous-wave optical parametric oscillators (CW-OPOs) are efficient and highly coherent light sources in the near and mid-infrared. Due to their tunability, these sources are of considerable interest for high-resolution spectroscopy of molecules and trace-gas detection [11.1890]. Simplified and improved frequency standards are currently being considered, based on the strong frequency and phase correlation of the OPO's signal and idler output waves [11.1891, 1892].

After the first demonstration of CW OPOs in 1968 by *Smith* et al. [11.1846] and *Byer* et al. [11.1847] significant progress is this field was made in the beginning of the 1990s, supported by advances in crystal growth techniques [11.1854], low-loss optical components, and CW solid-state lasers.

Table 11.51 Typical pump power at threshold for CW TRO, DRO, SRO

OPO	Pump threshold (mW)	References
TRO	< 1	[11.1880]
DRO	100	[11.1881]
SRO	2600	[11.1882]

As discussed above, pump power at threshold decreases with increasing cavity finesse for each of the wavelengths. Typical values for the pump power at threshold are listed in Table 11.51 for CW OPOs with different numbers of resonant waves (TRO, DRO, SRO).

The pump power at threshold of singly resonant OPOs is significantly higher than 1 W, even in a high-finesse cavity with no significant output coupling of the resonant wave. Since most commercially available single-frequency lasers provide maximum pump powers in the order of a few watts, most CW OPOs demonstrated in the past have been doubly or triply resonant devices.

The threshold pump intensity can be calculated from the coupled wave equations in analogy to the parametric gain assuming all three waves (pump, signal, and idler) are infinite plane waves, with uniform intensity across the beam, neglecting focusing and double refraction. The gain is considered to be unidirectional and the pump depletion is always small at threshold.

At the steady-state threshold, the gain balances the resonator losses for each resonator round-trip. The threshold condition for a SRO is

$$E_s(0) = (1-\alpha_s)E_s(l_c)\,, \tag{11.188}$$

where α_s are the round-trip losses of the resonant signal wave and l_c is the crystal length. In the low-gain limit and assuming small losses, the parametric gain coefficient (11.174) can be written [11.1851] as

$$\Gamma^2 l_c^2 = 2\alpha_s\,. \tag{11.189}$$

Then we obtain the pump intensity at the SRO threshold

$$I_{p,th} = \alpha_s \frac{n_p n_s n_i}{\omega_s \omega_i d_{eff}^2 l_c^2} \operatorname{sinc}^{-2}\left(\frac{\Delta k l_c}{2}\right)\,. \tag{11.190}$$

With $\Gamma^2 l_c^2 = \alpha_i \alpha_s$ the pump intensity at the DRO threshold is similarly derived as

$$I_{p,th} = \frac{\alpha_i \alpha_s}{4} \frac{n_p n_s n_i}{\omega_s \omega_i d_{eff}^2 l_c^2} \operatorname{sinc}^{-2}\left(\frac{\Delta k l_c}{2}\right)\,. \tag{11.191}$$

A low threshold is achieved when a long nonlinear crystal with a high figure of merit is used inside a resonator with low losses. In general, the pump threshold is lower for higher signal and idler frequencies. However, via the sinc function of the phase mismatch the pump threshold is exposed to an additional and much stronger dependence on the signal and idler wavelength. A minimum threshold is achieved for signal and idler wavelengths with $\Delta k = 0$. As a consequence, the OPO always seeks to oscillate as close as possible to the phase-matched wavelengths.

Usually, CW OPOs are pumped with focused beams to enhance the pump power density. In this case the assumption of plane waves is no longer valid and the pump, idler, and signal waves must be considered as Gaussian beams [11.1893]. In this case, the intensity shows an inhomogeneous distribution along the propagation axes z and the intensity and phases are not constant within each of the xy-planes. Only for loose focussing can these inhomogeneities be neglected and (11.190) is still a good estimation of the pump intensity at threshold. The pump power at threshold for tight focussing has been derived in a detailed mathematical treatment [11.1859, 1894], which is beyond the scope of this chapter. For optimized confocal focussing [11.1843], the pump power at threshold is given by

$$P_{\mathrm{p,th}} = \frac{4\pi c^2 n_\mathrm{s} n_\mathrm{i} \alpha_\mathrm{s}}{\mu_0 \omega_\mathrm{s} \omega_\mathrm{i} \omega_\mathrm{p} d_\mathrm{eff}^2 l_\mathrm{c}} \,. \tag{11.192}$$

As opposed to the l_c^{-2} dependence of the threshold intensity for plane waves, (11.190) for the pump power of Gaussian beams decreases linearly with the crystal length.

Once above threshold a part of the pump power P_p is converted into the appropriate signal and idler waves as long as the effective gain is larger than 1. An important parameter is the pump depletion, which occurs until the gain is saturated and the steady state is reached. The analytical description of the internal conversion efficiency η_int can be obtained under steady-state conditions assuming small cavity losses and optimum phase matching. The conversion efficiency

$$\eta_\mathrm{int} = 1 - \frac{P_\mathrm{out,p}}{P_\mathrm{in,p}} \tag{11.193}$$

depends on the ratio of the incoming and the transmitted pump power and is a function of the pump ratio N_0 [11.1894]:

$$N_0 = \frac{P_\mathrm{p}}{P_\mathrm{p,th}} \,. \tag{11.194}$$

The maximum conversion efficiency for plane waves comes to 100% for a pump ratio of $N_0 = (\pi/2)^2$. The extension of this model to Gaussian intensity distributions with plane wavefronts yields maximal conversion efficiency of 71% supposing a pump ratio of 6.5. The conversion efficiency is reduced by the inhomogeneous intensity distribution of the pump wave as well as distortions of the wavefronts.

Due to parasitical losses in the cavity (Fresnel losses at the surfaces, diffraction and absorption), the measured output power is lower than predicted by the internal efficiency. Therefore, it is useful to determine an external (utilizable) conversion efficiency, which in steady-state conditions is

$$\eta_\mathrm{ext,s} = \frac{T}{T+L} \frac{\omega_\mathrm{s}}{\omega_\mathrm{p}} \eta \,, \tag{11.195}$$

assuming small transmission T of the output mirror and small losses L for the resonant signal wave.

In order to operate the CW OPO continuously with low fluctuations in output power and frequency, the cavity length needs to be stabilized. The main sources of cavity length fluctuations are thermally induced fluctuations of the refractive index, mostly in the crystal, and acoustically and thermally induced perturbations of the position of the cavity mirrors. Fluctuations caused by these sources are usually significant just for low-frequency ranges, i. e., $\nu \leq 10\,\mathrm{kHz}$, which can be compensated, for example, by an electronic stabilization device. (For higher-frequency components, i. e., $\nu > 10\,\mathrm{kHz}$, the noise of the pump laser is significant instead of the cavity length fluctuations.) For an OPO with pump enhancement resonance, a change of the cavity length induces a mismatch between the cavity resonance frequency and the pump laser frequency, resulting in an increased OPO threshold and decreased output power. If the OPO is resonant for the signal or the idler wave or for both simultaneously, the change of the cavity length leads to fluctuations of the signal and idler frequencies and to mode hops and cluster hops. One possible method to stabilize the cavity length is to increase the passive stability in a monolithic setup [11.1895]. However, pump-enhanced OPOs and doubly resonant OPOs usually require active control of the cavity length [11.1896]. To stabilize a cavity resonance to a laser frequency several methods have been successfully demonstrated [11.1897–1899]. Active frequency stabilization of solid-state or diode laser pumped CW OPOs to external references has resulted in output bandwidths in the MHz range [11.1900–1902] or below [11.1903,1904]. Long-term stabilization

of a doubly resonant parametric oscillator where the frequency instability is below 1 kHz has been demonstrated [11.1903].

One of the most crucial components of CW OPOs is the nonlinear material. For successful CW OPO operation it is of particular importance that the crystals' nonlinearity is high and noncritical phase matching is possible. Crystals used so far are noncritical phase-matched $LiNbO_3$, KTP, LBO, $Ba_2NaNb_5O_{15}$, and $KNbO_3$, whereas especially KTP and its arsenate isomorphs $KTiOAsO_4$ (KTA) and $RbTiOAsO_4$ (RTA) turned out to be attractive materials for CW OPOs. Wavelength tuning of NCPM OPOs requires either temperature tuning of the crystal or wavelength tuning of the pump laser. Because of the low-temperature tuning capability of the KTP crystal family wavelength tuning in such OPOs depends on tunable pump sources. Many investigations have been performed with DROs and pump-enhanced OPOs to achieve continuous tunability. A significant increase of the continuous tuning range was realized with dual-cavity design [11.1885, 1887, 1906]. Low-threshold operation has been demonstrated with a TRO and pump-enhanced SRO KTP OPO pumped with a single-stripe GaAlAs diode laser [11.1906, 1907]. High idler powers of 840 mW in the wavelength range of 2.4–2.9 μm have been achieved with KTP and KTA OPOs designed as an intracavity SRO configuration and pumped by Ti:sapphire lasers [11.1908]. An important step was the realization of a singly resonant CW OPO [11.1878].

In recent years the availability of novel quasi-phase-matched nonlinear material and high-power solid-state lasers enabled significant advances in the development of CW OPOs. The high optical nonlinearity of periodically poled $LiNbO_3$ (PPLN) and long interaction lengths up to 50 mm enables the operation of CW SROs pumped by CW solid-state lasers. With the pumping of such a 50 mm long PPLN crystal with the 13.5 W output of a diode-pumped Nd:YAG laser, infrared radiation tunable in the range of 3.25–3.95 μm with an output power of 3.6 W has been reported [11.1909]. The measured pump depletion was as high as 93%. Wavelength tuning was achieved through temperature tuning or by using different poling periods implemented on the crystal. A step toward compact efficient and powerful CW OPOs was performed with the realization of a diode-laser-pumped singly resonant PPLN OPO [11.1905]. The SRO consists of a 38 mm long PPLN in a four-mirror cavity (Fig. 11.222). Pumping with 2.5 W of 925 nm laser radiation from an AlGaAs master-oscillator power-amplifier (MOPA)

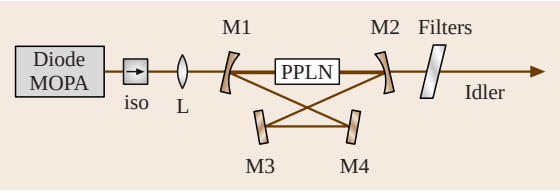

Fig. 11.222 Experimental setup of the diode laser pumped singly resonant OPO (SRO). The pump beam from the MOPA system propagates through a 60 dB isolator (iso) and focuses into the PPLN crystal. All mirrors of the ring cavity are highly reflecting for the signal wave and highly transmitting for the pump and idler wave. The idler output behind M2 is filtered from the residual pump and signal radiation by dielectric filters [11.1905]

system, 480 mW of single-frequency idler radiation was generated. The tuning range of the idler covers 2.03–2.29 μm. Recently, a singly resonant CW-OPO emitting mid-IR radiation with an output power of more than 1 W pumped by a monolithic diode laser was demonstrated [11.1902]. In addition, several investigations have been performed with pump-enhanced SROs in PPLN. Tunable radiation was generated in the range of 2.29–2.96 μm with an output power of 140 mW pumped by 800 mW delivered from a miniature diode-pumped single-frequency Nd:YAG laser [11.1910]. An extension of the wavelength into the mid-IR between 4.07–5.26 μm was demonstrated by pumping a PPLN PESRO by CW single-frequency Ti:sapphire radiation [11.1911]. Another pumping design was performed using a high-power fiber laser. The Yb-doped fiber laser generated mid-IR idler radiation in the range 2.98–3.7 μm using a 40 mm long PPLN crystal. Pumping with 8.3 W laser power the OPO generated 1.9 W [11.1912]. Rapid tuning the wavelength of a ytterbium fiber laser by an intracavity acousto-optical tunable filter allowed for fast tuning of a CW-OPO between 3160–3500 nm. The obtained output power was 1.13 W on the idler wave at a wavelength of 3200 nm [11.1913]. Low threshold operation of a singly resonant CW OPO with a threshold as low as 780 mW was demonstrated using a DFB fiber laser and fiber amplifier as the pump source [11.1914]. The OPOs bandwidth was 1 MHz. By tuning the frequency of the pump laser a fine tuning of the idler wave up to 130 GHz was achieved. Recently, an optimally-output-coupled fiber laser pumped CW OPO was reported. This setup provides output power of 9.8 and 7.7 W in the signal and idler wave, respectively. With a pump power of 28.6 W this gives an extraction efficiency of 61% [11.1915].

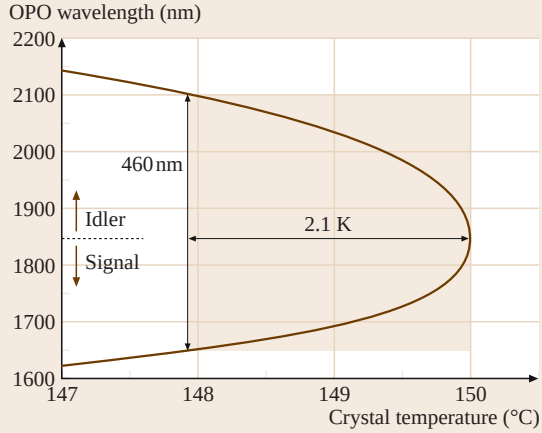

Fig. 11.223 Temperature tuning curve of a near-degenerate PPLT OPO calculated for a pump wave of 925 nm and a grating period of 27.3 μm [11.1920]. *Shaded areas*: the parametric gain bandwidth of the 35 mm long PPLT crystal at degeneracy is as large as 460 nm. The Sellmeier coefficients can be found in [11.1929]

Besides the successful demonstration of powerful PPLN OPOs two severe disadvantages of PPLN are the appearance of photorefractive effects and green induced infrared absorption (GRIIRA), which may disturb the phases of the passing waves or even damage the crystal. Especially OPO pumped in the visible suffer from these limitations. So some effort is being made to minimize these effects by optimizing the growing technique to produce stoichiometric crystals and by doping the crystals with MgO, for example. Other QPM materials have also been developed and successfully used for OPOs, such as periodically poled KTP (PPKTP) [11.1916–1918], RTA (PPRTA) [11.1919], and lithium tantalate (PPLT) [11.1920–1926]. As one result of these efforts a green pumped high power CW-OPO based on MgO:sPPLT tunable between 848–1430 nm has been demonstrated [11.1921]. In this experiment an idler output power of more than 1.51 W was achieved. A similar output power (1.59 W) but with single frequency radiation was published shortly after [11.1922]. In the following work optimization lead to an idler output power of even 2.59 W [11.1923]. Using a frequency doubled fiber laser at 532 nm with an output power of 9.6 W CW OPO radiation was demonstrated. The idler output power was 2 W between 850–1408 nm [11.1924]. Even 9.6 W single frequency radiation was demonstrated pumping the OPO with a high-power single-frequency fiber laser [11.1925]. Similar experiments were performed with an optically pumped semiconductor laser at 532 nm [11.1926]. An idler output power of more than 1.78 W and a signal power of more than 0.9 W between 856–1404 nm were observed in this experiment. Meanwhile even in 5 mol% MgO:PPLN an 532 nm pumped OPO was successfully demonstrated. The output power was more than 300 mW at an idler wavelength of 1416 nm [11.1927]. Combining an active cavity length control and a synchronized resonator internal etalon for wavelength tuning a narrow band and continuously tunable green pumped CW OPO at 1163 nm was demonstrated in MgO:PPLN [11.1928].

Wide wavelength tunability has been reported in the range between 1.5–4 μm in PPLN [11.1930] and 1.55–2.3 μm in PPLT [11.1920] pumping the OPOs near degeneracy, which provides large parametric gain bandwidths for a given poling period, crystal temperature and pump wavelength (Fig. 11.223). In PPLT the wavelength tuning is achieved by changing the crystal temperature within an interval of only 10 K. Operating a CW OPO with subsequent frequency-doubling wavelength tunability from the visible to the mid-IR range between 550–2830 nm was recently demonstrated. A comparison between the performance of PPKTP and PPLN was performed within these investigations [11.1918]. Mode hop free tuning over 110 GHz around 3.4 μm was performed by simply tuning the wavelength of the pump source, which was a fiber amplified DBR diode laser [11.1931]. Using a widely tunable Ti:sapphire ring laser tuning the OPO wavelength between 2.5–3.5 μm (signal) and between 3.4–4.4 μm (idler) has been demonstrated using pump wavelength tuning [11.1932]. In this case, an output power of 0.8 W and a mode hop free scanning range of 40 GHz was obtained. Recently, single mode CW OPOs based on bulk Bragg gratings were demonstrated capable of producing multiwatt output power on the signal as well as on the idler wave with a side-mode suppression better than 29 dB [11.1933]. Scanning the grating temperature allowed for frequency tuning of 120 GHz. With bulk Bragg gratings meanwhile even stable operation in vicinity of degeneracy has been demonstrated [11.1934].

The cited examples clearly indicate the dynamic in this field. Further research in new ferroelectrics generating radiation beyond 5 μm and the improvement of the existing materials concerning dimensions, homogeneity, and structural design will lead to high-efficiency compact integrated optical systems.

Nanosecond Optical Parametric Oscillators

Optical parametric oscillators pumped with nanosecond pulses are the most well-established OPO systems generating powerful tunable radiation in the spectral range from the visible to the near infrared. Despite the fact that the first demonstrated optical parametric oscillator [11.1845], which was a nanosecond pulsed OPO, was already demonstrated in 1965, reliable nanosecond OPOs were not established before the late 1980s. The appearance of new nonlinear materials with large nonlinearity and high damage thresholds (larger than $1\,\mathrm{J/cm^2}$) such as BBO, LBO, and the improvement of the optical quality of KTP or $KNbO_3$ was the start of an intense OPO evolution. These materials together with the optimized spatial beam quality and high peak powers of modern nanosecond Q-switched lasers made it possible to reach the threshold of the single-resonant OPO configuration.

The basic principle of optical parametric oscillation for nanosecond OPOs is the same as for CW OPOs; however, due to the finite length of the pump pulse (typical pulse lengths are 2–30 ns) the OPO does not reach the steady-state regime. In nanosecond OPOs, the cavity length is about a few centimeters, which corresponds to less than 100 round-trips for the pump pulse. The steady-state threshold is no longer valid because of the transient character of pulsed OPOs. The dynamic behavior was considered in a model developed by *Brosnan* and *Byer* [11.1935] using a time-dependent gain analysis. They calculated the buildup to threshold for a signal resonant optical parametric oscillator by assuming a Gaussian temporal profile for the incident pump pulse intensity and a Gaussian spatial distribution for the pump and the signal beams. Additionally their model assumes single pass of the pump wave and considers the effects of mode overlap and spatial walk-off.

They introduced the time-dependent parametric gain coefficient Γ_t

$$\Gamma_\mathrm{t} = \sqrt{g_\mathrm{s}}\,\Gamma\,\mathrm{e}^{-\left(\frac{t}{\tau}\right)^2}\,, \tag{11.196}$$

where τ is the $1/\mathrm{e}^2$ intensity half-width of the Gaussian pump pulse. The spatial coupling efficient g_s

$$g_\mathrm{s} = \frac{\omega_\mathrm{p}^2}{\omega_\mathrm{p}^2+\omega_\mathrm{s}^2} \tag{11.197}$$

describes the mode overlap between the resonant signal wave and the pump wave. The influence of the Poynting vector walk-off defines the effective parametric gain length Λ

$$\Lambda = l_\omega \mathrm{erf}\left(\frac{\sqrt{\pi}}{2}\frac{l_\mathrm{c}}{l_\omega}\right)\,, \tag{11.198}$$

with the walk-off length, which depends on the birefringence angle ρ,

$$l_\omega = \frac{\sqrt{\pi}}{2}\frac{\omega}{\rho}\sqrt{\frac{\omega_\mathrm{p}^2+\omega_\mathrm{s}^2}{\omega_\mathrm{p}^2+\omega_\mathrm{s}^2/2}}\,. \tag{11.199}$$

The threshold energy fluence for the single-resonant OPO is derived from the coupled wave equations, assuming low pump depletion, as

$$J_\mathrm{th} = \frac{2.25}{\kappa g_\mathrm{s}\Lambda^2}\tau \times\left(\frac{l_\mathrm{r}}{2\tau c}\ln\frac{P_\mathrm{s,th}}{P_\mathrm{s,0}} + 2\alpha_2 l_\mathrm{c} + \ln\frac{1}{\sqrt{R}} + \ln 2\right)^2\,, \tag{11.200}$$

with $\kappa = 2\omega_\mathrm{s}\omega_\mathrm{i}d_\mathrm{eff}^2/\left(n_\mathrm{p}n_\mathrm{s}n_\mathrm{i}\varepsilon_0 c^3\right)$, where R is the reflectivity of the mirrors, α_2 are the internal losses of the resonant wave inside the crystal, l_r is the optical cavity length and l_c is the length of the crystal. The threshold identifies the detectable level of the signal energy, which corresponds to a typical energy of $100\,\mu\mathrm{J}$, giving a threshold power to noise ratio of $\ln(P_\mathrm{th}/P_\mathrm{s}) = 33$. The time required from the parametric gain of the signal field starting from the noise level P_0 to reach the oscillation threshold P_th is called the rise time of the parametric oscillator. The rise time is an important parameter in the design and operation of a parametric oscillator and can be calculated from the time-dependent coupled amplitudes equations. For efficient conversion, the rise time must be as short as possible. *Pearson* et al. [11.1936] carried out a detailed investigation of the rise time as a function of various experimental parameters, such as pump pulse length, cavity length, cavity losses, and the pump ratio N_0 (11.194). Important experimental parameters to minimize the rise time are high pump energy densities and a short cavity length. Beyond the influence of the rise time the threshold energy density can be reduced by using long pump pulse durations τ, optimizing the reflectivity R and avoiding intracavity losses α. Additionally the nonlinearity of the crystal should be large and the length of the crystal should be as long as possible with regard to the limitation through the Poynting vector walk-off.

The spectral bandwidth of a singly resonant optical parametric oscillator depends primarily on the gain

bandwidth, which is determined by the dispersion, the birefringence, and the length of the nonlinear crystal. In addition, the bandwidth is determined by the spectral properties of the resonator, the correlation between the resonator modes and the characteristics of the pump laser, the wavelength, spectral bandwidth, intensity, and divergence. Because of the short pump pulse duration for nanosecond pumped OPOs there is only a weak spectral-mode condensation and the nanosecond OPO does not reach the stationary state, unlike the CW OPO. Usually, the nanosecond OPO bandwidth is estimated from the gain bandwidth, as there is no exact analytical description of the spectral bandwidth of pulsed OPOs. Neglecting any saturation *Brosnan* and *Byer* [11.1935] deduced an expression for the spectral condensation depending on the number p of cavity round-trips

$$\Delta\nu(p) = \frac{1}{\sqrt{p}}\Delta\nu\,. \qquad (11.201)$$

A more exact prediction concerning the theoretical bandwidth can be calculated using numerical simulations [11.1937, 1938].

Nanosecond pulsed optical parametric oscillators are powerful devices of widely tunable coherent light. With the nonlinear crystals BBO and LBO such OPOs provide coherent radiation in the entire spectral range from the UV (300 nm) to the near IR (2.5 μm). The advantageous properties of these crystals are high optical damage threshold, high nonlinearities, a wide transparency range, and a large birefringence. Since the first successful operation of a BBO OPO reported by *Fan* et al. in 1989 [11.1939] significant progress in OPO technology has been achieved. In the investigations reported so far, BBO OPOs have been pumped with the second, third, and fourth harmonics of a Q-switched Nd:YAG laser at 532 nm [11.1939, 1940], 355 nm [11.1940–1945], 266 nm [11.1940, 1946], and with the fundamental of an XeCl excimer laser at 308 nm [11.1947, 1948]. The highest output energies and efficiencies have been obtained with the third harmonic of a Q-switched Nd:YAG laser. The generated output energies are in the range 100–200 mJ/pulse and external conversion efficiencies of up to 61% have been reported [11.1940, 1949].

Similar advances have been demonstrated for the LBO OPO that covers almost the same spectral range [11.1937, 1950–1956]. The power densities at threshold for the 355 nm pumped LBO OPO are typically higher by a factor of two compared to those of equivalent BBO OPOs, due to the lower effective nonlinear coefficient. However, LBO possesses a smaller spatial walk-off angle compared to BBO [ρ(LBO) ≈ 0.25ρ(BBO)] allowing the use of longer LBO crystals to compensate the lower nonlinearity. The experimental comparisons of LBO and BBO [11.1937, 1954] demonstrate the advantageous properties of LBO as large angular acceptance and low spatial walk-off (which can even be zero for temperature-tuned noncritical phase matching). These properties are valuable if the OPO is to be operated with low-pump-energy laser sources ($\leq$ 3 mJ) [11.1957], whereas BBO with restricted angular acceptance and larger nonlinearity is more suitable for high-pump-energy laser sources ($>$ 100 mJ).

In the past, many investigations were performed primarily for the type I critically phase-matched BBO OPO pumped by the third harmonic of a Nd:YAG laser. This well-established standard OPO typically consists of a 12–15 mm long BBO crystal placed in a linear signal resonant Fabry–Pérot resonator. Changing the phase-matching angle in the range of 10° the OPO covers a tuning range of 400–710 nm for the signal wave and 710–3100 nm for the idler wave. Experimentally the idler tuning is restricted by an increase of absorption in the crystal for wavelengths longer than 2600 nm. The pump energy density at threshold is about 200 mJ/cm^2. Pumped with 2–10 ns long pulses such OPO devices operate routinely with conversion efficiencies in the range of 20–50% whereby the optical damage threshold of the OPO components limits the pump ratio. The spectral bandwidth of the type I phase-matched 355 nm-pumped BBO OPO varies from 0.2 nm in the blue spectral range ($\lambda = 400$ nm) to more than 10 nm at degeneracy ($\lambda = 710$ nm). The spectral bandwidth of the idler wave equals (expressed in wavenumbers or GHz) that of the corresponding signal frequency.

In the past, many efforts have been made to reduce the spectral bandwidth of OPOs. Significant line narrowing, even to single-mode operation, can be achieved with the insertion of frequency selective elements (such as gratings or etalons) into the OPO resonator or with external injection seeding of the OPO. Although these methods can provide single-mode operation, the disadvantages are obvious. First, the addition of frequency-selective elements increases the resonator length, the cavity losses and thus the oscillation threshold. Therefore, higher pump densities are required and a compromise is needed between the necessary pump power and the damage threshold of the optical components. Second, continuous wavelength tuning may be affected by the complexity of such devices.

With the development of volume holographic gratings (VBGs) it recently became possible to include the grating in the standard cavity design. In a green pumped KTP OPO – with a VBG as the output coupler – signal radiation at 975 nm with a bandwidth of 0.16 nm (50 GHz) was demonstrated [11.1958]. In this experiment wavelength tuning over 60 nm while maintaining the spectral bandwidth was accomplished in a folded cavity by turning the VBG. Even narrow band radiation close to degeneracy of signal and idler radiation was achieved with VBGs. This is difficult to obtain with standard mirrors, due to the large gain bandwidth as illustrated in Fig. 11.223. In PPKTP the VBG resulted in an 80 times narrower spectrum at 2008 nm compared to a conventional setup [11.1959]. In further experiments in PPKTP narrow band radiation in the vicinity of the degeneracy of signal and idler wavelength at 2.128 μm was shown [11.1960]. Similarly, an output energy of 61 mJ with a bandwidth of less than 1.4 nm at 2.128 nm was experimentally obtained in a MgO:PPLN VBG-OPO [11.1961]. Using a transversely chirped Bragg grating as an output coupler, a narrow band PPKTP OPO was widely tuned by a simple translation of the grating [11.1962]. A tuning range of the signal radiation between 1011–1023 nm was possible with a bandwidth of 0.5 nm and a suppression of the background by better than 30 dB.

The spectral line narrowing via injection seeding also avoids the disadvantages of additional frequency selective elements; the threshold is even reduced, because of a shorter rise time [11.1963]. Nevertheless, successful injection seeding in pulsed OPOs depends on many fundamental parameters of the OPO operation. Besides proper collinear alignment and divergence adaptation between the seed radiation and the seeded OPO wave, frequency matching between the cavity mode and the seed frequency is essential. Despite these difficulties successful line narrowing has been demonstrated with both methods [11.1943, 1949, 1964–1966]. A theoretical description of the spectral characteristics of free-running or injection-seeded OPO systems are given in several numerical models [11.1937, 1938, 1967, 1968].

The investigation and the control of the spatial beam quality of nanosecond OPOs is still a challenge. As a result of large pump-beam diameters, high nonlinear gain in the crystal and a large Fresnel number of the optical resonator the beam quality factor M^2 of the generated radiation are often high ($> 2-10$) and thus far from the diffraction limit ($M^2 = 1$). Most of the numerical models simulating the spatial behavior of nanoseconds OPO

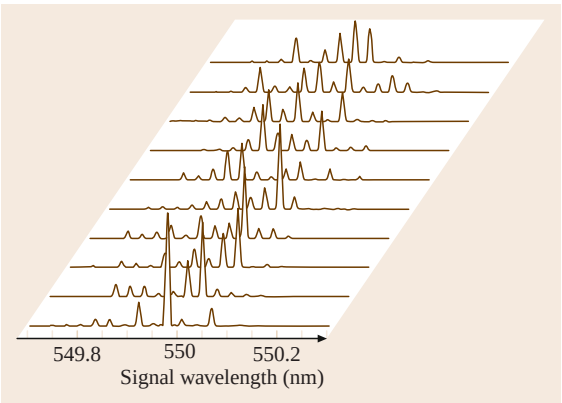

Fig. 11.224 Mode spectra of the signal wave (550 nm) recorded for ten successive OPO pulses. The OPO is operated at 1.44 times above threshold. The mode spacing is 28.8 GHz (0.96 cm^{-1}) [11.1938]

are time integrated [11.1969–1972]. Recently, time-resolved experimental and numerical investigation of the spectral and spatial dynamics of nanosecond OPO was reported [11.1973, 1974]. The result of the different investigations is that the OPO starts on the optical axis with an almost Gaussian beam profile. However, during the buildup of the pulse the fields undergo an inhomogeneous gain caused by the birefringence walk-off in the OPO crystal, pump depletion and back-conversion and as consequence the M^2 value increases with the size of the pump energy, pump depletion, and back-conversion.

Some investigations of the spectral and temporal dynamics of the OPO were performed using a BBO OPO, which consists of a 2–3 mm long crystal in a 3.5 mm long cavity [11.1938, 1974]. Due to the wide mode spacing of about 1 cm^{-1} each single mode can be considered. Figure 11.224 shows the statistical mode fluctuation of ten successive pulses. Thus, the short-cavity OPO proofs the macroscopic manifestation of the zero-point fluctuation of the vacuum.

Based on numerical and experimental results some improvement on the spectral and spatial performance of nanosecond OPOs were developed based on novel pumping and resonator configurations [11.1866, 1975–1981].

For the generation of wavelengths up to 5 μm the appropriate crystals are KTP, KTA, and $KNbO_3$ [11.1982–1985]. Further extension to wavelengths beyond 5 μm can be achieved in $ZnGeP_2$, CdSe, and $AgGaSe_2$ [11.1986–1991]. To avoid two-photon absorption in the materials these crystals must be operated with pump wavelengths longer than 1.5 μm. Nanosecond OPOs

have been demonstrated with a tuning range up to 14 μm. They provide conversion efficiencies up to 40%, generating output powers of about 5 W or pulse energies of 5 mJ [11.1989, 1990]. The difficulty of finding the appropriate pump lasers for these materials has been overcome with cascaded OPO systems published for $AgGaSe_2$ and CdSe [11.1990, 1992–1994], and ZGP [11.1995–1999].

A new generation of nanosecond OPOs appeared with the availability of periodically poled QPM materials such as PPLN, PPKTP, PPKTA, and PPRTA. These crystals have large effective nonlinearities (8–16 pm/V), up to eight times higher than in a corresponding BBO crystal, and possess long interaction lengths. Typically, the apertures of the QPM crystals are 1 mm high. Therefore, these materials are well-suited for the generation of mid-IR radiation pumped with high-repetition low-power-pump pulses [11.2000–2002]. Noncollinear OPOs based on PPLN with tilted domain walls allowed avoidance of backconversion and improved beam quality [11.2003]. Recently even a THz OPO based on LN was demonstrated, using a high repetition rate, q-switched, single-mode Nd:YVO_4 laser as the pump source [11.2004]. With the development of wide large-aperture PPRTA crystals, QPM becomes suitable also for high-power applications [11.2005, 2006]. Meanwhile even MgO:PPLN crystals with an aperture height of 5 mm have been successfully periodically poled and used for high power applications [11.2007, 2008]. The large nonlinearity of PPLN enables the operation of efficient single-pass optical parametric oscillators [11.2002, 2009–2011], as well as efficient and widely tunable optical parametric generators [11.2012]. More recently, tunable single-frequency generation was demonstrated with injection-seeded PPLN OPOs and PPLN OPGs [11.2013–2015].

Synchronously Pumped Optical Parametric Oscillators

Optical parametric oscillators synchronously pumped by mode-locked solid-state lasers are powerful devices for the generation of tunable, ultrashort laser pulses. The first CW synchronously pumped picosecond OPO was demonstrated by *Piskarskas* et al. in 1988 [11.2016] and the first synchronously pumped femtosecond OPO by *Edelstein* et al. in 1989 [11.2017].

Many reports of such OPOs generating pulses in the picosecond or femtosecond regime have been published in recent years [11.2018–2020]. Ultrafast laser systems are attractive pump sources for optical parametric oscillators. They combine high peak pulse intensities providing sufficient nonlinear gain with a moderate energy fluence preventing optical damage of the material. However, bearing in mind the instantaneous character of nonlinear polarization, the optical gain is obtained exclusively during the time interval of the pump pulse length. In contrast to nanosecond OPOs, the time interval of ultrashort pulses ($\tau < 100$ ps) is too short to allow a finite number of cavity round-trips. Therefore, the basic operation principle of ultrafast optical parametric oscillators is synchronous pumping to achieve macroscopic amplification of the parametric waves from quantum noise. In this pumping scheme the length of the optical parametric oscillator is matched to that of the pump laser resonator, so that the round-trip transit time in the OPO resonator corresponds to the time between two pump pulses. The consecutive coincidence of parametric and pump wave in the nonlinear crystal amplifies the gain until it overcomes the threshold.

In general, two types of synchronously pumped OPOs are to be distinguished: the pulsed synchronously (or quasi-CW) and the continuous synchronously pumped OPOs. CW synchronously pumped OPOs are pumped with a continuous train of ultrashort pulses as they are emitted by CW mode-locked neodymium lasers or Kerr lens mode-locked Ti:sapphire lasers, while the pump sources of pulsed synchronously pumped OPOs are mode locked Q-switched Nd lasers generating a train of ultrashort pulses contained within a nanosecond or microsecond envelope.

The physical description of CW synchronously pumped OPOs is equivalent to the steady-state formalism for CW OPOs considering the peak intensity of the pump pulses determining the nonlinear gain. Pulsed synchronously pumped OPOs show the transient behavior of nanosecond OPOs, so their analysis must take into account the rise-time effects caused by the finite time duration of the nanosecond pulsed envelope [11.1920]. An analysis of synchronously pumped OPOs can be found for plane-wave conditions [11.2021] and for Gaussian beams in CW synchronously pumped OPOs [11.2022, 2023].

Most early synchronously pumped OPOs were pulsed OPOs [11.2018] because of the significant higher peak pump pulse powers compared to CW mode-locked pump lasers at that time. Picosecond optical parametric oscillation even in the SRO configuration was generated using the nonlinear materials KTP [11.2024], BBO [11.1867], and LBO [11.2025]. However, due to the pulsed pump characteristic the output of such OPOs does not consist of a really repetitive pulse train, and the amplitude, intensity, and pulse

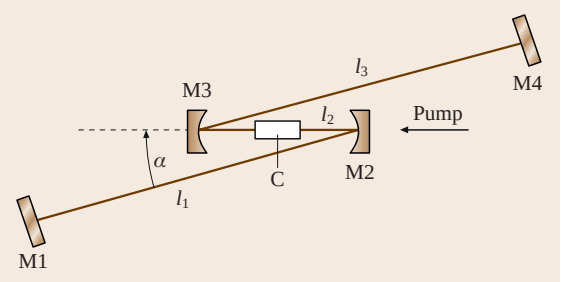

Fig. 11.225 Experimental setup for a linear standing wave resonator consisting of two plane mirrors M1 and M4 and two spherical mirrors M2 and M3. The pump laser beam is focused into the crystal C between the spherical mirrors M2 and M3. The total resonator length depends on the distance between two successively pump pulses

duration of the output pulse can vary under the pulse envelope. In applications where no high peak powers are needed CW synchronously pumped OPO are advantageous because of their continuous train of output pulses. Moreover, with the availability of efficient CW mode-locked lasers and more-reliable nonlinear materials the research in this field is focused on CW synchronously pumped OPOs.

In practice, synchronous pumping is a reasonable pumping mechanism only for high repetition rates (> 50 MHz), otherwise the resonator length becomes too long and unpractical. For example, typical repetition rates of Kerr lens mode-locked Ti:sapphire lasers are about 80 MHz, which corresponds to an OPO resonator length of 1.85 m. The tolerance of the resonator length detuning can be calculated from $\Delta l_{\text{res}} = \Delta\tau(c/2)$, which is half the geometrical pump pulse length. The theoretical detuning calculated for 1 ps is about 150 μm, however experimentally even shorter detuning tolerances of 40 μm are affordable [11.2026].

Commonly used resonator designs for synchronously pumped OPOs are ring or standing-wave resonators, where the latter is favorable for compactness reasons (its length is half that of the ring). A typical standing-wave resonator for synchronously pumped OPOs is shown in Fig. 11.225; it consists of two plane and two spherical mirrors.

Picosecond Optical Parametric Oscillators. Picosecond optical parametric oscillators synchronously pumped by CW mode-locked solid-state lasers are powerful devices for the generation of tunable ultrashort laser pulses, especially in the IR spectral region. For many applications in high-resolution spectroscopy a high spectral intensity and a narrow bandwidth is required. As the light of such OPOs is almost Fourier limited ($15\,\text{ps} = 1\,\text{cm}^{-1}$) picosecond pulses (with $t > 10$ ps) have a sufficient selectivity for spectroscopy, in contrast to pulses in the femtosecond regime. Similar to the nanosecond pulsed OPOs the high peak powers of modern CW mode-locked lasers easily overcome the threshold of SRO resonators. As a consequence, most synchronously pumped CW OPOs operate in the SRO configuration.

In the past, there have been various ways to generate tunable picosecond IR radiation by CW synchronously pumped OPOs. In most synchronously pumped picosecond OPOs, the use of noncritical BPM prevents a reduction of interaction length due to walk-off between the focused beams inside the nonlinear crystal. Wavelength tuning of noncritical BPM OPOs requires a variation of the pump wavelength or the crystal temperature.

A temperature-tuned picosecond LBO OPO has been reported [11.2027] that generates continuously tunable radiation between 650 nm and 2.5 μm with a single crystal. The average output power achieved by this system was below 100 mW.

By using tunable pump laser systems like the Kerr-lens mode-locked Ti:sapphire laser pump wavelength tuning offers a convenient tuning mechanism. A noncritical-phase-matched picosecond KTP OPO [11.2028] generates tunable picosecond pulses in the spectral ranges of 1–1.2 μm for the signal and 2.3–2.9 μm for the idler wave via wavelength tuning of the pump between 720–853 nm. Average output powers of up to 700 mW in 1.2 ps pulses have been achieved with a pump power of 1.6 W at a 82 MHz repetition rate.

The combination of wavelength tuning of the Ti:sapphire laser and temperature tuning in LBO has been performed under type I noncritical-phase-matching condition, providing continuously tunable picosecond pulses in the spectral range of 1–2.4 μm [11.2029]. The pump power was 1.2 W in 1–2 ps pulses at a 81 MHz repetition rate and generated an average OPO output power of about 325 mW. Using the arsenate isomorphs of KTP, such as KTA and RTA, the wavelength range of the OPO can be extended up to 3.6 μm [11.2030]. Due to their wider transparency range and the lack of gray tracking inside the crystal these materials are advantageous for IR picosecond OPOs.

Further extension of the tuning range of picosecond OPOs into the mid-IR was demonstrated with a critical-phase-matched $AgGaS_2$ OPO pumped by a Q-switched mode-locked Nd:YAG laser [11.2031]. This OPO had

an idler tuning range of 3.5–4.5 μm and a maximum output power of 2 W.

Picosecond pulse generation in the visible spectral range has been demonstrated in an LBO OPO pumped with the third harmonic of a CW mode-locked Nd:YLF laser [11.2032]. The generated output power was about 275 mW in the spectral range of 453–472 nm in 15 ps long pulses at a repetition rate of 75 MHz.

In general, it should be pointed out that the device Ti:sapphire-laser-pumped KTP or KTA OPO is a versatile tool for the generation of tunable picosecond pulses in the entire spectral region from the UV to the near-IR. The frequency-conversion schemes involved, such as second, third, and fourth harmonics of the Ti:sapphire laser, optical parametric oscillation in KTP and frequency doubling of the OPO's signal wave, have been summarized in experimental investigations for picosecond and femtosecond radiation [11.2033, 2034].

High-power operation of a singly resonant critical-phase-matched picosecond OPO has been reported, which was pumped by the fundamental of a mode-locked Nd:YLF laser at 1.053 μm [11.2035]. This device generates 12 ps long signal pulses at 1.55 μm for 40 ps long pump pulses at a repetition rate of 76 MHz. A total average output power of 2.8 W was achieved with 800 mW in the idler wave at 3.28 μm.

The new generation of mode-locked lasers are diode-pumped CW mode-locked Nd:YVO_4 oscillator–amplifier laser systems. Such an all-solid-state laser system operating at 1.064 μm with 7 ps pulse lengths at repetition rates of about 83 MHz delivers average output powers of 29 W. Pumping a noncritical-phase-matched KTA OPO the OPO output power reaches the multiwatt region, providing a signal wavelength of 1.53 μm with an output power of 14.6 W and an idler output power as high as 6.4 W at 3.47 μm in the mid-IR [11.2036]. The total average output power of 21 W corresponds to an external efficiency of 70%. However, both systems operate at a specific signal and idler wavelength without any tunability.

With the availability of QPM nonlinear materials like PPLN, PPLT, and PPKTP, PPRTA new perspectives have arisen in the research of efficient tunable picosecond OPOs. With the advantageous properties of these materials such as their large nonlinearities, transparency in the mid IR, and the capability of choosing an optimized phase-matching condition for the interacting waves, for example noncritical phase matching, they become ideal candidates to realize singly resonant synchronously pumped OPOs with low thresholds, large tunability, and efficient output powers. A high-power 80 ps optical parametric oscillator based on PPLN with a total output power of 12 W (signal+idler) in the wavelength range 1.7–2.84 μm was demonstrated for a pump power of 18 W [11.2037]. Moreover, these unique material properties allow for efficient injection seeded optical parametric generation with a total output power of more than 9 W [11.2038]. Compact all-solid-state OPOs have been reported based on PPLN and PPRTA with a pump power threshold as low as 10 mW [11.2039, 2040]. The generated radiation covers the wavelength range from 3.35–5 μm with total output powers of up to 400 mW in 1–5 ps pulses. The power of the idler wave was up to 100 mW. The spectral range of the PPLN OPO has been extended even beyond 5 μm [11.2041, 2042] and idler output powers of 0.5 to 140 mW in the MIR have been achieved. In PPLT tunable radiation (995–1340 nm signal, 2.1–3.6 μm idler) in bandwidth limited pulses with durations of 2.6 ps has been generated. The output power was nearly 1 W [11.2043]. The main limitation for MIR OPOs is the high absorption for radiation beyond 4 μm even in PPLN. Meanwhile numerical calculations have been used to optimize the crystal length in order to balance the parametric gain and the absorption losses in the high absorption regime of lithium niobate. Based on the numerical results an optimized experimental setup with an output power of 1.1 W at 4.5 μm and of more than 3 W at 3 μm for 6 ps long pulses with a repetition rate of 160 MHz was demonstrated [11.2044]. Recently, THz wave generation in a tandem setup using PPLN and QPM-GaAs has been demonstrated [11.2045, 2046]. Within a synchronously pumped OPO a resonantly enhanced DFG process generated an average power of 1 mW THz radiation [11.2045].

The operation of a PPLN OPO at GHz repetition rates was demonstrated by pumping the PPLN OPO with a fiber-amplified gain-switched diode laser with repetition rates of 114 MHz to 1 GHz [11.2047] or an all-solid-state neodymium laser at 10 GHz [11.2048]. Rapid wavelength access was achieved with the use of a mode-locked diode laser master-oscillator power-amplifier (MOPA) system providing 7.8 ps pulses at 2.5 GHz repetition rate. The InGaAs oscillator–amplifier system delivered an output power of 900 mW, which was converted to 78 mW idler power tunable in the spectral range of 2.2–2.8 μm [11.2049].

A high-power picosecond PPLN-OPO was performed by synchronously pumping a PPLN crystal with the fundamental wave of a CW mode-locked Nd:YLF laser. The tuning range of the PPLN OPO is for the

signal radiation 1.765–2.06 μm and 2.155–2.61 μm for the idler radiation, respectively. High average output powers for the signal and idler radiation of 2.55 W and 2.4 W have been achieved in 45 ps long pulses at a 76 MHz repetition rate for an input pump power of 7.4 W, which corresponds to a total external conversion of about 67%. The measured pump depletion was 71% [11.2050].

Much emphasis is placed on further extension of the tuning range of picosecond systems into the IR. For this purpose OPO/OPA and OPG/OPA devices are of great interest [11.2051, 2052] as their output powers and tuning ranges are sufficient to be used for difference-frequency mixing into the mid-IR. The difference frequency mixing in GaSe or CdSe [11.2053–2055] of signal and idler frequencies generated from a PPLN OPO seeded KTP-OPA provides picosecond pulses tunable at 3–24 μm.

Femtosecond Optical Parametric Oscillators. Tunable femtosecond OPOs are attractive light sources for time-resolved spectroscopy of chemical and biological reactions. Femtosecond pulses are characterized by their high peak powers, which easily overcome the threshold of a singly resonant OPO configuration. The short pulse length of about 100 fs is combined with a huge spectral bandwidth of several nanometers (≈ 10 nm) and dispersion effects, such as group velocity dispersion, group velocity mismatch (i. e., temporal walk-off), and spectral acceptance bandwidths can no longer be neglected. The group-velocity dispersion causes a pulse broadening whereas the temporal walk-off lowers the nonlinear gain and/or changes the time characteristic of output pulse. For efficient frequency conversion, the temporal walk-off must be minimized by an appropriate choice of the crystal length. Typical crystal lengths of femtosecond OPOs are only 1–2 mm, and therefore high nonlinearities are desirable for low operation thresholds. The group velocity dispersion can be minimized via dispersion compensation in the OPO cavity. Additionally to these dispersion effects, other higher-order nonlinear effects come with the high peak pump powers, such as self-phase modulation and cross-phase modulation, which result in a chirped OPO output pulse [11.1858].

The start of an extensive development of femtosecond OPOs was initiated with the commercial availability of the Kerr-lens mode-locked Ti:sapphire laser. The first material used in synchronously pumped femtosecond OPOs was KTP [11.2056–2058] in noncollinear critical-phase-matching conditions and collinear noncritical-phase-matching conditions. Due to the higher transmission in the mid-IRA OPOs with KTA [11.2059, 2060], RTA [11.2061], $CsTiOAsO_4$ (CTA) [11.2062, 2063], and $KNbO_3$ [11.2064] generate a wider wavelength range of 1–5 μm with pulse durations of less than 100 fs. Typical maximum output powers of such devices are 100–200 mW for the signal and 50–100 mW for the idler wave.

The periodically poled nonlinear materials PPLN, PPRTA and PPKTP are of particular importance for femtosecond OPOs because noncritical phase matching becomes possible even for the extended wavelength tuning. This feature results in compact, low-threshold, efficient OPO devices. The wavelength tuning of such femtosecond QPM OPOs is performed via grating, pump wavelength, or cavity tuning and covers a spectral range from 1.7–5.4 μm in PPLN [11.2065], 1.06–1.22 μm (λ_s) and 2.67–4.5 μm (λ_i) in PPRTA [11.2066], and 1–1.2 μm in PPKTP [11.2067]. Comparing these QPM materials, PPLN and PPRTA have an advantage because of their large transmission range, where PPLN possesses the higher nonlinearity. However, PPLN suffers from process-induced photorefractive defects, which may be suppressed by heating the crystal to temperatures higher than 100 °C. Recently MgO-doped PPLN-OPO was investigated [11.2068] allowing reliable OPO operation at room temperature.

Femtosecond pulses in the wavelength range of 500–700 nm are of interest for many applications such as frequency metrology, optical microscopy, and time resolved spectroscopy. However, this spectral range is not covered by the commonly used Kerr-lens-mode-locked Ti:sapphire laser or its harmonics. A possibility to cover this wavelength range are optical parametric oscillators pumped with the frequency doubled radiation of a Ti:sapphire laser. Such a setup using BBO for frequency doubling as well as for the OPO was already demonstrated in 1994 [11.2069]. With the availability of new improved materials like BiB_3O_6 this scheme became attractive again [11.2070–2072]. Fs-pulses tunable between 480–710 nm with an average power of up to 270 mW and a pulse duration of 120 fs have been reported. Further intracavity frequency doubling in BBO allowed to generate 100 mW in the wavelength range 250–350 nm.

Another successful scheme for generating ultrashort, visible pulses are Ti:sapphire-laser pumped OPOs in the near infrared NIR with intracavity frequency conversion of the resonant radiation. Intracavity frequency doubling of the signal radiation in a KTP-OPO was demonstrated with a conversion efficiency of 11.4%, us-

ing two birefringent phase-matched crystals [11.2073]. A detailed theoretical and experimental study of intracavity frequency conversion in OPOs was published already in 1993 [11.2074, 2075]. This scheme is in particular interesting when using QPM materials, since both processes can be integrated within a single crystal with a length of a few millimeters. This allows the design of very compact systems, since no recollimation or refocusing of the resonant wave are required. In addition, no compensation of a temporal walk-off between the pump and the idler pulses is required, which is mandatory in the femtosecond time domain. Intracavity cascaded first-order second harmonic generation of the signal radiation of a synchronously pumped femtosecond OPO in a single MgO:PPLN was demonstrated recently [11.2076]. An experimental investigation of a synchronously pumped idler resonant femtosecond OPO with first-order sum frequency mixing of the idler and the pump radiation within a single MgO:PPLN crystal produced 190 mW at a wavelength of 598 nm and a pulse duration of 140 fs [11.2077].

Tunable radiation in the range of 4–8 μm has been achieved using a cascaded $AgGaSe_2$ OPO, which was pumped with the idler of a CTA OPO. This system generates average powers of 35 mW in 300–600 fs long pulses at a repetition rate of 82 MHz.

Moreover, optical parametric generators and amplifiers are powerful tools for the generation of ultrashort pulses into further infrared regions [11.2078]. The generation of femtosecond pulses in the spectral range 3–12 μm with almost bandwidth limited pulses of 100–200 fs have been reviewed for different parametric processes and a number of relevant materials [11.2079].

Many new perspectives for the generation of intense ultrashort pulses are given by parametric amplification of chirped laser pulses. The basic principle of optical parametric chirped pulse amplification (OPCPA) is that stretched linearly chirped pump pulses are amplified in a noncollinear phase-matched OPA. After the single-pass amplification, the pulses are compressed, providing high energy in short pulse lengths of 10 fs or less. The noncollinear phase-matching scheme is important because of the huge spectral bandwidths of femtosecond pulses. For ideal OPCPA the pump pulse duration corresponds to the length of the chirped pulse. The spatial beam profile should be rectangular (flattop), and the gain should be constant temporally and spatially. *Dubietis* et al. [11.2078] published the first proposal and demonstration of OPCPA. The first experimental demonstrations of OPCPA were performed in degenerate LBO, KDP, and BBO [11.2080–2084]. Amplification of 10^{10} has been achieved in single-pass amplification.

The use of noncollinear phase matching enables efficient parametrical amplification of nondegenerate wavelengths despite large spectral bandwidth.

The generation of high energies is possible by employing visible picosecond pump pulses and temporally stretched seed pulses. At a center wavelength of 800 nm and a pump wavelength of about 530 nm in BBO and LBO gain bandwidths broader than 2000 cm^{-1} are obtained, which is sufficient to amplify Fourier-limited pulses with 5 fs duration [11.2080]. Due to the large damage thresholds of both materials, high pump intensities can be applied.

Recently energies of 2 TW in 7.6 fs pulses were obtained in BBO in a three-stage setup. The system was pumped by 7 ps 532 nm radiation with a repetition rate of 30 Hz. The seeding was done by 6.2 fs Ti:sapphire pulses. The recompression was realized in a conventional two-grating setup and the higher dispersion orders were precompensated with a 640-element LCD spatial light modulator [11.2085]. Similarly, 16 TW light pulses were achieved in a two-stage setup with a pulse duration of 8 fs [11.2086] by *Krausz* and coworkers at repetition rates of 10 Hz. They employed a grism stretcher and an acousto-optic modulator to compensate the dispersion in the two BBO crystals and the material compressors consisting of SF 47 and fused silica glass.

At present research activities are addressing high repetition rate systems [11.2087] and an extension of the center wavelength into the midinfrared [11.2088, 2089]. Further new materials like BiBO are being investigated as amplifying media [11.2090, 2091].

The amplification of ultrabroad bandwidth few cycle pulses by OPCPA requires careful consideration and management of higher order dispersions [11.2092, 2093].

QPM materials are also advantageous in OPCPA. Broad-bandwidth amplification is no longer restricted to collinear phase matching at degeneracy or to noncollinear phase matching but can be obtained at practically any center wavelength in the crystals' transparency window. Additionally, QPM OPA can be increased by using engineered grating profiles, such as chirped gratings [11.1874], fanned gratings [11.1875], and aperiodic gratings [11.2094].

Nondegenerate OPCPA has been demonstrated in PPKTP at a wavelength of 1573 nm pumped by

a Nd:YAG laser [11.2095] and close to degeneracy at a wavelength of 1053 nm pumped by a Nd:glass laser [11.2096].

This chapter described the basic properties and current performance of CW, nanosecond, and ultrashort optical parametric oscillators. Today, these parametric systems are powerful tunable light sources providing a spectral range from the visible to the mid-IR in all time regimes. The main progress in this field is based on the development of more sophisticated optical materials and efficient, reliable laser systems. With the realization of QPM materials there was an important breakthrough towards compact widely tunable OPOs. Especially for CW OPOs, QPM materials are the key element for the realization of widely tunable singly resonant OPOs. The high nonlinear gain of QPM materials enables the reduction of the optical parametric oscillation to optical parametric generation, which leads to more-simple devices. The combination of diode-pumped solid-state laser systems and QPM crystals, which already leads to direct diode-pumped OPOs, is the way to future, compact tunable laser systems that may be realized in integrated designs.

OPOs have become an indispensable and versatile tool for many sophisticated technical applications such as spectroscopy, mass spectrometry, display technology, telecommunications, or micromachining. Moreover, optical parametric generation and oscillation starts from quantum noise and thus open a window to the world of quantum mechanics. Thus, finally the OPO itself is still an interesting physical system to be explored in the field of quantum mechanics.

11.10 Generation of Coherent Mid-Infrared Radiation by Difference-Frequency Mixing

The fundamental infrared (IR) or mid-IR region of the electromagnetic spectrum between, say 3–20 μm, is of special interest for many applications, notably molecular spectroscopy [11.2097]. The reason is that most organic and inorganic molecules exhibit strong vibrational–rotational transitions in this wavelength region. This is illustrated in Fig. 11.226, where the absorption ranges of some important functional groups of molecules are plotted for wavelengths of 2–20 μm (top), whereas absorption features of a few selected molecules are depicted in the center. In view of applications in air monitoring the (relative) transmission through the terrestrial atmosphere is plotted at the bottom of Fig. 11.226.

This atmospheric absorption is obviously dominated by the presence of water vapor and CO_2. The atmospheric windows at 3–5 and 8–14 μm are clearly visible.

In addition to the ultraviolet–visible and the near-IR range, the mid-IR region has attracted a lot of interest in recent times owing to the numerous applications of trace-gas sensing in rather diverse fields including environmental monitoring and climate research, industrial and process surveillance, workplace safety, agriculture (e.g., ethylene or ammonia detection, surveillance of fermentation), homeland security (e.g., chemical warfare or explosives detection) and medical diagnosis (e.g., human breath monitoring). It has been demonstrated in numerous cases that laser spectroscopy offers the potential for high sensitivity and selectivity, multicomponent capability, and large dynamic range. These are all crucial properties for trace-gas sensing. An important aspect of laser-based sensors is that usually no sample preparation, i. e., neither pretreatment nor preconcentration, are required, in contrast to many competing techniques. Apart from an appropriate detection scheme, which enables sensitive absorption measurements, a mid-infrared tunable laser source is a prerequisite for successful trace-gas sensing and analysis. In addition to tunability, a narrow line width guarantees sufficient specificity of detection in multicomponent real-world gas mixtures. In the preferred mid-IR range, the choice of coherent sources is, however, rather limited. Table 11.52 lists tunable lasers with wavelengths longer than 3 μm. It essentially includes the conventional well-established line-tunable CO and CO_2 gas lasers, continuously tunable semiconductor lasers (lead-salt diode and quantum cascade lasers), color center lasers, novel crystalline solid-state lasers and nonlinear optical devices (optical parametric oscillators (OPOs) and difference-frequency generation (DFG) sources).

Recent progress in solid-state lasers, interband cascade lasers (ICL) [11.2098] and in quantum cascade lasers (QCLs) appears promising. Solid-state laser materials such as Ce^{2+}:ZnSe or Fe^{2+}:ZnSe offer tuning ranges of 2.2–3.1 μm [11.2099] or 4–4.5 μm, respectively (though the latter only when pulsed and with cryogenic cooling) [11.2100]. New developments in

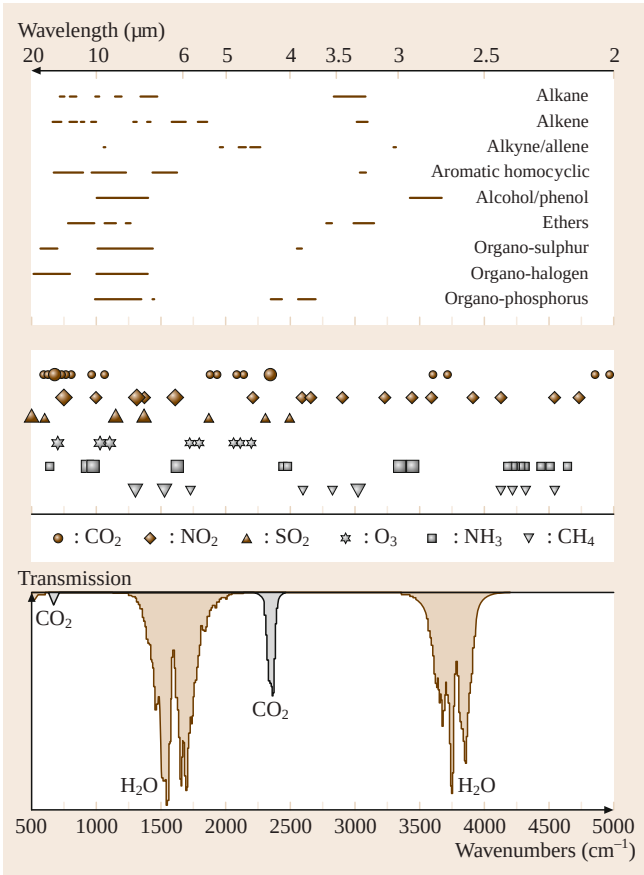

Fig. 11.226 Absorption ranges of important molecular functional groups (*top*) and of selected molecules (*center*). The size of the symbols is related to the absorption strength. Atmospheric transmission is depicted at the *bottom* ◀

QCLs equipped with external cavities yield a continuous tuning range of around 10% of the central wavelength and – at least partly – room-temperature continuous-wave operation [11.2101, 2102]. Despite these attractive prospects the broadest tuning range, best wavelength coverage, room-temperature operation and highest flexibility in terms of wavelength selection is currently still achieved with nonlinear optical devices (DFG and OPOs) [11.2103]. Here we focus on DFG as the scheme that has been widely used in recent times to access mid-IR wavelengths for trace-gas sensing. In fact, these important applications have fostered further developments of DFG systems.

11.10.1 Difference-Frequency Generation (DFG)

Difference-frequency generation (DFG) represents a nonlinear optical effect that is related to the nonlinear susceptibility of second order ($\chi^{(2)}$) of a material. Other related effects are second-harmonic generation (SHG) and sum-frequency generation (SFG). Hence, DFG represents a three-beam interaction process that is mostly used to generate tunable coherent mid-infrared radiation, although it has also been employed for THz generation.

Birefringent and Quasi-Phase Matching, Quasi-Phase Matching and Conversion Efficiency

In difference-frequency generation the light of two laser beams is mixed in a nonlinear crystal and light with a frequency of the difference of the two incident frequencies is generated. The generated frequency is given by energy conservation

$$\hbar\omega_\mathrm{p} - \hbar\omega_\mathrm{s} = \hbar\omega_\mathrm{i} \rightarrow \omega_\mathrm{i} = \omega_\mathrm{p} - \omega_\mathrm{s} \,. \qquad (11.202)$$

Table 11.52 Tunable continuous-wave mid-IR laser sources with wavelengths ≥ 3 μm. RT: room temperature, LN_2: liquid nitrogen (77 K), TE: thermoelectric cooling, SHG: second-harmonic generation, QCL: quantum cascade laser, OPO: optical parametric oscillator, DFG: difference-frequency generation

Laser	Wavelength (μm)	Tuning characteristics	Power	Operation
CO	5–6 (2.7–4, overtone)	Only line tunable	50 mW to W	LN_2 cooling, also ≤ 0 °C
CO_2	9–11 (4.5–5.5, SHG)	Only line tunable	W	RT operation
Lead salt diode	4–30	≈ cm^{-1} mode hop-free	< 0.1 mW	Cryogenic cooling
QCL	4–> 24, THz	cm^{-1} to > 100 cm^{-1} per device	mW	LN_2/TE cooling, also RT
Color center	1–3.3	≈ 0.5 μm for single crystal	100 mW	LN_2 cooling
Solid-state	2.2–3.1	≈ 0.5–1 μm	≤ 1 W	RT operation
OPO	3–16	≈ μm for specific setup	≤ 1 W	RT operation
DFG	3–16	≈ μm for specific setup	μW to mW	RT operation

The laser with the highest frequency ω_p is called the pump laser, while the second laser is called the signal laser with a frequency ω_s. The generated idler beam has the lowest frequency ω_i. The phase-matching condition is given by the conservation of momentum

$$\Delta \boldsymbol{k} = \boldsymbol{k}_p - \boldsymbol{k}_s - \boldsymbol{k}_i = 0 \,, \tag{11.203}$$

where $\Delta \boldsymbol{k}$ is the phase mismatch, and $\boldsymbol{k}_p$, $\boldsymbol{k}_s$, and $\boldsymbol{k}_i$ are the wavevectors of the pump, signal, and idler beam, respectively. In the case of collinear wave propagation the wavevectors can be replaced by $|\boldsymbol{k}| = nc/\lambda$ and (11.203) changes to:

$$\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} = 0 \,, \tag{11.204}$$

where n is the refractive index at the corresponding wavelength, λ is the wavelength with the subscripts p, s, and i corresponding to pump, signal and idler, respectively, and c is the speed of light in vacuum. Phase matching in a birefringent crystal can be achieved by:

1. Angle tuning
2. Temperature tuning
3. Wavelength tuning (changing the wavelength of the pump and/or signal laser).

The most common way to achieve phase matching with a birefringent crystal is realized by angle tuning, i. e., by rotating the crystal until the phase-matching condition is fulfilled.

For infinite plane waves the idler intensity is given by [11.2105]

$$I_i = 2\frac{\omega_i^2 d_{eff}^2 L^2 I_s I_p}{c^3 \varepsilon_0 n_p n_s n_i} \mathrm{sinc}^2\left(\frac{\Delta \boldsymbol{k} L}{2}\right) \tag{11.205}$$

where d_{eff} is the effective nonlinear coefficient, L is the crystal length, I is the intensity of the laser beam for pump, signal and idler beams, respectively, ε_0 is the dielectric constant, and Δk is the phase mismatch. Hence the idler intensity scales with the product of the incident intensities $I_s I_p$ and the square of the crystal length L^2. This is valid as long as there is no pump depletion and negligible walk-off between the beams. These effects limit the useful crystal length and they are discussed in more detail in the section on nonlinear crystals. The effective nonlinear coefficient d_{eff} describes the nonlinearity of the crystal seen by the incident light and depends on the crystal structure, the direction of propagation, the polarization of the light, and the nonlinear coefficients d_{ij} (Table 11.53) given by the tensor of the nonlinear susceptibility $\boldsymbol{\chi}^{(2)} = 2\mathbf{d}$.

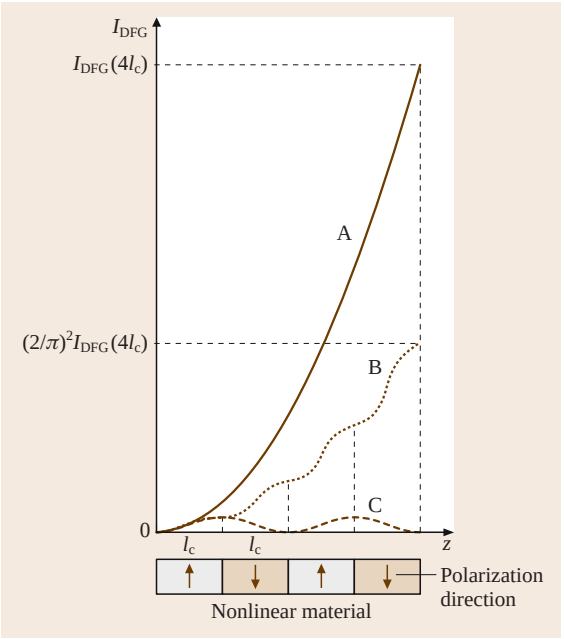

Fig. 11.227 Idler power generation for phase-matching condition $\Delta k = 0$ (A), non-phase-matching condition $\Delta k \neq 0$ (C) and quasi-phase-matching condition in the case of a periodically poled crystal (B). l_c denotes the coherence length [11.2104]

To achieve phase matching it can be taken advantage of the different refractive index for ordinarily and extraordinarily polarized light. Depending on the combination of polarization of the pump and signal beam and depending on positive or negative birefringence of the crystal, the phase matching is called type I, type II or type III, as defined in Table 11.54. For quasi-phase matching (see below) all three beams have the same polarization.

Equation (11.205) implies a possibility to generate light at the idler frequency without phase matching. I_i has a maximum at $\Delta k L/2 = m\pi/2$, where m is an integer. This yields the coherence length $l_c = \pi/\Delta k$ after which the newly generated idler light will interfere destructively with the light generated within the previous coherence length. Thus, after twice the coherence length all generated light is destroyed. This can be avoided by changing the polarization of the material by 180° after one or an odd multiple of the coherence length l_c because this will change the sign of the nonlinear coefficient, so the light will interfere constructively and a buildup of the generated light occurs, as illustrated in Fig. 11.227. This means that idler power can be gener-

Table 11.53 Nonlinear coefficients d_{ij} measured at wavelength λ_m, transparency range and approximate damage threshold for ns pulses of selected nonlinear optical crystals used in DFG

Table 11.54 Different phase matching types for DFG processes for positive and negative birefringent crystals. PM: phase matching, e: extraordinarily polarized, o: ordinarily polarized, QPM: quasi-phase matching

PM type	Birefringence	Pump beam	Signal beam	Idler beam
I	Positive	o	e	e
I	Negative	e	o	o
II	Positive	o	e	o
II	Negative	e	o	e
III	Positive	o	o	e
III	Negative	e	e	o
QPM		e	e	e

ated without fulfilling the phase-matching condition by using a periodically poled crystal. A quasi-phase matching (QPM) condition can be written by using the grating period $\Lambda = 2l_c$ of the crystal

$$\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} - \frac{1}{\Lambda} = 0\,. \tag{11.206}$$

For the same parameters as for the bulk material less idler power will be generated with quasi-phase matching than with birefringent phase matching by a factor of $(2/\pi)^2$. This factor is often included in d_{eff} by reducing its value by a factor $2/\pi$. Although the efficiency is lower than in the case of birefringent phase matching, often more power can be generated this way because the highest nonlinear coefficient can be used (e.g., for $LiNbO_3$ $d_{33} = -27\,pm/V$ (Table 11.53) instead of $d_{22} = 3.07\,pm/V$, which is relevant for birefringent type II phase matching). Since all involved polarizations are the same (extraordinarily polarized, Table 11.54), the walk-off angle is zero, therefore longer crystals can be used, resulting in higher idler power. Furthermore, the selection of pump and signal wavelengths is rather flexible. However, the production of periodically poled crystals is difficult and not possible for all crystals. Until now only $LiNbO_3$ (PPLN), $RbTiOAsO_4$ (PPRTA), $KTiOPO_4$ (PPKTP), and $KTiOAsO_4$ (PPKTA) are commercially available periodically poled. These are ferroelectric crystals that are poled by applying a strong electrical field. Another, non-ferroelectric material offered periodically poled is GaAs. In the beginning thin plates of GaAs with alternate polarization were stacked manually [11.2115]. Today orientation patterned GaAs, where the periodic poling is implemented during crystal growth [11.2116–2118], is becoming available.

Equation (11.205) is obtained under the assumption of infinite plane waves and no absorption. For Gaussian beams the relationship between idler power P_i, crystal length L, pump power P_p, signal power P_s, and absorption coefficient α of the crystal is given by [11.2119–2121]

$$P_i = P_p P_s \frac{32\pi^2 d_{eff}^2 L}{\varepsilon_0 c n_i \lambda_i^2 (n_s\lambda_p + n_p\lambda_s)} h(\xi, \sigma, \mu, \alpha, L)\,. \tag{11.207}$$

The focusing function $h(\xi, \sigma, \mu, \alpha, L)$ for diffraction-limited Gaussian beams is given by

$$h(\xi, \sigma, \alpha, L) = \mathrm{Re}\left(\frac{e^{-\frac{\alpha L}{2}}}{4\xi} \times \int_{-\xi}^{\xi} d\tau \int_{-\xi}^{\xi} d\tau' \frac{e^{-i\sigma(\tau-\tau') + \frac{\alpha L}{4\xi}(\tau+\tau')}}{1 + \tau\tau' - i\frac{1+\mu^2}{1-\mu^2}(\tau-\tau')} \right), \tag{11.208}$$

with

$$\xi = \frac{L}{b}\,, \tag{11.209}$$

$$\mu = \frac{k_s}{k_p} = \frac{n_s\lambda_p}{n_p\lambda_s}\,, \tag{11.210}$$

$$\sigma = -\pi b \left(\frac{n_p}{\lambda_p} - \frac{n_s}{\lambda_s} - \frac{n_i}{\lambda_i} - \frac{1}{\Lambda} \right)\,. \tag{11.211}$$

Here Λ is the grating period, and b is the confocal parameter of both the pump and signal beam and is given by the minimal beam waist $w : b = k_p w_p^2 = k_s w_s^2$, σ describes the phase mismatch. The focusing function h is discussed further below (see also Figs. 11.231, 232, 233 and 11.235). These equations are valid for both bulk and periodically poled crystals, only d_{eff} changes by a factor $2/\pi$ compared to the case of a bulk crystal. The focusing function describes two competing effects: the efficiency is increased by focusing the beams because of higher intensities, but at the same time reduced because of less collinear wavevectors. A possibility to overcome this problem is to use waveguide periodically poled nonlinear crystals [11.2122]. Here the beams are confined in a waveguide in the crystal leading to collinear wavevectors and high intensities at the same time. With this technique continuous-wave (CW) idler powers in the milliwatt range can be achieved whereas with bulk or periodically poled crystals the CW idler power is normally in the microwatt range. Waveguide difference-frequency generation is discussed in more detail below.

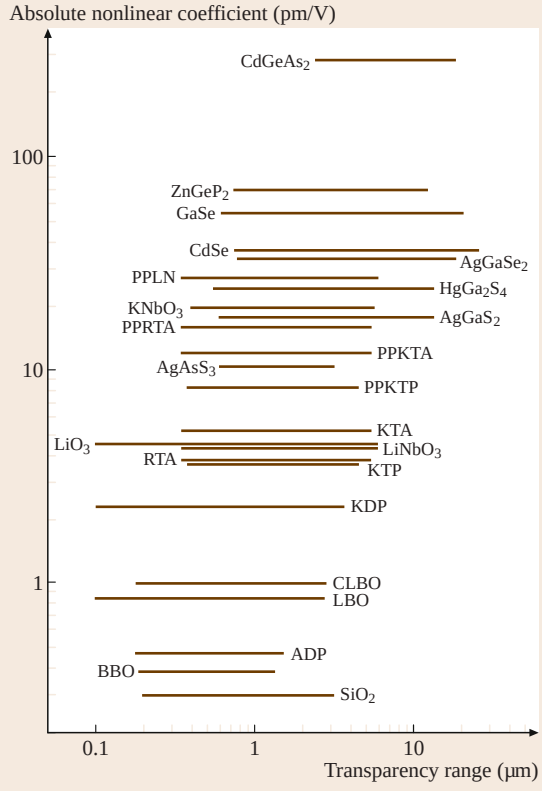

Fig. 11.228 Transparency range of some selected nonlinear crystals used for mid-IR DFG generation as a function of the absolute value of the nonlinear coefficient. For the periodically poled materials (PPLN, PPRTA, PPKTA, PPKTP), the nonlinear coefficient d_{33} is given [11.2104]

The limit $\xi \to 0$ gives the result for the infinite plane wave because $b \to \infty$ for plane waves. In this case the focusing function reduces to $h \approx \xi$, resulting in an idler power proportional to L^2, as in the case for the plane waves (11.205).

An often used nonlinear crystal for difference-frequency generation in the mid-infrared is $LiNbO_3$ because it can be made periodically poled (known as PPLN) and has a large nonlinear coefficient. Its effective nonlinear coefficient is given by $d_{\text{eff}} = 2/\pi d_{33} M_{ij} = -14.4\,\text{pm/V}$ with $d_{33} = -27\,\text{pm/V}$ and $M_{ij} = 0.85$ for $LiNbO_3$ at 3.3 μm [11.2123]. M_{ij} is the Miller factor, which describes the dispersion of the nonlinear coefficient [11.2110, 2124, 2125]. The factor $2/\pi$ is needed when using quasi-phase matching.

To calculate the phase-matching condition the refractive index needs to be known for all wavelengths. It is given by the temperature-dependent Sellmeier equation, e.g., for extraordinary polarized light in $LiNbO_3$ [11.2126]

$$n_e^2 = 5.35583 + 4.629\times10^{-7}F + \frac{0.100473 + 3.862\times10^{-2}F}{\lambda^2 - (0.20692 - 0.89\times10^{-8}F)^2} + \frac{100 + 2.657\times10^{-5}F}{\lambda^2 - 11.34927^2} - 1.5334\times10^{-2}\lambda^2 \,. \tag{11.212}$$

Here $F = (T - 24.5)(T + 570.82)$ describes the temperature dependence when T is the temperature in °C and λ is the wavelength in nm. This equation takes also the multiphonon absorption into account, which yields more-accurate data for wavelengths between 4 and 5 μm.

When choosing the grating period and the temperature of the crystal, the thermal expansion of the crystal also needs to be taken into account because it also influences the grating period, although much less than the change of the refractive index with temperature. The thermal expansion is (at 25 °C) $a_a = 15\times10^{-6}$ /K and $a_c = 7.5\times10^{-6}$ /K [11.2127] where the indices a and c correspond to the crystal axis. The refractive index of $LiNbO_3$ strongly depends on its composition, the Sellmeier equation in (11.212) is for congruent composition, it will be different for stoichiometric composition. Also the refractive index of, e.g., MgO doped $LiNbO_3$, as often used in experiments, differs from that of ordinary $LiNbO_3$.

Nonlinear Crystals

Numerous crystals show nonlinear optical effects, but only a few are useful for difference-frequency generation. The crystal material needs to be transparent at all wavelengths of pump, signal and idler beams, it should have a high nonlinear coefficient and a high damage threshold. In some cases, e.g., strong dispersion and weak birefringence, phase matching is not possible. These requirements limit the choice of nonlinear crystals. The optical properties of some nonlinear crystals used in DFG systems are listed in Table 11.53. Figure 11.228 shows the absolute nonlinear coefficient and the transparency range of selected crystals for comparison.

For an easier comparison and characterization of crystals and DFG setups reported in the literature, the following figure of merit (FOM) is useful

$$\text{FOM} = \frac{P_i}{P_p P_s L}\,, \tag{11.213}$$

Table 11.55 Figure of merit (FOM) for different setups and crystals. PP: periodically poled, OP: orientation patterned, ECDL: external-cavity diode laser

[a] FOM calculated with peak powers
[b] FOM calculated with average powers

where P_i, P_p and P_s denote the power of the idler, pump and signal beams, respectively, and L is the crystal length. This way the comparison is independent of the laser powers and crystal lengths chosen. In Table 11.55 this FOM is listed for some representative setups involving various crystals and combinations of pump and signal lasers. Some of the setups generate a CW idler beam by using two CW lasers for pump and signal; other setups have a pulsed idler beam by using two pulsed lasers or one pulsed and one CW laser.

When choosing the pump and signal lasers several issues have to be considered. The laser wavelengths need to be within the transparency range of the crystal, and the wavelengths and the polarizations should be chosen so that phase matching is possible. Another important aspect is the laser power. As the conversion efficiency is rather low, high laser powers are preferred, but too-high powers will damage the crystal, the surface of the crystal or the antireflection (AR) coatings on the crystal. The AR coating often has a lower damage threshold than the crystal itself. At high power levels of the pump laser other effects such as optical parametric generation (OPG) or amplification (OPA) could become even stronger than the difference-frequency generation, resulting in an enlarged line width. If the signal laser has much more power than the pump laser, pump depletion might be a problem. Therefore pump and signal laser and nonlinear crystals or tighter focusing have to be carefully matched. To estimate how low the signal power needs to be to avoid pump depletion, the following formula can be used

$$\eta = \frac{I_i}{I_p} = \frac{8\pi^2 d_{eff}^2 L^2 I_s}{\varepsilon_0 n_p n_s n_i c \lambda_i^2} \ll 1 \,, \tag{11.214}$$

where I_i, I_p, and I_s denote the idler, pump, and signal intensity, respectively, d_{eff} is the effective nonlinear coefficient, L is the crystal length, λ_i is the idler wavelength, ε_0 is the dielectric constant and n is the refractive index with the subscripts p, s, and i referring to pump, signal and idler, respectively. η is the conversion efficiency from pump beam to idler beam, where $\eta = 1$ implies that 100% of the pump beam is converted to the idler beam. This case gives the nonlinear interaction length L_{nl}, one of several characteristic lengths of a DFG system

$$L_{nl} = \sqrt{\frac{\varepsilon_0 n_p n_s n_i c \lambda_i^2}{8\pi^2 d_{eff}^2 I_s}} \,. \tag{11.215}$$

Crystal lengths longer than L_{nl} will not increase the idler power because of pump depletion. The aperture length L_{an} is the distance after which the beam is displaced by $2w_0$ because of walk-off effects and is given by

$$L_{an} = \sqrt{\pi}\frac{w_0}{\rho_n} \,, \tag{11.216}$$

where w_0 is the minimal beam waist and ρ_n is the walk-off angle. The diffraction length L_{diff} is the length after which the beam diameter has increased by a factor of $\sqrt{2}$. Longer crystals or tighter focusing will not increase the idler power. This effect can be calculated more precisely by using the focusing function in (11.207)

$$L_{diff} = 4kw_0^2 \,. \tag{11.217}$$

For pulsed lasers the interaction length L_{qs} represents a further important issue

$$L_{qs} = \sqrt{\pi}\tau \left(\frac{1}{v_{g_1}} - \frac{1}{v_{g_2}}\right)^{-1} \,, \tag{11.218}$$

where τ is the pulse duration, v_{g1} and v_{g2} are the group velocities of the pump and the signal beams, respectively. L_{qs} describes the length after which the pulses from the two beams are separated by τ. Another characteristic length for pulsed laser is the dispersion length

L_{ds}, given by

$$L_{ds} = \frac{\tau^2}{g_n} , \tag{11.219}$$

where g_n is the group-velocity dispersion. This length describes the length after which the pulse duration has doubled. With these characteristic lengths first estimations for crystal lengths and pulse durations can be made.

11.10.2 Waveguide Difference-Frequency Generation

For difference-frequency generation in bulk crystals focusing the pump and signal beams increases the conversion efficiency due to higher intensities but only up to a certain point. When the diffraction length (11.217) reaches the crystal length then the idler power does not increase any further with tighter focusing because of the diffraction of the beams. This problem can be solved by using waveguide nonlinear crystals. In a waveguide the light is confined in a small area leading to high intensities over the whole length of the crystal. Therefore, conversion efficiencies that are orders of magnitude higher than those of bulk crystals can be achieved. Using periodically poled crystals allows quasi-phase matching simplifying the use of waveguides and wavelength tuning can easily be achieved by changing the crystal temperature.

There are several ways of fabricating waveguides in nonlinear crystal, e.g., by annealed proton exchange [11.2141–2143], by indiffusion of titanium [11.2131, 2144] or building a ridge waveguide by cutting the crystal with a dicing saw. Annealed proton exchange and titanium indiffusion create waveguides by changing the refractive index in the treated region. Both methods have been applied to periodically poled $LiNbO_3$. The latter fabricates waveguides by diffusing titanium stripes into the crystal at very high temperatures (1060 °C [11.2144]) for several hours, the periodic poling is done afterwards. For waveguide fabrication by annealed proton exchange the crystal is first poled periodically, then a chrome mask pattern is applied to the surface with openings where the waveguide channels should be. Next, the crystal is exposed to benzoic acid at 170 °C and finally it is annealed in air at 340 °C [11.2142]. With those two methods waveguide channels with only a small thickness can be made (e.g., 160 nm with titanium diffusion [11.2131]), but they give the possibility of making a large variety of waveguide shapes like tapers or segmented sections [11.2145].

Waveguides of several micrometers thickness can be obtained by fabricating ridge waveguides and using a direct bond technique [11.2122, 2146]. For this a periodically poled $LiNbO_3$ wafer (waveguide layer) is brought in close contact with a $LiTaO_3$ wafer (cladding layer) in a clean atmosphere and is annealed at 500 °C to achieve complete bonding at atomic level. Next, the thickness of the waveguide layer is reduced to several micrometers by lapping and polishing. Then ridge waveguides with a width of several micrometers are fabricated by using a dicing saw. With these ridge waveguides mid-infrared radiation of several milliwatts within selected wavelength segments between 2.3–4.6 μm have been generated [11.2122, 2132, 2147–2153]. Since the intensities are very high, photorefractive damage is an important issue. Doping of the nonlinear crystal with, e.g., magnesium or zinc can improve the damage resistance of the crystal. For example, continuous wave output powers of up to 65 mW have been demonstrated with Zn:$LiNbO_3$ waveguides by using pump and signal intensities of about 500 mW [11.2132].

There are several possibilities to couple the light from pump and signal laser into the waveguide. For example, the two beams can be combined with free-space optics and then be coupled into the waveguide by using an objective lens. This method is useful for high-power application, where optical fibers can become damaged, but it is sensitive to misalignment. Another possibility is to couple the lasers into polarization maintaining fibers and then combine them with a wavelength division multiplexer. This ensures a perfect overlap of the pump and signal beam, it is very robust, and the laser sources can easily be exchanged. The fiber end with the combined beams can then be aligned to the crystal waveguide by using a micropositioning stage and it may be glued to the waveguide. The fiber can also be aligned and attached to the waveguide by the V-groove connection technique, where a silica glass block with a V-groove is glued to the waveguide chip [11.2147, 2154]. This V-groove allows very precise alignment of the fiber. Fixing the fiber end in the groove with glue gives a very rigid system, but it limits the temperature range within which the nonlinear crystal can be used.

One major difference between difference-frequency generation in a waveguide and in a bulk crystal is that the phase-matching (11.204) or (11.206) must be obtained for the waveguide modes where the different modes experience different refractive indices. The phase-matching condition is then given

by

$$\frac{n_{gq}\left(\lambda_p\right)}{\lambda_p} - \frac{n_{g'q'}\left(\lambda_s\right)}{\lambda_s} - \frac{n_{g''q''}\left(\lambda_i\right)}{\lambda_i} - \frac{1}{\Lambda} = 0\,, \tag{11.220}$$

where $n_{gq}(\lambda)$ is the effective refractive index of the TM_{gq} mode at the wavelength λ. The waveguides are usually designed to be single-mode at the idler wavelength, but they are multimode at the pump and signal wavelengths. This leads to the effect that the phase-matching condition is fulfilled at different wavelength for the different modes. This has the advantage that broadband phase-matching or simultaneous phase-matching at multiple wavelengths can be achieved by carefully engineering the waveguide geometry [11.2150, 2153]. The disadvantage is that the idler intensity might decrease because the pump and signal intensity are distributed over several modes but only the ones fulfilling the phase-matching condition generate mid-infrared radiation [11.2131, 2142, 2156]. This effect can be reduced by choosing a favorable waveguide geometry, e.g., tapered waveguides that provide single-mode propagation for both pump and signal wavelength [11.2143].

11.10.3 DFG Laser Sources

The literature on DFG laser sources, new nonlinear crystal materials and applications has become extensive in recent years. By far the largest part of these systems have been, and still are, developed for spectroscopic gas sensing and analysis application. A recent overview of systems is given in [11.2104]. In the following we describe a typical DFG setup that has been implemented in our laboratory for measurements on isotopomers of trace gases. Precise isotope ratio measurements of trace gases represent an important contribution to the solution of key questions in various areas, e.g., differentiation between natural and anthropogenic origin of specific compounds. Isotopic compositions are of interest in such diverse fields as ecological CO_2 exchange, volcanic emission, medical diagnostics, extraterrestrial atmospheres, etc.

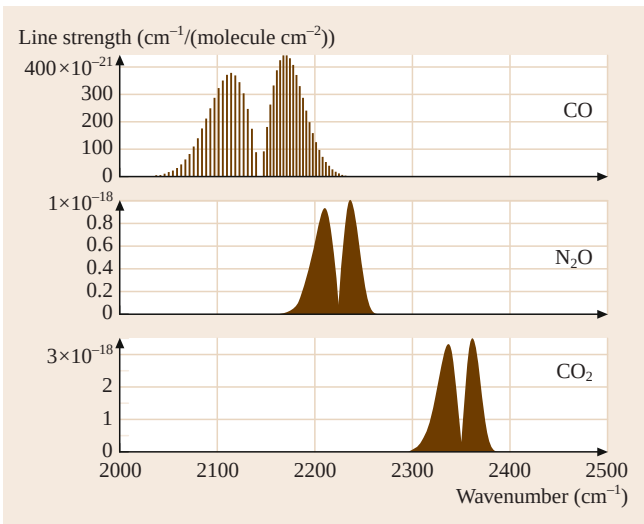

Fig. 11.229 Absorption lines of CO, N_2O and CO_2 as a function of wavenumber in the mid-IR region [11.2155]

Detailed Discussion of a DFG Laser Source

Isotopic composition of trace gases such as CO_2, CO or N_2O are of special interest. These molecules with their isotopomers exhibit strong absorption lines between 4.3 to 4.7 μm (Fig. 11.229). Therefore a continuous-wave DFG source, which enables continuous tuning and narrow line width (to differentiate between isotopomers), was implemented. In the following sections the theoretical calculations, the setup and the characterization of this system is described.

Calculations of Optimal Crystal Length and Beam Parameter. For the wavelengths of interest we chose $LiNbO_3$ as nonlinear optical medium because it has a transmission range from 0.4 to 5.0 μm, a large nonlinear coefficient, and it can be produced periodically poled.

However, $LiNbO_3$ has an absorption band at 5 μm so the absorption between 4 and 5 μm cannot be neglected. The absorption coefficient at 4.3 μm is 0.25 cm^{-1}, at 4.6 μm it is 0.55 cm^{-1} and at 4.7 μm 0.75 cm^{-1} [11.2157]. There are other crystals that can be used at this wavelength, e.g., $AgGaS_2$ or $AgGaSe_2$ (Table 11.53), but they are not available periodically poled, so birefringent phase matching has to be used. This means the crystal length needs to be shorter because of walk-off effects and it is not possible to use the maximum nonlinear coefficient. Furthermore alignment is more critical than with a periodically poled crystal. Finally, wavelength tuning is also an important issue. When working with such crystals angle tuning has to be used, which makes wavelength tuning over larger ranges more complicated. Often noncritical phase matching is used, because of its larger acceptance bandwidth, but for a certain idler wavelength the pair of signal and pump wavelength is fixed in this case. This limits the choice of lasers and normally two diode lasers

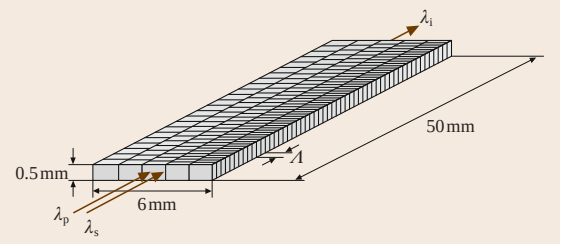

Fig. 11.230 A periodically poled crystal with several gratings for different wavelengths. $\lambda_{p,s,i}$: pump, signal, idler wavelength, respectively; Λ: grating period

have to be used with lower output power than other lasers.

In contrast, when using quasi-phase matching, the phase matching is realized by choosing a grating period, so nearly every combination of lasers can be used, for example, an external cavity diode laser (ECDL) that can be conveniently wavelength tuned, and a Nd:YAG laser that delivers high laser power. Phase matching is achieved by choosing the correct grating period Λ, which can be adjusted to other wavelengths by changing the temperature of the crystal because of the temperature dependence of the refractive index (11.212). When scanning the wavelength for spectroscopy, the crystal temperature can be changed simultaneously to achieve mid-IR wavelength ranges of several hundred nm with only one grating period. Depending on wavelength the temperature acceptance bandwidth can be quite large (Fig. 11.236b). Even larger wavelength ranges can be achieved by using a crystal with several gratings, as shown in Fig. 11.230. Typical grating periods for our wavelength range are approximately 23 µm. As a result it appears advantageous to use PPLN for the envisaged 4.3–4.7 µm wavelength range rather than a bulk $AgGaS_2$ or other crystal despite the non-negligible absorption of PPLN.

According to (11.207) the idler power increases with the crystal length but also the absorption increases, therefore there is an optimum crystal length for this wavelength region. The maximum of the focusing function h (11.208) is not at $\sigma = 0$ but, e.g., at $\sigma = 1.3$ for a pump wavelength of 863 nm, a signal wavelength of 1064 nm and a crystal length of 5 cm (Fig. 11.235), so the maximum idler power is not obtained at perfect phase matching, but for a slightly different grating period. However, to simplify the calculations, σ was set to 0. The focusing function and hence the idler power has a clear maximum at about $\xi = L/b = 1.3$ (Fig. 11.231). It depends only slightly on wavelength and absorption. Therefore for a chosen crystal length L there is an optimal confocal parameter b.

When the idler power is plotted as a function of crystal length L and of the confocal parameter b, it can be seen that a long crystal combined with a large confocal parameter yields higher idler power (Fig. 11.232). However, in a real experiment the confocal parameter is limited by the thickness of the crystal and crystals longer than 6 cm are not easily commercially available.

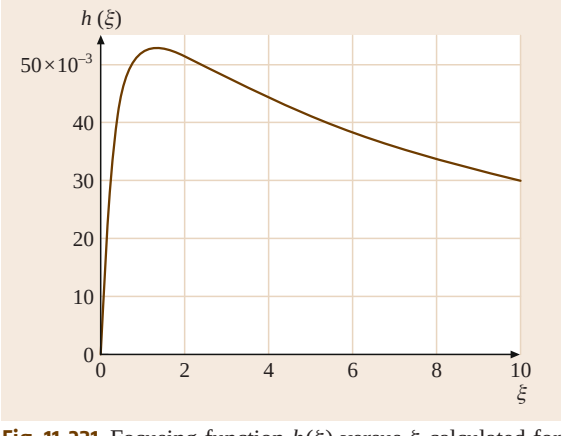

Fig. 11.231 Focusing function $h(\xi)$ versus ξ calculated for $\lambda_p = 868$ nm, $\lambda_s = 1064$ nm, $\alpha = 0.75\,\mathrm{cm}^{-1}$, $\sigma = 0$, and $L = 5$ cm. The maximum is at $\xi = 1.3$ and for small ξ the focusing function h is proportional to ξ. The symbols are explained in (11.207, 208, 209, 210, 211)

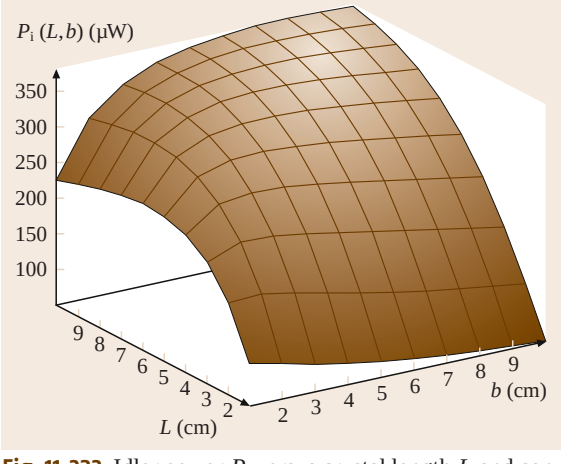

Fig. 11.232 Idler power P_i versus crystal length L and confocal parameter b calculated at a pump wavelength of 853 nm. The idler power increases with increasing crystal length and confocal parameter

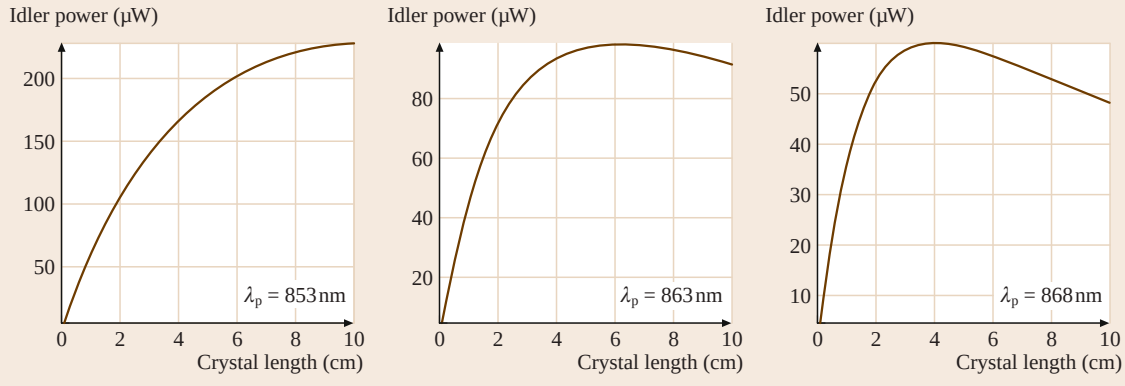

Fig. 11.233 Idler power as a function of crystal length for pump wavelengths λ_p of 853 nm, 863 nm, 868 nm. The signal laser is a Nd:YAG laser fixed at $\lambda_s = 1064$ nm. The calculations were made with $\sigma = 0$ and keeping $\xi = L/b = 1.3$ at the maximum. At 853 nm the ideal crystal length is longer than 10 cm, at 863 nm it is 5.9 cm, at 868 cm it is 4.0 cm

One problem with longer crystals is that crystal defects have too much influence. The thickness of the crystal is limited by the production process of the periodically poled grating. This is done by applying an electric field to change the orientation in the crystal, which requires very strong electric fields. This limits the thickness to 1 mm. Most crystals have a thickness of 0.5 mm, resulting in a better grating quality than for a thickness of 1 mm.

In Fig. 11.233 it can be seen how the idler power changes for different crystal lengths. The calculations were made with $\sigma = 0$ and keeping $\xi = L/b = 1.3$ at the maximum. The result is that at $\lambda_p = 853$ nm ($\lambda_s = 1064$ nm, $\lambda_i = 4.3$ μm) the optimal length is longer than 10 cm, at $\lambda_p = 863$ nm ($\lambda_i = 4.6$ μm) it is 5.9 cm, and at $\lambda_p = 868$ nm ($\lambda_i = 4.7$ μm) it is 4.0 cm. We chose a crystal length of 5 cm, implying $b = 4$ cm, which gives a minimal beam waist of 0.13 mm. The diffraction of such a Gaussian beam is small enough that it propagates within the crystal over the whole length.

Based on (11.207), an idler power of 55–170 μW is expected for a pump power of 150 mW, a signal power of 2 W and a crystal length of 5 cm.

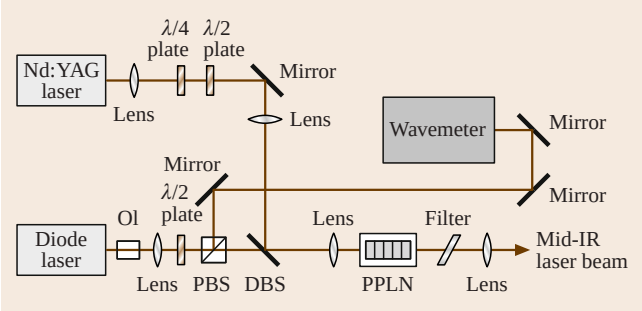

Fig. 11.234 Setup for difference-frequency generation. OI: optical isolator, PBS: polarizing beam splitter, DBS: dichroic beam splitter, PPLN: periodically poled $LiNbO_3$

Setup and Characterization. The continuous-wave DFG system described here consists of an external cavity diode laser (ECDL) as pump laser, a continuous-wave Nd:YAG laser as signal laser and a MgO-doped periodically poled $LiNbO_3$ crystal (MgO:PPLN). The ECDL (Sacher TEC-120-850-150) has a power of 150 mW and a wavelength range of 820–875 nm. To cover the idler wavelength range of 4.3–4.7 μm, pump wavelengths of 852–868 nm are needed. The Nd:YAG laser (Innolight Mephisto) has a CW power of 2 W and a wavelength of 1064.5 nm. The MgO:PPLN crystal (HC-Photonics) is 5 cm long and 0.5 mm thick. It has several gratings with periods of 21.45, 22.00, 22.50, 23.10, and 23.65 μm, each with a width of 1.2 mm. For the wavelength of interest in this experiment, only the grating period of 23.1 μm is needed, it is quasi-phase matched for the different wavelengths by changing the temperature from 30 to 130 °C. The crystal is antireflection coated for the pump, signal and idler wavelengths.

The laser beams are focused by several lenses (including cylindrical lenses, not shown in Fig. 11.234) so that the minimal beam radius is 0.13 mm within the crystal. The $\lambda/4$ and $\lambda/2$ plates are used to match the beam polarization for quasi-phase matching in the PPLN crystal. A small part of the pump beam is directed to a wavemeter. The recorded pump wavelength then yields the idler wavelength. After the crystal a ger-

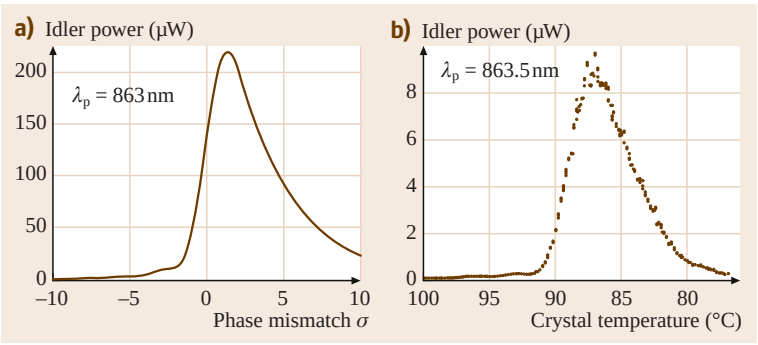

Fig. 11.235 **(a)** Idler power as a function of phase mismatch σ (11.211), calculated for a pump wavelength of 863 nm, a signal wavelength of 1064 nm, and a crystal length of 5 cm. **(b)** Measured idler power as a function of crystal temperature corresponding to phase mismatch, at a wavelength of 863.5 nm and a crystal length of 5 cm. It can be seen that the measured and the calculated curve have a similar shape

manium filter is used to block the near-infrared light. The setup is depicted in Fig. 11.234.

This DFG system was tested and characterized by focusing the mid-IR beam onto a detector (VIGO PDI-2TE-5, TE-cooled) and recording the signal with a lock-in amplifier with a time constant of 100 ms. For modulating the laser power with a frequency of 1.8 kHz, a chopper was placed after the Nd:YAG laser. To find the crystal temperature for phase matching, the temperature was increased in steps of 0.2 °C or 0.5 °C while keeping the pump wavelength constant (Fig. 11.235).

The temperature for phase matching is 6.6–11.2% higher than theoretically calculated (Fig. 11.236a) and the temperature acceptance bandwidth increases with longer wavelengths and is 2.5–3.7 °C (Fig. 11.236b). The power of the CW mid-infrared beam amounts to 23 μW at 4.3 μm and 5 μW at 4.76 μm (Fig. 11.236c). It decreases for increasing wavelengths due to the crystal absorption near 5 μm. The generated idler power is about four to ten times lower than calculated, most probably due to imperfections in the crystal, its grating quality and non-Gaussian beam shape of the ECDL pump laser.

For measurements of the isotopic composition of trace gases, the laser line width should be sufficiently narrow to resolve adjacent molecular lines clearly, also when recorded at reduced gas pressure. The line width of our CW mid-IR source has been estimated to be approximately 1 MHz and thus fulfills the requirements by far.

Measurement of Isotopic Composition of Trace Gases. We measured the isotopic ratios of $^{13}C/^{12}C$ and $^{18}O/^{16}O$ in CO_2 and CO, and of $^{15}N/^{14}N$ in N_2O. N_2O is of special interest because $^{14}N^{15}N^{16}O$ and $^{15}N^{14}N^{16}O$ have the same mass, so they cannot be distinguished by conventional mass spectrometry whereas laser spectroscopy enables an easy identification. Our measurements were done with the DFG system described above and direct absorption spectroscopy with an astigmatic Herriott cell (New Focus 5611) with an optical path length of 10 m. The setup is shown in Fig. 11.237.

One problem in measuring isotopomers is that the concentration of the main isotopomer is typically a hundred times higher than that of the less-abundant iso-

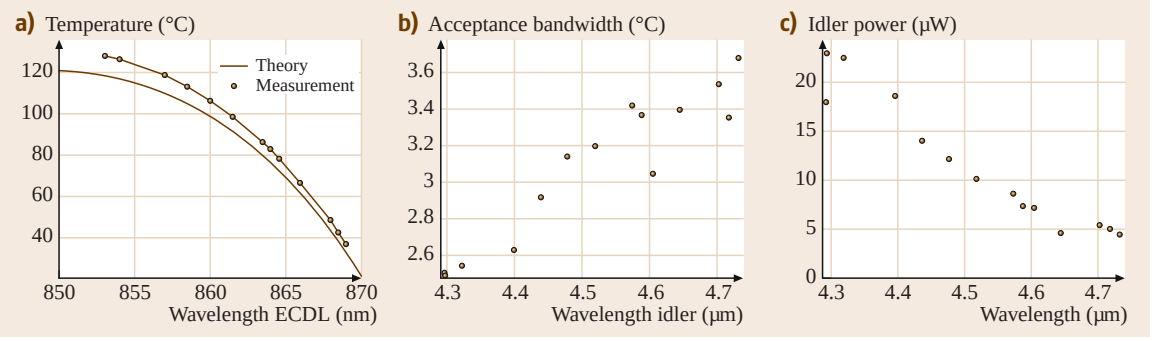

Fig. 11.236 **(a)** Quasi-phase-matching temperature as a function of pump wavelength. **(b)** Acceptance bandwidth as a function of the temperature. **(c)** Idler power as a function of the idler wavelength

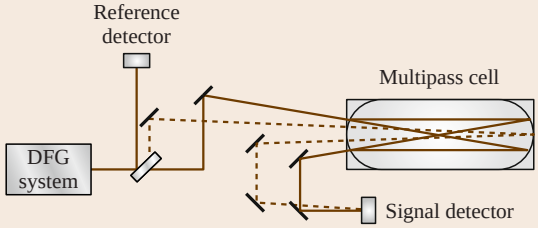

Fig. 11.237 Setup for transmission spectroscopy. In the astigmatic Herriott cell there are two paths, one of 10 m (*solid line*) and one of 40 cm (*dashed line*)

topomer. There are two possibilities to overcome this problem, either to measure two lines of similar strength resulting in a strong temperature sensitivity of the measurement, or by choosing lines with similar lower energy levels but with very different line strength. The astigmatic multipass Herriott cell offers the possibility to enter the cell at a different angle than usual, so that the beam leaves the cell after only two passes (Fig. 11.237). This makes it possible to measure two lines of very different line strength by using two different path lengths (the balanced-path-length detection scheme) [11.2158].

As an example, Fig. 11.238 shows the result of a measurement on CO_2 isotopomers in ambient air at a concentration of 350 ppm. The measurements were performed at a total pressure of 50 mbar and at room temperature. The experimental data are fitted with Voigt curves to calculate the concentrations of the isotopomers.

The derived isotope ratios of $^{13}C/^{12}C$ for CO_2 are $1.3\% \pm 0.2\%$ (only long path) and $1.4\% \pm 0.3\%$ (balanced-path-length detection scheme), which is in good agreement with the natural abundance of 1.1%. The isotope ratio $^{18}O/^{16}O$ of CO_2 is deduced as $0.44\% \pm 0.06\%$ (only long path) and $0.47\% \pm 0.11\%$ (balanced-path-length detection scheme), which again is in good agreement with the natural abundance of 0.39%. A more-detailed discussion of these studies, which also includes measurements of CO and N_2O isotopomers, can be found in [11.2159]. A further study on N_2O isotopomers, testing different detection schemes for low concentrations (100 ppm) has been published in [11.2160].

11.10.4 Discussion of a Pulsed DFG Laser Source

In this section we present a pulsed PPLN-based DFG spectrometer. This system has been used for photoacoustic spectroscopy of methane [11.2161] and methyl bromide [11.2130], and for the detection of doping substances in urine in the vapor phase [11.2162]. Currently we investigate the chemical composition of surgical smoke [11.2163,2164], a gaseous by-product of surgery that originates from the application of lasers, ultrasonic scalpels, and high-frequency electroknives in human surgery [11.2165]. Some previous studies have revealed a multitude of chemical species present in surgical smoke [11.2166–2168], but there is a lack of quantitative data.

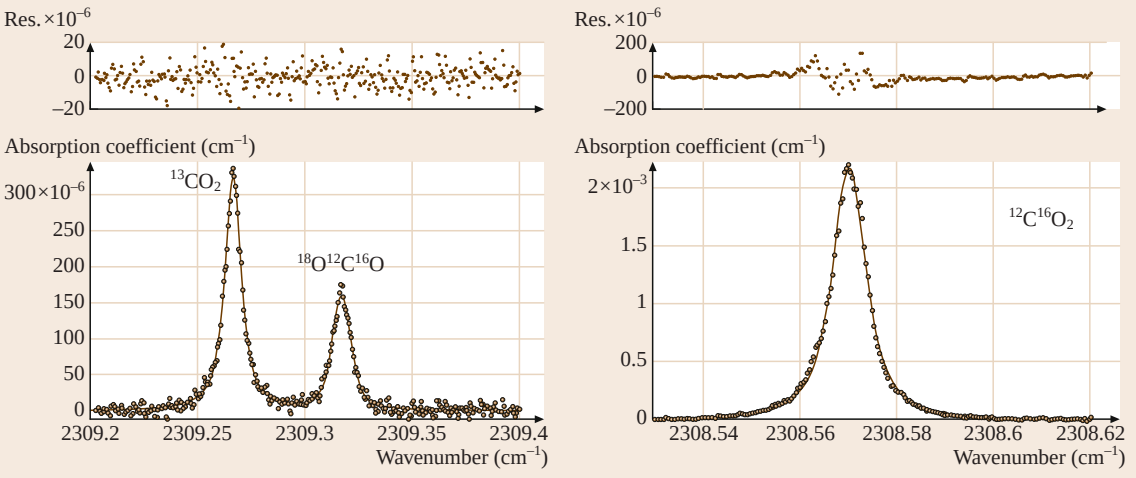

Fig. 11.238 Absorption lines of different isotopomers of 350 ppm CO_2 in ambient air. Experimental data (*dots*) and Voigt fit (*solid line*) for 10 m path length, residuals on *top*

Experimental Setup

The pulsed DFG spectrometer is illustrated in Fig. 11.239. The signal laser is a fiber-coupled ECDL (Model TSL-210, Santec Corp., Japan) tunable from 1520 to 1600 nm with an output power of at least 5 mW and a specified linewidth of < 1 MHz. The wavelength of the ECDL is monitored by coupling about 1% of the power into a wavemeter (Burleigh, model WA-1100, USA.) via a polarization-maintaining (PM) filter coupler (Opto-Link Corp. Ltd., Hong Kong). A $f = 400$ mm lens is placed about 3 cm behind the fiber output coupler, followed by a half-wave plate used to rotate the polarization in the vertical direction. The pump laser is a passively Q-switched Nd:YAG laser (InnoLight GmbH, model M800, Germany). It operates at 1064.5 nm with a repetition rate of 4–8 kHz and ≈ 6 ns pulses. The average output power lies around 300 mW with pulse peak powers of the order of 5 kW. A collimating $f = 200$ mm lens is followed by a quarter-wave and half-wave plate, which are needed to linearize and rotate, respectively, the plane of polarization of the Nd:YAG laser beam. A dichroic mirror combines pump and signal beam prior to a $f = 75$ mm lens. A small fraction of the pump beam traverses the dichroic mirror and is captured by a fast Si photodiode (Hamamatsu, model S4753, Japan) which provides the trigger pulse for the data acquisition. An undoped periodically poled lithium niobate (PPLN) crystal (Crystal Technology, USA) is held inside an oven (Super Optronics, USA). The PPLN crystal is 50 mm long, 10 mm wide, 0.5 mm thick, and has 8 different poling periods (from 28.5 to 29.9 μm in steps of 0.2 μm). A $f = 99$ mm CaF_2 lens collimates the idler after the PPLN crystal. The pump and signal beam are removed with a germanium filter. The idler is coupled into the multipass cell with a $f = 379$ mm and $f = 300$ mm CaF_2 lens. The Herriott-type high temperature multipass cell (HTMC) [11.2162, 2169] is a stainless steel cylinder provided with bellows for compensation of thermal expansion, and internal metallic mirrors. The longest absorption path length is 35 m. A rotary (Alcatel, France) and a turbo pump (Leybold-Heraeus, Turbovac 50, Germany) permit evacuation of the HTMC down to a pressure of 10^{-2}–10^{-3} mbar. Prior to coupling the idler into the HTMC, about 10% of the power is reflected by a beam splitter and focused by a $f = 200$ mm CaF_2 lens onto the reference detector. The beam transmitted through the HTMC is focused by a $f = 100$ mm CaF_2 lens onto the transmission detector. Two-stage thermo-electrically cooled and preamplified photo-voltaic (HgCdZn)Te detectors optimized for operation at 4 μm with a peak responsivity of 120 kV/W of incident power are used in this setup (Vigo Systems SA, model PDI-2TE-4/VPDC-0.1i, Poland). With the available signal and pump laser, the idler can be tuned continuously between 2817 (3.55) and 3144 cm^{-1} (3.18 μm). Quasi phase-matching (QPM) [11.2170] occurs through selection of an appropriate poling period in conjunction with temperature tuning of the crystal [11.2164]. The range 2900–3144 cm^{-1} can be covered with the $\Lambda = 29.9$ μm poling period while tuning the PPLN temperature from 40 to 173 °C; the range 2817–2920 cm^{-1} can be cov-

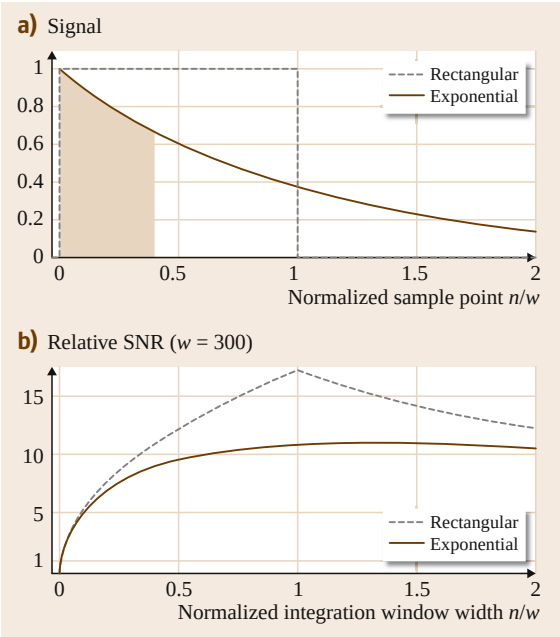

Fig. 11.240 **(a)** Rectangular-shaped (width w) and exponentially decaying (decay time w) signals, both with peak amplitude 1. Integrating the signal from 1 to n yields the area $A(n)$ (11.222). **(b)** Relative SNR (11.224) as a function of (normalized) integration window width for a pulse width of $w = 300$ sample points. Best SNR is achieved for $n/w = 1$ for the rectangular-shaped signal, and $n/w \approx 1.26$ for the exponentially decaying signal

ered with the $L = 29.5\,\mu$m poling period while tuning the temperature from 80 to 150 °C. The linewidth of the idler is approximately 150 MHz.

Data Acquisition and Processing

The idler is pulsed (8 kHz repetition rate, 6 ns pulses). The voltage pulses generated by the two detectors are digitized by an analog-to-digital converter (ADC, Gage, model CS14100, USA). The acquisition is triggered by the signal provided by the Si photodiode. The signals are sampled with a sampling rate of 50 MHz ($\Delta t = 20$ ns) and a resolution of 14 bit. This sampling rate is sufficient despite the nanosecond pulses (which would require sampling rates in the GHz range) because the detectors and the built-in amplifiers have a bandwidth of only 100 kHz. A short laser pulse results in a fast rise of the detector signal (within 1 sample point, 20 ns), followed by an exponential decay with a time constant of $\tau \approx 6\,\mu$s (about 300 sample points at 50 MHz sampling rate). The total path length L of the beam inside the HTMC can be determined by measuring the time delay between the arrival of the two pulses on their respective detectors.

It is convenient, in terms of signal-to-noise ratio (SNR), to integrate the pulse shapes instead of only recording the peak values. Consider a sampled signal $\boldsymbol{y} = (y_1, y_2, \ldots)$ with peak amplitude 1 and noise σ. If only the peak were measured, the SNR would be

$$\mathrm{SNR_p} = \frac{1}{\sigma}\,, \tag{11.221}$$

where the subscript p stands for peak. If instead we choose to integrate the signal $\boldsymbol{y}$ by building the sum

$$A(n) = \sum_{k=1}^{n} y_k \tag{11.222}$$

with noise $\sigma_A(n) = \sigma\sqrt{n}$, then the SNR would become

$$\mathrm{SNR_A}(n) = \frac{A(n)}{\sigma\sqrt{n}}\,. \tag{11.223}$$

Of interest is the SNR with integration relative to the SNR of the peak. We call this quantity R

$$R = \frac{\mathrm{SNR_A}(n)}{\mathrm{SNR_p}} = \frac{A(n)}{\sqrt{n}}\,. \tag{11.224}$$

For a rectangular-shaped and an exponentially decaying signal (Fig. 11.240a), R is plotted in Fig. 11.240b. For the rectangular-shaped signal with a fixed pulse width w, R is given by

$$R = \kappa(w) \cdot \begin{cases} \sqrt{n/w}\,, & n/w \le 1 \\ \sqrt{w/n}\,, & n/w > 1 \end{cases} \tag{11.225}$$

and is maximal for $n/w = 1$. The factor κ depends on w, but not on n. This result is intuitively clear, as integrating over more points further increases the noise but not the signal area. For the exponentially decaying signal with a fixed decay time w, as in our case, R is given by

$$R = \kappa(w)\frac{1 - \exp(-n/w)}{\sqrt{n/w}} \tag{11.226}$$

with

$$\kappa(w) = \frac{1}{\sqrt{w}[1 - \exp(-1/w)]} \tag{11.227}$$

and peaks at $n/w \approx 1.26$. For pulses with decay times longer than 100 sample points, κ simplifies to $\kappa(w) \approx \sqrt{w}$ and the peak value of R can be expressed as

$$R^{\max} \approx 0.638\sqrt{w}\,. \tag{11.228}$$

For an exponentially decaying pulse with a decay time of $w = 300$ sample points, an integration window of about $n = 1.26w \approx 380$ sample points provides an SNR that is ≈ 11 times larger than that of the peak value. Figure 11.240b shows that the SNR is not heavily affected if one chooses a larger integration window. Averaging N pulses further improves the SNR by a factor $\sqrt{N}$.

Under the assumption that the areas A_T and A_R (11.222) of the reference (R) and transmission (T) detector are proportional to the incident power, power normalization can be accomplished with

$$Q(\lambda) = \frac{A_T(\lambda)}{A_R(\lambda)} \,. \tag{11.229}$$

Even so, Q is not totally immune to power fluctuations [11.2164]. While Q is proportional to the sample transmittance T, other effects (etalon effects, mirror and window losses) need to be taken into account. If these effects are combined into a function $f(\lambda)$, then Q can be written as

$$Q(\lambda) = T(\lambda)\, f(\lambda) \,. \tag{11.230}$$

The baseline function f can be determined by measuring Q for a sample with no absorption (e.g., N_2)

$$Q_{N_2} = f \,. \tag{11.231}$$

The transmittance T of an unknown sample is then given by the ratio

$$T = \frac{Q_x}{Q_{N_2}} \,, \tag{11.232}$$

where the subscript x stands for the unknown sample. Unfortunately, the baseline function f is not exactly reproducible [11.2164]. The reproducibility of f can be estimated by measuring repeatedly the same sample. Changes between two measurements of the same sample will produce a fake transmission T (11.232)

$$T = \frac{Q_1}{Q_2} = \frac{f_1}{f_2} \,, \tag{11.233}$$

where the subscripts 1 and 2 refer to the first and second measurement of the sample, and f_1, f_2 are the baselines during the first and second measurement, respectively. Efforts to ensure that f changes minimally between measurements are described in detail in [11.2164].

Characterization of the Laser Spectrometer

Quasi-phase matching (QPM) requires the crystal to be at the correct temperature for the given pump and signal wavelengths, and for the selected poling period of the crystal. In principle, knowledge of thermal expansion properties, poling period, and refractive index of lithium niobate [11.2126], would allow us to compute the temperature for which QPM is achieved by solving (11.206) for the temperature T, bearing in mind that both n and Λ are temperature-dependent. An alternative approach, shown in Fig. 11.241a, is to measure the idler power for different wavelengths while tuning the PPLN crystal temperature. For every signal laser wavelength, the peak of the corresponding *parabola* can be determined: it is the temperature for which the idler power is maximal. Plotting the signal wavelengths versus these peak values provides a relationship between signal wavelength and optimal crystal temperature

$$\lambda_s^{\text{opt}}(T_c) = a_3 T_c^3 + a_2 T_c^2 + a_1 T_c + a_0 \,, \tag{11.234}$$

where the coefficients $a_0, \ldots, a_3$ are fit parameters determined by fitting a cubic polynomial to the data points (Fig. 11.241b).

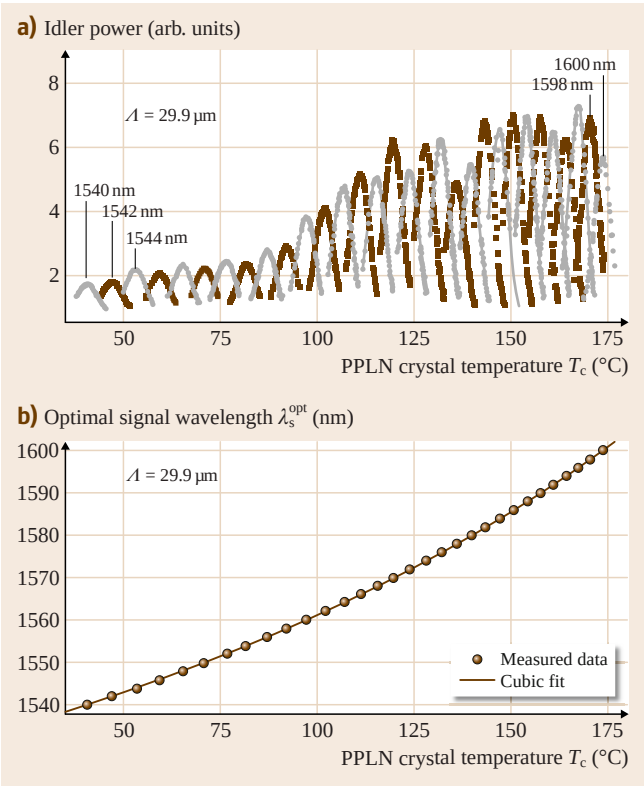

Fig. 11.241 **(a)** Idler power versus PPLN crystal temperature for different signal laser wavelengths (1540, 1542, . . . , 1600 nm). **(b)** Signal wavelength λ_s^{opt} for which the idler power is maximal at the given PPLN crystal temperature T_c. The poling period of the PPLN crystal is 29.9 µm

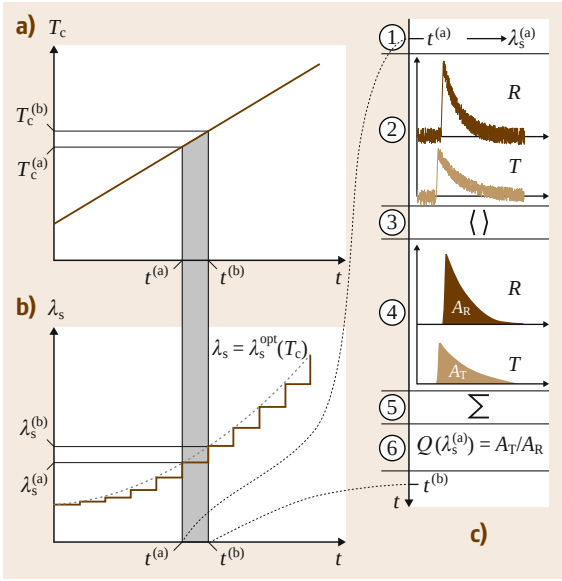

Fig. 11.242a–c Illustration of the operation of the pulsed DFG spectrometer. **(a)** Crystal temperature T_c versus time t. The slope of the curve is given by the ramp r (11.235). **(b)** Signal wavelength λ_s versus time t. The *dotted line* is the optimal wavelength $\lambda_s^{opt}(T_c)$ (11.234) for the crystal temperature T_c, while the *solid line* is the actual signal wavelength. Measurements take place in the time intervals where the curve is flat. **(c)** Sequence of events taking place in the *gray shaded area* in **(a)** and **(b)**. At $t^{(a)}$ the signal wavelength is set to $\lambda_s^{(a)}$ (1); several pulses are then acquired (2) and averaged (3) (R: reference detector, T: transmission detector). The averaged pulses (4) are integrated (5) and the ratio Q (11.229) is computed (6)

The peak value of the voltage pulses measured on both detectors varies between 30 mV for low PPLN crystal temperatures (40 °C) up to 800 mV for high temperatures (> 130 °C). The noise of a single sample point is ≈ 4 mV, so that the SNR of the peak value varies between 7.5 and 200. By integrating the pulses over 380 sample points, an improvement of a factor ≈ 11 in SNR is expected from (11.228). By averaging 512 pulses a further improvement by a factor $\sqrt{512}$ is to be expected, so that the final SNR of Q (11.229) should be $11\sqrt{512}/\sqrt{2} = 176$ times larger than the SNR of the peak value ($\sqrt{2}$ arises from the fact that both the numerator and denominator in (11.229) are affected by uncorrelated noise). Measured SNRs vary between 10^3 and 10^4, reasonably close to the expected values of 1.3×10^3 for low peak values (30 mV) and 3.5×10^4 for large peak values (800 mV).

The ultimate sensitivity of the spectrometer can be computed from the SNR values given in the previous paragraph. However, the actual sensitivity turns out to be lower due to baseline drifts (described by changes in the baseline f, (11.230). The minimum measurable absorbance when the sensitivity is limited by baseline drifts is 5×10^{-3} [11.2164].

Operation of the Laser Spectrometer

A rotary pump and a turbopump, connected in series, are used to evacuate the HTMC (Fig. 11.239). No additional equipment is required to fill the cell from a sample bag: the sample bag is connected via a tube to the evacuated HTMC, and by opening a valve the atmospheric pressure compresses the sample bag, thus filling the cell.

The spectrometer is completely computer-controlled by a home-written LabVIEW (National Instruments, USA) program. Given a desired wavelength range to be measured, the temperature of the PPLN crystal is set to a value about 5 °C below the initial temperature T_0 (computed with (11.234)). A temperature ramp r (typically 2 K/min) is then set on the controller of the crystal oven. When the temperature reaches T_0, the measurement timer t is started. The crystal temperature T_c can then at any later time be computed with

$$T_c = T_0 + r \cdot t \,. \qquad (11.235)$$

The process of the data acquisition is illustrated schematically in Fig. 11.242. For the current value of the crystal temperature T_c the corresponding optimal signal wavelength $\lambda_s = \lambda_s^{opt}(T_c)$ (11.234) is set, and the program waits briefly (200 ms) for the ECDL to reach the set wavelength and stabilize. Several pulses (typically 512) are then digitized by the ADC card and averaged. This only takes about 100 ms given the repetition rate of the laser of 8 kHz. The wavelength of the signal laser is measured with the wavemeter, since there are occasional discrepancies between the set and real wavelength. The area below the averaged pulses of both detectors and the ratio Q (11.229) are computed. This measurement cycle takes about 500 ms and is repeated continuously until the final wavelength has been reached.

The only parameter being actively changed during the measurement is the wavelength of the signal laser (ECDL). It can either be computed in real time,

$$\lambda_s(t) = \lambda_s^{opt}\,(T_c(t)) = \lambda_s^{opt}(T_0 + r \cdot t)\,, \qquad (11.236)$$

where λ_s^{opt} is given by (11.234), or it can be computed *a priori* for reasonably spaced values of the

measurement time t (e.g., 500 ms), and saved into a file (timetable). The LabVIEW program then only needs to look up the wavelength to set for the current value of the measurement timer t. This approach ensures that for a fixed temperature ramp r all measurements are carried out following the same temperature-time profile (due to the ramp r) and wavelength-time profile (due to the timetable). This has proved to reduce baseline drifts between successive measurements [11.2164].

According to (11.230), a second measurement is necessary to determine the baseline function f. This measurement should be performed under the same conditions as the previous sample to avoid pressure and temperature-dependent deformations of the HTMC. A nonabsorbing gas such as nitrogen or carbon dioxide is generally used. The transmittance T is then computed with (11.232).

Surgical Smoke Analysis

In a current study we investigate the chemical composition of surgical smoke [11.2165] produced during laparoscopic (keyhole, minimally invasive) surgery. Gas samples are collected in Tedlar bags (CEL Scientific, USA) and brought to our lab for analysis. The spectrum of such a sample is shown in Fig. 11.243a. The total path length is 35 m and the wavenumber step size is $\geq 0.05\,\mathrm{cm}^{-1}$, while the laser linewidth is about a factor 10 smaller ($150\,\mathrm{MHz} = 0.005\,\mathrm{cm}^{-1}$). Since the transmittance T (or, equivalently, the absorbance) of the samples can be computed as described in the previous paragraph, there is no need to calibrate the spectrometer. Instead, the measured spectrum can be compared to spectra of pure substances obtained under similar conditions of pressure and temperature to provide both a qualitative and quantitative analysis. For this, we use an improved version of the mix-match algorithm [11.2171], first proposed by *Nyden* [11.2172] and *Lo* and *Brown* [11.2173]. As a library of reference spectra we use the PNNL database [11.2174], which provides FT-IR spectra of 360 substances in the gas phase at atmospheric pressure. The algorithm correctly identified the three main components sevoflurane (Fig. 11.243b), methane (Fig. 11.243c), and water vapor (Fig. 11.243d). The anesthetic sevoflurane ($C_4H_3F_7O$, CAS Nr. 28523-86-6) is not part of the PNNL database. Its spectrum was measured with the DFG spectrometer (Fig. 11.243b) and then added to the set of substances present in the PNNL database. The algorithm also computes concentrations for the identified compounds: 240 ppm sevoflurane, 32 ppm methane, and 0.95% water vapor. Subtracting the spectra of these three substances at the given concentrations from the measured spectrum yields the residual spectrum in Fig. 11.243e. The deviations from zero can be explained by small errors in the measurement of the signal laser wavelength, drifts in the wavelength of the Nd:YAG laser (not measured), and by the lower resolution of the FT-IR spectra in the PNNL database (typically $0.1\,\mathrm{cm}^{-1}$ versus $0.05\,\mathrm{cm}^{-1}$ of the DFG spectrometer).

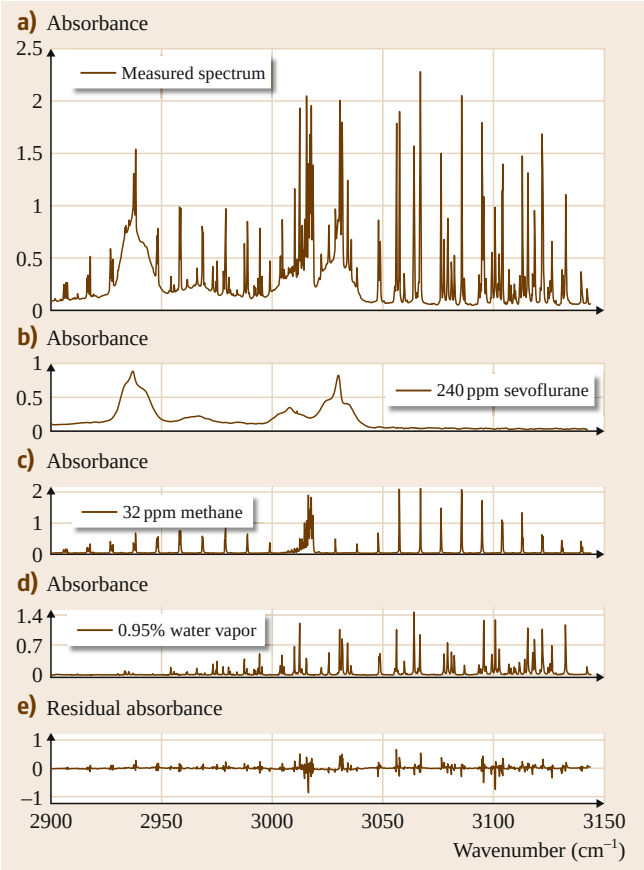

Fig. 11.243 (**a**) Spectrum of surgical smoke collected during laparoscopic surgery (path length = 35 m). (**b**) Spectrum of 240 ppm sevoflurane measured with the DFG laser spectrometer. Spectra of 32 ppm methane (**c**) and 0.95% water vapor (**d**), both taken from the PNNL database. (**e**) Difference between (**a**) and the sum of the three substances in (**b**), (**c**) and (**d**). The discrepancies are due to inaccuracies in the wavelength measurements, and to the lower resolution of the FT-IR spectra

The composition shown in Fig. 11.243b varies from sample to sample. Typically, methane appears at lower concentrations than in the shown sample (Fig. 11.243a), and in many cases is not detected at all. The concen-

trations for water vapor and sevoflurane, on the other hand, are typical. Previous studies with smoke generated in vitro on animal meat [11.2163] have also revealed ethane and ethene (ethylene), in addition to methane and water vapor. Concentrations ranged between 4.2–41 ppm for methane, 0.7–11 ppm for ethane, 7.1–37 ppm for ethene, and 0.15–2.3% for water vapor.

Sevoflurane exhibits mainly broad absorption features ($\approx 50\,\mathrm{cm}^{-1}$), while water vapor and methane absorption lines are much narrower ($\approx 1\,\mathrm{cm}^{-1}$). The quantitative analysis of such a gas mixture requires a narrow-band, broadly and continuously tunable laser source. Although other sources emitting in the investigated spectral range exist, DFG-based lasers fulfill the above requirements excellently.

11.10.5 Outlook

Tunable coherent sources in the mid-infrared range play an important role. This is manifested by the ever-growing number of publications. The development is fostered by numerous applications, primarily in gas sensing. The requirements with respect to sensitive and selective monitoring devices with multicomponent capability are manifold: access to a broad wavelength range, broad – preferentially continuous – wavelength tunability, narrow line width (i. e., much narrower than typical molecular absorption line widths), preferentially room-temperature (RT) or near-RT operation, and compact and robust setups for field applications. In this respect, continuous-wave and pulsed DFG systems represent a very valuable choice. Since their first realization in 1974 [11.2175], DFG-based devices have reached a mature level and even commercial systems are available meanwhile. Today, their wavelength range can be chosen between, e.g., 2 and 19 μm only depending on the available pump and signal sources and nonlinear crystals. The tuning of a DFG source is straightforward and continuous, and the wavelength generated can be accurately determined via the near-infrared input wavelengths. The line width is basically given by the line width of the pump and signal laser. This enables narrow mid-IR line widths as required for high-resolution spectroscopy. In contrast to alternative mid-IR sources, DFG systems are generally room-temperature devices except for the crystal, which may require heating in a small temperature-controlled oven. Line widths of continuous-wave DFG sources are in the MHz range, which makes them attractive for studies requiring high spectral resolution such as the briefly discussed isotopomer measurements. DFG sources are rather low-power lasers with CW powers in the μW to mW range. With fiber amplifiers for the near-IR pump and signal sources, higher powers can be achieved if necessary [11.2129]. Recent developments in waveguide technology in PPLN [11.2122] or KTP appear particularly attractive in view of higher conversion efficiencies. Last but not least, a DFG system can be made compact in view of today's diode lasers and diode-pumped solid-state lasers used as pump and signal sources.

In view of the variety of applications a further impetus for DFG systems can be expected. Current developments in several areas appear promising: the availability of compact and powerful signal and pump lasers, fiber amplifiers, new nonlinear crystal materials including organic media to access further wavelength ranges, new materials with higher nonlinear optical coefficients, birefringent bulk crystals with better quality, larger crystal sizes and higher damage thresholds, quasi-phase matching becoming available for more crystals than today, waveguide technology, etc. These developments will contribute to improve the performance of DFG devices, enhance their distribution, lower their costs and hence further increase their role as attractive spectroscopic tools.

11.11 Free-Electron Lasers

The free-electron laser (FEL) is a system consisting of a relativistic electron beam and a radiation field interacting with each other while they propagate through an undulator [11.2176, 2177]. The main components of the free-electron laser are electron accelerator, undulator, and optical resonator (optional for an FEL oscillator). The undulator is a periodic magnetic structure with a planar or helical magnetic field that causes periodical transverse deflections of the electron-beam trajectory [11.2178]. Optical resonators are fairly similar to those used in conventional lasers. FEL devices have been realized with nearly all types of accelerators: electrostatic accelerators, RF linear accelerators, induction accelerators, microtrons, storage rings, etc. The wavelength range covered by FELs spans from centimeters down to Ångström [11.2179, 2180] (Ta-

Table 11.56 Parameter space of free-electron lasers as of 2010

Radiation	
Wavelength	0.12 nm–10 mm
Peak power	Up to 10–20 GW
Average power	Up to 14 kW
Pulse duration	≈ 1–2 fs to CW
Driving electron beam	
Energy	200 keV–15 GeV
Peak current	1–4000 A
Undulator	
Period	0.5–20 cm
Peak magnetic field	0.1–1.3 T
Undulator length	0.5–112 m

ble 11.56). The scale of the FEL setup is mainly defined by the scale of the driving accelerator. For FELs operating in the millimeter wavelength range this could be a room scale, while unique devices such as VUV and x-ray FELs user facilities have a scale comparable with conventional third-generation synchrotron radiation facilities (Fig. 11.244).

Fig. 11.244 Aerial view of the experimental hall for the FLASH user facility in Hamburg (*center*) and the tunnel for the superconducting accelerator and undulator (*covered with grass*). The hall in the *upper right corner* houses the injector part of the linac. The total length of the FLASH facility is 300 m. The maximum energy of electrons is 1 GeV, and the minimum radiation wavelength is 6 nm. The undulator of the FLASH (photo in the *upper left corner*) is a permanent magnetic device (period 2.73 cm, gap 12 mm, peak field 0.47 T). The undulator system is subdivided into six segments, each 4.5 m long

11.11.1 Principle of Operation

The FEL is not actually a laser; it is most closely related to vacuum-tube devices. As with vacuum-tube devices, FEL devices can be divided in two classes: amplifiers and oscillators (Fig. 11.245). An FEL amplifier is a single-pass device, and there is no feedback between the output and input. The FEL oscillator can be considered as an FEL amplifier with feedback. For an FEL oscillator in the optical wavelength range the feedback is carried out by means of an optical resonator. FELs based on the oscillator principle are limited on the short-wavelength side to ultraviolet wavelengths primarily because of mirror limitations. Free-electron lasing at wavelengths shorter than the ultraviolet can be achieved with a single-pass high-gain FEL amplifier.

The field of the electromagnetic wave only has transverse components, so the energy exchange between the electron and the electromagnetic wave is due to the transverse component of the electron velocity. The latter occurs due to periodical wiggling of the electron in the undulator. The driving mechanism of free-electron lasers is the radiative instability of the electron beam, which develops due to the collective interaction of electrons with the electromagnetic field in the undulator. The basic principle of radiation-induced instability can be described within the standard picture for the generation of the synchrotron radiation. Electrons propagate along a sinusoidal path and emit synchrotron radiation in a narrow cone in the forward direction. When an electron beam traverses an undulator, it emits radiation at the resonance wavelength $\lambda = (\lambda_w/2\gamma^2)(1+K^2/2)$. Here, λ_w is the undulator period, $mc^2\gamma$ is the electron beam energy, $K = eH_w\lambda_w/2\pi mc$ is the dimensionless undulator strength parameter, and H_w is the maximum on-axis magnetic field strength of the undulator. Although the electromagnetic wave is always faster than the electrons, a resonant condition occurs such that the radiation slips a distance λ relative to the electrons after one undulator period. The fields produced by the moving charges in one part of the undulator react on moving charges in another part of the undulator. Thus, we

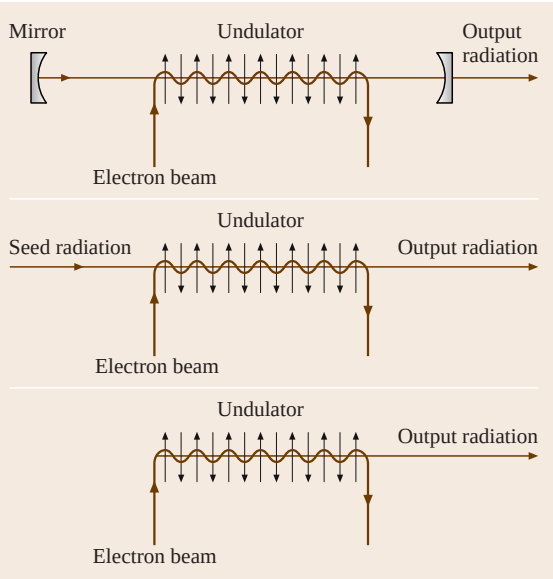

Fig. 11.245 Free-electron laser configurations: oscillator (*top*), seeded amplifier (*middle*), and self-amplified spontaneous emission (SASE) FEL (*bottom*)

deal with some tail–head instability, which leads to a growing concentration of particles wherever a small perturbation started to occur (Fig. 11.246). In the beginning – without microbunching – all N electrons can be treated as individually radiating charges producing the power of the spontaneous emission $\propto N$. With complete microbunching, all electrons radiate almost in phase. This leads to a radiation power $\propto N^2$ and thus to an amplification of many orders of magnitude with respect to the spontaneous emission of the undulator.

The figure of merit for FEL performance is the radiation power gain during one pass of the undulator. The gain primarily depends on the value of the peak beam current. Another quantity of importance for the development of the radiative instability is the electron beam density in the six-dimensional phase space. Low beam quality (large energy spread and emittance) leads to degradation of the FEL gain. Errors in the periodical magnetic structure also degrade FEL performance. Presently accelerator techniques and undulator technology have reached such a level that it is possible to have power gains of the order of 10^7 for the amplification of the radiation of a subnanometer wavelength range.

11.11.2 Current Status and Perspective Applications of Free-Electron Lasers

Free-electron lasers hold several potential advantages: continuous tunability of the radiation wavelength, the possibility to obtain high levels of average output power, and the possibility to obtain high conversion efficiencies of the net electrical power to radiation power. An important feature of FEL radiation is that it has a high degree of transverse coherence. In other words, FEL radiation can always be focused on to a spot whose size is defined totally by diffraction effects. This feature reveals a wide range of possibilities for FEL applications in the transportation of the radiation over long distances and in obtaining high focused intensities.

However, FELs are relatively expensive devices, and thus their applications are in the fields not covered by conventional radiation sources, in the far-infrared wavelength range and the THz gap (the submillimeter wavelength range). Another field for FEL applications is the generation of short-wavelength radiation, from the vacuum ultraviolet down to x-ray range. Technological developments are on the way, aiming at industrial applications of powerful FELs, and the use of FELs for energy transfer in space is also under consideration. Organization of user operation at the FEL facilities is similar to that used at synchrotron radiation facilities: the host organization constructs and serves free-electron laser and user beam lines, and users perform their experiments according to the schedule of the facility.

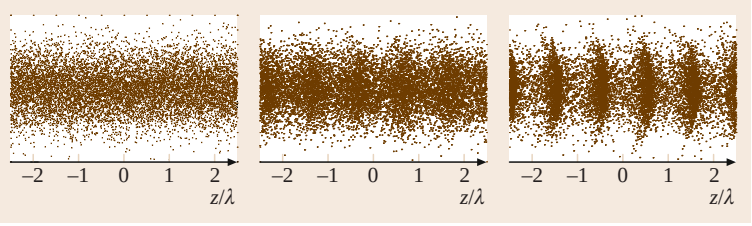

Fig. 11.246 Distribution of the electrons in the electron beam (longitudinal cut). The *left*, *middle*, and *right* snapshots are taken at the beginning, middle, and the end of the undulator. Electron beam density is modulated periodically with the period of the resonance wavelength due to the radiative instability

Linac-Based FEL User Facilities

There are several operating linear accelerator (linac)-based FEL user facilities (in China, France, Germany, Japan, Korea, The Netherlands, Russia, and USA) working for scientific applications [11.2181–2194]. The wavelength range covered with these facilities spans from 200 nm to a few hundred micrometers. Typical parameters of the FELs driven by RF linear accelerators are: pulse duration of a few picoseconds, peak power in the MW range, and micropulse repetition rate in the range 10 MHz–3 GHz. FELs driven by normal conducting RF accelerators operate in pulsed mode with a macropulse repetition rate of 10–100 Hz. The macropulse duration is defined by the length of the RF pulse, typically 1–20 μs. Thus, the average radiation power is in the watt range. FELs driven by superconducting accelerators operate in continuous mode and produce a high level of average output power, up to a few kW. Linac-based FEL facilities are recognized nowadays as a unique tool for scientific applications that require tunable coherent radiation in the infrared wavelength range. The general tendency is that the wavelength region of interest for users at these facilities is moving into the far-infrared and THz gap.

FEL User Facilities at Storage Rings

Several storage rings are equipped with free-electron lasers [11.2195–2198]. Typical parameters of the radiation are: wavelength range of 190–700 nm, pulse duration of some tens of picoseconds, average power of 10–300 mW, and peak power in the kW range. Operation in a locked-mode regime allows the peak power to be increased by an order of magnitude. The general tendency is that users' interest in these facilities is gradually reducing due to the limited features compared with conventional lasers.

High-Average-Power FELs

Recent progress in accelerator technology has paved the way for construction of high-average-power linear accelerators. The quality of electron beams produced by such machines is sufficient to drive free-electron lasers. Application of the energy-recovery technique allows a high level of overall efficiency to be achieved. Pilot facilities are already in operation in Japan, Russia, and USA [11.2192–2194]. The demonstrated level of the average radiation power is 14 kW in the 3–20 μm wavelength range [11.2193] and about 0.4 kW in the THz gap [11.2192]. Projects of next-generation FELs based on energy-recovery linacs aim at increasing the average power into the tens of kilowatt range, and also to build high-power FELs operating in the UV range [11.2199–2205].

Potential industrial applications of high-average-power FELs involve material processing (for instance, the treatment of polymer surfaces), lithography, isotope separation, and chemical applications. Production of pure isotopes on an industrial scale may have a big impact on future developments. For instance, isotope ^{28}Si is a radiation-resistant material of great interest for space research and the nuclear energy industry. The thermal conductivity of the pure isotope ^{28}Si is 50% higher than that in the natural mixture, which seems very attractive for the semiconductor industry. The are also many other isotopes of great practical interest such as ^{13}C (medical applications) and ^{15}N (for the study and current control of use of nitrogen fertilizers in agriculture and agrochemistry). The basic process of isotope separation is a selective multiphoton dissociation of molecules. The required resonance wavelength range is in the range 2–50 μm. The required energy in a pulse is no less than 0.1 mJ and monochromaticity of 10^{-2}–10^{-4}, depending on the type of reaction. Industrial production of isotopes requires FELs with average power exceeding 10 kW. Construction of such facilities is on the way, and the first results are expected in the near future.

X-ray Free-Electron Lasers

At the start of this century, we saw a revolution in synchrotron source intensities. This revolution stemmed from the technique of free-electron lasers combined with recent progress in accelerator technologies, developed in connection with high-energy linear colliders [11.2206]. X-ray FELS (XFELs) have made a new regime of intensities accessible, thus opening up a fundamentally new physical domain.

A new era of synchrotron radiation research began with the first user experiments on a vacuum UV FEL based on self-amplified spontaneous emission (SASE) [11.2207, 2208]. Pioneering results were obtained at the TESLA test facility (TTF) at the Deutsches Elektronen-Synchrotron DESY (Hamburg, Germany), using radiation pulses at a wavelength of 98 nm with a 40 fs pulse duration and a peak power of 1.5 GW [11.2209, 2210] (Fig. 11.247). Compared to present-day synchrotron radiation sources its peak brilliance is more than 100 million times higher (Fig. 11.248), the radiation has a high degree of transverse coherence and the pulse duration is reduced from hundreds of picoseconds down to ten-femtosecond time domain. While modern third-generation synchrotron

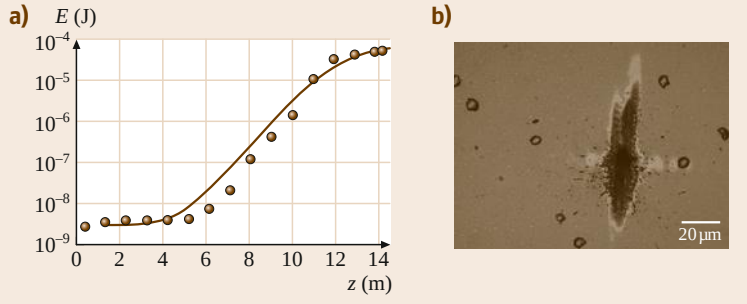

Fig. 11.247 **(a)** Average energy in the radiation pulse versus undulator length for TTF FEL at DESY [11.2209]. **(b)** interaction of powerful VUV radiation with solids [11.2207]. Ablation of a gold target after one pulse of the TTF FEL at DESY. The radiation wavelength is 98 nm, the pulse duration is 40 fs, and the peak power density is about 100 TW/cm^2

light sources are reaching their fundamental performance limit, recent success in the development of the VUV FEL at DESY has paved the way for the construction of a novel type of light source that will combine most of the positive aspects of both a laser and a synchrotron.

It is worth mentioning that an essentially quantum terminology SASE (introduced after amplified spontaneous emission (ASE)) does not reflect the actual physics of the x-ray FEL. The amplification process in the x-ray FEL (SASE FEL) has its origin in density fluctuations in the electron beam. The latter effect is completely classical. In an x-ray FEL the radiation is produced by the electron beam during a single pass of the undulator [11.2212–2214]. The amplification process starts from shot noise in the electron beam. Any random fluctuations in the beam current correspond to an intensity modulation of the beam current at all frequencies simultaneously – including of course, the frequency to which the undulator is tuned. When the electron beam enters the undulator, the presence of the beam modulation at frequencies close to the resonance frequency initiates the process of radiation. The FEL collective instability in the electron beam produces an exponential growth (along the undulator) of the modulation of the electron density on the scale of undulator radiation wavelength (Figs. 11.246, 247). The fluctuations of current density in the electron beam are uncorrelated, not only in time but also in space. Thus, a large number of transverse radiation modes are excited when the electron beam enters the undulator. These radiation modes have different gains. Obviously, as the undulator length progresses, the high-gain modes will predominate increasingly, and we can regard the XFEL as a filter, in the sense that it filters from arbitrary radiation field those components corresponding to the high-gain modes. Hence, for a long enough undulator, the emission will emerge in nearly complete transverse coherence. An intensity gain in excess of 10^7 is obtained in the saturation regime. At this level, the shot noise of the electron beam is amplified up to complete microbunching, and all electrons radiate almost in phase, producing powerful, coherent radiation.

The amplification bandwidth of a high-gain FEL amplifier is restricted by the resonance properties of the undulator, that is, by the number of undulator periods N_w within one gain length (the distance over which the power increases by the factor of $e = 2.718$).

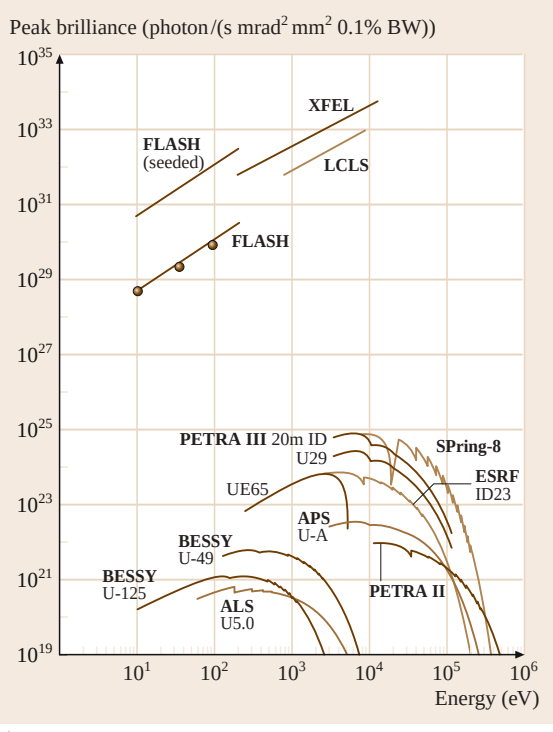

Fig. 11.248 Peak brilliance of x-ray FELs versus third-generation storage rings light sources. *Circles* show the experimental performance of the FLASH free-electron laser at DESY [11.2211]

Table 11.57 Main parameters of present and future x-ray FELs [11.2211, 2215–2218]

	2010: FLASH	2010: LCLS	2015: European XFEL
Radiation			
Wavelength	4.2–45 nm	Down to 0.12 nm	Down to 0.05 nm
Peak power	Up to 5 GW	10–20 GW	Up to 150 GW
Average power	100 mW	100 mW	Up to 500 W
Pulse duration	≈ 10–100 fs	≈ 2–100 fs	0.2–100 fs
Driving electron beam			
Energy	0.3–1.2 GeV	Up to 15 GeV	Up to 17.5 GeV
Peak current	1–3 kA	1–3.5 kA	Up to 5 kA
Undulator			
Period	2.73 cm	3 cm	3.6–8 cm
Peak magnetic field	0.5 T	1.25 T	0.5–1.4 T
Undulator length	27 m	112 m	Up to 200 m

The spectrum of transversely coherent fraction of the radiation is concentrated within the narrow band, $\Delta\lambda/\lambda \simeq (2\pi N_w)^{-1}$. The typical amplification bandwidth of the XFEL is of the order of 0.1%. The electron beam in an XFEL transfers enormous peak power. For instance, for typical XFEL parameters (electron energy of 17.5 GeV and peak current 5 kA) it is about 100 TW. The conversion efficiency of kinetic energy of electrons to the light is of the order of the amplification bandwidth, thus the peak power of x-ray radiation is in the multi-GW range (Table 11.57).

Experimental realization of XFELs has developed very rapidly during the last decade. The first demonstration of the SASE FEL mechanism took place in 1997 in the infrared wavelength range [11.2219]. In September 2000, a group at Argonne National Laboratory (ANL) became the first to demonstrate saturation in a visible (390 nm) SASE FEL [11.2220]. In September 2001, a group at DESY (Hamburg, Germany) demonstrated lasing to saturation at 98 nm [11.2209, 2210], and later on down to 32, 13, and 4.2 nm [11.2211, 2215, 2221]. The experimental results were achieved at FLASH (free-electron-laser in Hamburg, Fig. 11.244). Currently FLASH produces GW-level, laser-like VUV radiation pulses with 10–150 fs duration in the wavelength range 4.2–45 nm. Regular user operation of FLASH as a user facility started in 2005 [11.2221].

Success of pilot SASE FEL devices led scientific community and funding agencies to the recognition of the direction and launching several large-scale projects around the world capable of operating in the hard x-ray wavelength range: Linac Coherent Light Source (LCLS) in USA, SPring–8 Compact SASE Source (SCSS) in Japan, European XFEL in Hamburg, Germany, and SwissFEL x-ray laser in Switzerland [11.2216, 2217, 2222, 2223]. While LCLS, SCSS and SwissFEL are funded by national funding agencies, the European XFEL is an international project [11.2224, 2225]. The cost of the projects is rather high (gigadollar scale) and is comparable with that of the best third generation synchrotron light sources [11.2225]. The LCLS project is currently the most developed. Just recently LCLS reached design parameters producing coherent hard x-ray radiation in the wavelength range 0.12–1 nm [11.2218]. It is equipped with one undulator and several user instruments and serves as an x-ray laser user facility for scientific experiments. LCLS produces x-ray pulses with over 10 GW of peak power and variable pulse duration from a few femtosecond up to one hundred femtosecond. Users of this facility are able to operate with intensities of the focused radiation of the order of 10^{17}–10^{18} W/cm^2. SCSS and European XFEL facilities are under construction and scheduled to start user operation in the years 2011 and 2015, respectively. It is expected that decision on funding of the SwissFEL will be approved soon allowing fast construction and start of the facility operation in 2016. All projects are essentially based on the same physical principles briefly described above ([11.2226, 2227] for more details). The main technical difference between projects is the linear accelerator: an existing room-temperature linac for LCLS, SCSS and SwissFEL, and a superconducting linac for the European XFEL. XFEL based on superconducting accelerator technology will enable not only a jump in peak brilliance of ten orders of magnitude, but also an increase by five orders of magnitude in the average brilliance. There is also a group of FEL projects (such as SPARC, FERMI@Elettra, sFLASH, and the SCSS test accelerator) designed to operate in the VUV and soft-xray wavelength range

and test techniques for production of radiation with improved properties in terms of coherence and pulse duration [11.2215, 2228–2231].

In the period from 1985 to 2002 the FEL Conference Proceedings were published in *Nuclear Instruments and Methods*, Section A. Starting from 2004 they are collected in electronic form on a WEB page dedicated to accelerator physics http://www.JACoW.org.

11.12 X-ray and EUV Sources

The extension of lasing into the x-ray region has been investigated by a wide variety of methods since the first demonstration of the visible laser in 1960. Laser operation in the hard-x-ray region, which can be categorized as wavelengths shorter than 0.2 nm, has been recently realized by x-ray free electron laser at SLAC National Accelerator Laboratory, much progress on the development of coherent light sources by conventional-laser-based methods has been also made in the soft-x-ray (0.2–30 nm) and extreme-ultraviolet (EUV, 30–100 nm) regions during these 25 years. There are two major methods to produce coherent short-wavelength radiation in these spectral regions. One is the use of transitions in highly charged ions in high-density plasmas created by laser irradiation of various targets or electric discharge. The other is the generation of very high harmonics of intense laser pulses. Each method has its advantages. X-ray lasers based on high-density plasmas can produce much higher energy per pulse and narrower spectra. High harmonics can be generated with compact, high-repetition rated lasers and produce a wide range of the spectrum from 100 to 3 nm. The use of these sources depends on the application and will be complementary.

11.12.1 Plasma X-ray Lasers

The development of an x-ray laser has been one of the elusive dreams of laser physicists. Proposals for excitation schemes for x-ray lasers date back to 1965, when the possibility of achieving soft-x-ray amplification by collisional recombination was first suggested by *Gudzenko* and *Shelepin* [11.2232]. This was followed by proposals for photoionization pumping of x-ray lasers in 1967 [11.2233] and of electron-impact excitation schemes [11.2234]. The latter were inspired in part by the earlier success in the development of visible and ultraviolet ion lasers excited by electron collisions. However, the drastic scaling of the pump power requirements with decreasing wavelength and the low reflectivity of optics at soft-x-ray wavelengths, combined with the short lifetime of the excited levels involved in the lasing process, made the realization of soft-x-ray lasers a very challenging task [11.2235, 2236]. Several experiments carried out during the 1970s and early 1980s yielded the observation of population inversion and gain [11.2237]. Nevertheless, the experimental demonstration of large amplification at soft-x-ray wavelengths was not realized until 1984. *Matthews* et al. [11.2238] at the Lawrence Livermore National Laboratory reported soft-x-ray amplification at wavelengths of 20.6 and 21.0 nm in Ne-like Se by electron collisional excitation. An exploding-foil-target x-ray laser demonstrated by *Matthews* et al. and the observed spectra are shown in Fig. 11.249 and Fig. 11.250, respectively. In parallel with this, *Suckewer* et al. [11.2239] at Princeton University reported amplification at 18.2 nm in H-like C by recombination excitation. These pioneering works were soon followed by numerous successful soft-x-ray amplification exper-

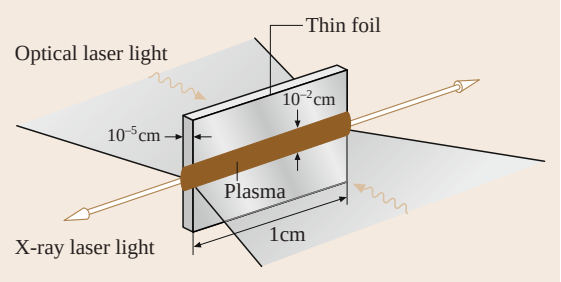

Fig. 11.249 Schematic drawing of an exploding-foil-target x-ray laser

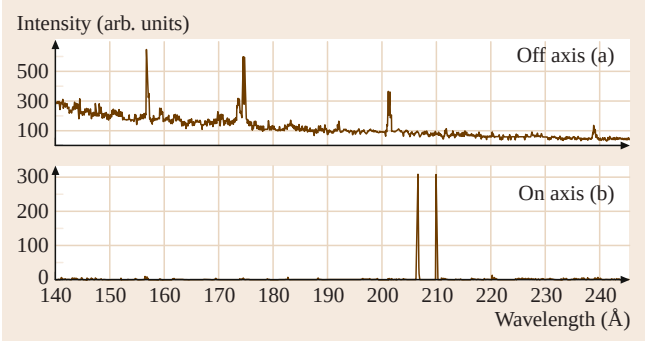

Fig. 11.250 Grazing-incidence spectrograph data from (a) off axis and (b) on axis

iments conducted using of the world's most powerful lasers as pump sources [11.2240–2242]. Subsequent experiments achieved soft-x-ray laser operation in the saturated-gain regime [11.2243], and brought several potential applications to fruition [11.2244, 2245]. These applications include microscopy, holography, diagnostics of dense plasmas, and the excitation of nonlinear photoluminescence in crystals. In spite of their pioneering works, these soft-x-ray lasers have not been used as a laboratory tool because both schemes required huge laser energies of several hundred joules and were operated at a low repetition rate. Since saturated amplification at a *water window* wavelength has not been accomplished even with the world largest laser driver [11.2246], a new excitation scheme has been sought for obtaining soft-x-ray lasers operating at shorter wavelengths. Many efforts have been directed in order to reduce the driver laser energy. The reduction of the pump laser energy is essential for the realization of tabletop x-ray lasers for potential applications [11.2247].

Electron Collision Excitation

Ions with specific numbers of electrons have a fully occupied outer-shell structure and survive over a wide range of plasma parameters. This is a significant advantage for plasma x-ray lasers because it results in a high relative abundance of the lasing ions over a wide range of temperature and density. To date, amplification has been observed in those ions. For example, the electronic structure of highly ionized selenium with 24 electrons removed (Se^{24+}) is similar to that of neutral neon (Ne-like), and the transitions are also similar to those of neutral neon [11.2248]. Such a comparison is referred to as isoelectronic scaling of energy levels and transitions.

Figure 11.251 shows a simplified energy-level diagram of the Ne-like Se ion scheme. The 3p laser upper states are populated mainly by electron collision excitation from the $2p^6$ Ne-like ion ground state. The population inversions are maintained by the rapid radiative decay of the 3s lower states to the ground state. The Ne-like scheme is well studied and is the most robust for electron collisional soft-x-ray lasers. However, it has the disadvantages that a large pump power is required to produce population inversion at a given wavelength. The nickel-like scheme was first proposed by *Maxon* et al. [11.2249] and proved to be useful for shorter-wavelength amplification, below 10 nm [11.2250]. Although the lasing scheme of the Ni-like ions is directly analogous to that of Ne-like

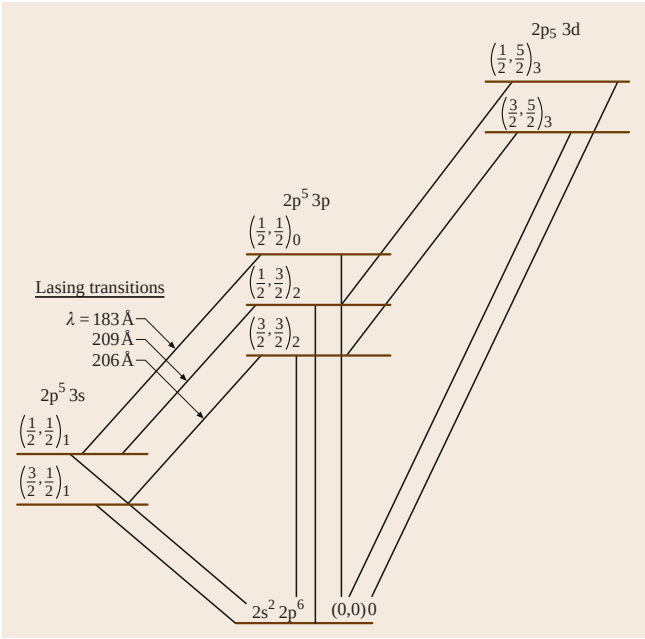

Fig. 11.251 Simplified energy-level diagram for Ne-like Se

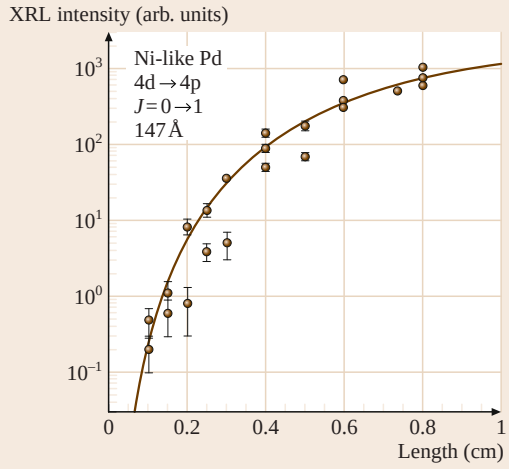

Fig. 11.252 Intensity of 14.7 nm x-ray laser line for 1–8 mm Pd target lengths

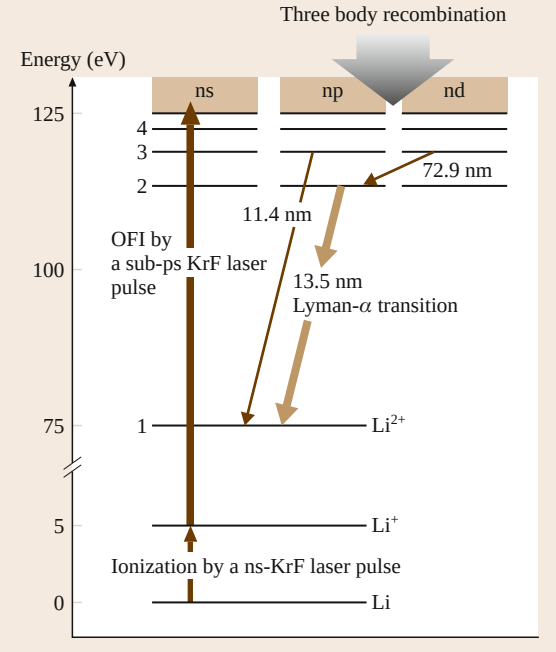

Fig. 11.253 Schematic energy diagram of the 13.5 nm Lyman-α transition soft-x-ray laser by OFI

ions, its higher quantum efficiency for a given ionization state allows the required pumping energy to be significantly reduced. Gain-saturated amplification in the Ni-like scheme has been obtained at wavelengths as short as 7.3 nm [11.2251].

Transient Collision Excitation

The transient collisional excitation (TCE) scheme first proposed by *Afanasiev* and *Shlyaptsev* [11.2252] is a variation of electron collisional excitation. TCE has attractive properties such as:

1. The gain coefficients are 1–2 orders of magnitude larger than those obtained for the same transition in the quasi-steady-state regime.
2. The laser energy required for amplification can be reduced greatly, resulting in the realization of table-top x-ray lasers.

In the TCE scheme, an intense picosecond laser pulse overheats the preformed plasma at a rate faster than other collisional processes. The preformed plasma, containing lasing ions such as Ne-like and Ni-like ions, is produced by a preceding low-intensity nanosecond laser pulse. Transient gains in excess of 100 cm^{-1} have been predicted theoretically. Similar to the quasi-steady-state scheme, TEC was firstly demonstrated in an Ne-like ion [11.2253] and has been successfully applied to Ni-like ions [11.2254]. Saturated amplification with a gain coefficient as high as 63 cm^{-1} has been reported from Ni-like Pd at 14.7 nm with a total pump energy as low as 7 J [11.2255]. Figure 11.252 shows the evolution of the 14.7 nm laser line along the plasma column. In order to further reduce the required pump energy and increase the repetition rate, a novel pump scheme using the excitation pulse incident on the plasma column at a grazing-incidence angle has been reported [11.2256]. The grazing-incidence pumping (GRIP) scheme has allowed lasing for Ni-like Mo at 18.9 nm with only 150 mJ total pump energy at a repetition rate of 10 Hz The GRIP scheme uses refraction of the short pulse at a predetermined electron density to allow a reduction in the pump energy.

Optical-Field Ionization X-ray Lasers

There are two kinds of plasma production scheme for x-ray laser media by use of high-power lasers. The optical-field ionization (OFI) scheme is completely different from the conventional plasma production scheme. The OFI is direct ionization by a strong optical field, which modifies the Coulomb potential of the atoms or ions to create free electrons by tunneling ionization [11.2257]. In contrast to conventional plasma x-ray laser schemes using electron collisional ionization, the OFI scheme requires an intense laser power rather than the large laser energy. Recent advances in the technology of ultrashort-pulse generation and am-

plification have achieved laser powers high enough to realize OFI x-ray lasers with a tabletop device. The requirement for low pump energy will also allow soft-x-ray lasers to operate at high repetition rates, which is critical for most of the promising applications.

By applying this scheme to low-atomic-number media, a plasma consisting of fully stripped ions and free electrons is produced on a time scale much shorter than their collisional and radiative time. In other words, the temperature of electrons produced by the OFI is not determined by the charge state of ions, but can be controlled separately by ionizing-laser parameters such as the polarization and wavelength [11.2258]. By means of a quasistatic model, *Burnett* and *Corkum* [11.2259] showed that cold dense multiply ionized plasmas could be produced by OFI, which are suitable for recombination x-ray lasers. *Nagata* et al. [11.2260] demonstrated amplification of the Lyman $\alpha(n = 2 - 1)$ transition at 13.5 nm in H-like Li by the recombination pumping scheme following the OFI. Using a sub-picosecond KrF excimer laser focused at $10^{17}\,\mathrm{W/cm^{-2}}$, singly ionized lithium ions were further ionized to fully stripped states, resulting in population inversion with respect to the ground state of hydrogen ions (Fig. 11.253). A small signal gain of $20\,\mathrm{cm^{-1}}$ and a gain-length product of 4 have been observed. Subsequently, *Korobokin* et al. [11.2261] used a plasma waveguide in a LiF microcapillary to improve the propagation of the pump pulse and successfully increase the gain-length product to 5.5.

On the other hand, *Corkum* et al. also suggested the use of circularly polarized laser pulses for collisional excitation following OFI [11.2262]. *Lemoff* et al. proposed the specific systems [11.2263] and demonstrated lasing at 41.8 nm in eightfold-ionized Xe [11.2264]. In this experiments, circularly polarized Ti:sapphire laser pulse with an energy of 70 mJ and a duration of 40 fs was focused into a Xe static gas cell to create Pd-like Xe. The intense pump pulse produce the hot electrons which collisionally excite the Pd-like ions to the laser upper level. Recently, *Sebban* et al. reported the saturated amplification of the 41.8 nm line in Pd-like Xe with 0.6 J, 30 fs Ti:sapphire laser pulses. 5×10^9 photons per pulse were obtained at gain saturation [11.2265]. They also reported the lasing at 32 nm in nickel-like krypton [11.2266]. The experimental setup is shown in Fig. 11.254.

Discharge Excitation

Direct excitation of plasma x-ray lasers by an electrical discharge has the potential advantage of high efficiency and compactness over a laser-produced-plasma device. The uniform high-density plasmas required for x-ray amplification can barelybe produced by a conventional electric discharge. *Rocca* et al. proposed [11.2267] and demonstrated [11.2268] a capillary discharged

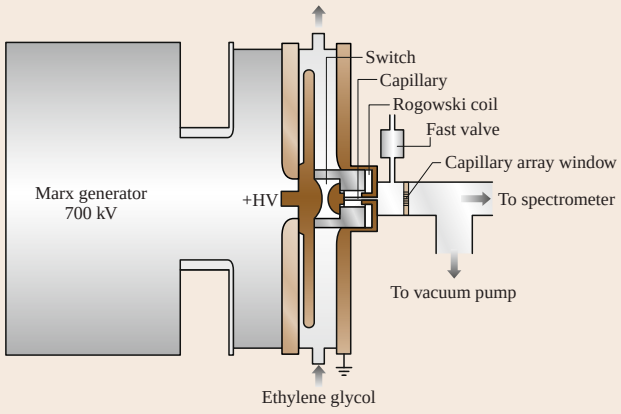

Fig. 11.256 Schematic illustration of the fast capillary discharge setup

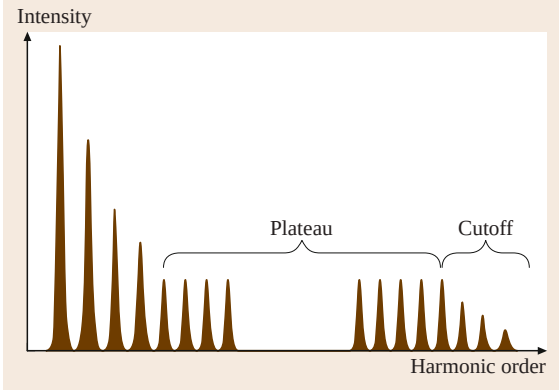

Fig. 11.257 Schematic drawing of typical harmonic spectrum

soft-x-ray laser operating on the 46.9 nm transition in Ne-like Ar in 1994. A fast electrical discharge in a capillary was used to excite plasma columns up to 20 cm in length with a peak current of 40 kA. Figure 11.255 shows the fast capillary discharge soft-x-ray laser setup. The variation of the spectra as a function of capillary length is shown in Fig. 11.256. A recently developed compact discharge occupies a space of only $0.4 \times 1\,\mathrm{m}^2$ in an optical table and produces an average output energy of 0.88 mJ at a repetition rate of 4 Hz. In two-pinhole interference experiments, a high degree of spatial coherence was observed by single-pass amplification in a 36 cm-long capillary. This compact soft-x-ray laser has been used in a variety of areas including plasma physics, material characterization, and the characterization of soft-x-ray optics [11.2269].

11.12.2 High-Order Harmonics

Survey

High-order-harmonic generation (HHG) has been extensively studied since it has promising potential for use as a coherent extreme ultraviolet and a soft-x-ray (XUV) source as an alternative to soft-x-ray lasers or synchrotron radiation sources. High-order harmonics are generated by focusing intense femtosecond laser pulses on a gaseous target supplied with a pulsed gas valve or with a static gas cell placed in a vacuum chamber. The harmonic spectrum has a very characteristic shape, that is, it falls off for the first few harmonics, then shows a plateau where all the harmonics have the same intensity strength, and finally ends with a sharp cut-off. A typical harmonic spectrum observed by the interaction of ultrashort high-intensity pulses with rare gases is shown in Fig. 11.257. The physical mechanism of HHG is explained semi-classically by the three-step model proposed by *Corkum* [11.2270]. First, an electron in the bound-state tunnels through the potential barrier modified by intense laser field (step 1). The freed electron is captured and accelerated by the laser field in the continuum, and the electron returns back to the parent ion when the laser field reverses its direction in the second half-cycle (step 2). Then, the electron recombines with the ion and emits, at this moment, the sum of the kinetic energy and ionization energy as a harmonic photon (step 3). This process is depicted in Fig. 11.258. Since this process occurs at every half cycle of the fundamental field and the generated harmonics are locked in phase, a group of neighboring harmonics produces a train of subfemtosecond pulses in the temporal domain. These spectral and short temporal properties make the high-order harmonics a unique coherent source in the XUV region and are opening new application fields.

Approach to Shorter Wavelength Generation

Since the demonstration of HHG in rare gases using a subpicosecond KrF excimer laser by *McPherson* et al. [11.2271] and a mode-locked Nd:YAG laser by *Ferray* et al. [11.2272] in 1987, much effort has been made to extend the harmonic wavelength to a shorter one with various pumping sources. *Macklin* et al. [11.2273] generated the 109th harmonic (7.4 nm) in neon gas excited with a 806 nm Ti:sapphire laser. *L'Huillier* and *Balcou* [11.2274] observed the 135th harmonic (7.8 nm) using a 1 ps Nd:glass laser. In these experiments, decrease of the neutral rare-gas medium

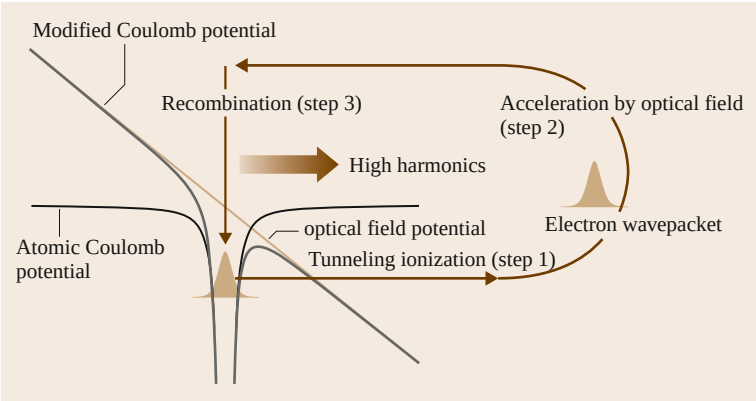

Fig. 11.258 Schematic drawing of the three-step model of high-order-harmonic generation

limits the achievable wavelength because of the occurrence of ionization during the interaction. Progress of ultrashort-pulse laser technology has enabled the use of extremely short pulses with high intensity, which allows the circumvention of the limitation due to ionization [11.2275, 2276]. That is, the effective interaction intensity before the occurrence of ionization can be increase with the extremely short pulses. Consequently, harmonic wavelengths well within the *water window* region have been attained. With a sub-10 fs Ti:sapphire laser, *Spielmann* et al. [11.2277] obtained coherent continuum emission shorter than 2.5 nm, which corresponds to a photon energy greater than 0.5 keV. However, the output photon flux and conversion efficiency of this approach are quite low due to phase mismatch induced by *plasma* free electrons, because a high intensity greater than the ionization threshold is required for 0.8 μm Ti:sapphire laser driving. Recently, *Takahashi* et al. demonstrated efficient generation of high harmonics in the water-window region using a 1.6 μm driving laser and neutral rare gas medium [11.2278]. Since the cutoff energy of high harmonics is roughly proportional to $I\lambda^2$ as described below, the use of a longer wavelength laser has the advantage of generating shorter wavelength high harmonics.

Theoretical Progress

Theoretical understanding of HHG must be based on two processes:

1. A single-atom response in the driving laser field
2. A macroscopic response including propagation effects.

Both responses must be taken into account to make a comparison between the experimental and theoretical results.

The emission property of harmonic radiation from a single atom is determined by the induced atomic polarization, or dipole acceleration, which is calculated from the solution of the time-dependent Schrödinger equation (TDSE). *Krause* et al. [11.2279] showed that the photon energy $E_{\max}$ of the highest harmonic in the plateau is give by $E_{\max} = I_p + 3.17U_p$, where I_p is the ionization energy of the nonlinear medium and $U_p = 9.33 \times 10^{-14} I\lambda^2$ (eV) is the ponderomotive energy of the electron subjected in the pump laser field I (W/cm^2) at a wavelength of λ (μm). In a semiclassical picture [11.2270], the physical origin of this expression is explained in terms of tunneling ionization of the atom, followed by acceleration of the ionized electron in the pump field and recombination with its parent ion. During the acceleration by the optical field, the electron obtains the maximum energy of $3.17U_p$. When this electron recombines with the parent ion, the electron releases this energy plus the ionization energy as a harmonic photon.

Since calculation based on the TDSE is quite time consuming, it is very difficult to combine the numerical results of TDSE with the propagation equations. The calculation load is considerably relieved by using the model of *Lewenstein* et al. [11.2280, 2281]. This model is based on the strong-field approximation and is valid in the region $U_p > I_p$. *L'Huillier* et al. developed a propagation code coupled to the Lewenstein model and successfully described the harmonics characteristics observed in various experiments [11.2282, 2283].

Phase Matching

In order to increase conversion efficiency and improve the spatial quality of high harmonics, phase matching is essential. It is, however, not easy to satisfy the phase-matching condition along the interaction length

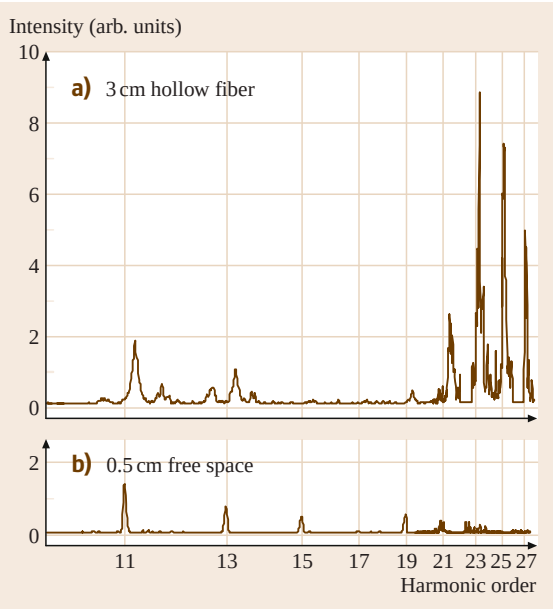

Fig. 11.259a,b Observed harmonic spectral distribution emerging **(a)** from a 3 cm hollow fiber and **(b)** in 0.5 cm free space. Ar gas pressure is 5 torr

because, in contrast with low-order-harmonic generation in the perturbative regime, the dipole phase is dependent on the driving laser intensity [11.2284]. Furthermore, in addition to the medium's dispersion, nonlinear phenomena such as self-focusing and plasma defocusing of the pump pulse also make the experimental achievement of phase matching quite troublesome.

Several techniques to control the phase-matching conditions have been investigated. Phase matching can be achieved by controlling the balance of:

1. The Gouy phase shift and atomic dispersion [11.2285, 2286]
2. Nonlinear phase shift and plasma dispersion [11.2287] or
3. Waveguide dispersion of hollow fiber and atomic dispersion [11.2288, 2289].

A geometrical phase and a dipole phase that have opposite dispersions are compensated by adjusting the focal position around a gas jet. This method is extended to a loosely focused geometry and successfully improved conversion efficiency and beam quality [11.2290]. The use of a hollow fiber provides a few advantages for high-harmonic generation. Due to the flat phase front of the driving (pumping) laser in the hollow fiber, one can avoid undesirable phase modulation of the harmonics, which originates from the intensity-dependent phase change around the focus [11.2284]. This facilitates the clear and easy identification of the phase-matching conditions by adjusting the medium density. The increase of the intensity–interaction length product would also lead to an improvement in conversion efficiency. Furthermore, the use of a hollow fiber results in lower beam divergence and better spatial coherence. Such improvements are very important for practical applications. With this new technique, several groups have reported harmonic generation. *Tamaki* et al. demonstrated HHG of a Ti:sapphire laser pulse in an Ar-gas-filled hollow fiber and showed hundredfold enhancement around the 25th harmonic [11.2291, 2292]. Figure 11.259 shows the observed harmonic spectra with and without the hollow fiber filled with 5 torr Ar gas. *Rundquist* et al. [11.2288, 2293] also reported phase-matched generation of the 29th harmonic and improvement of both the generation efficiency and the beam quality in the hollow fiber. However, the output energy from the hollow fiber was restricted to a few nanojoules because only a few millijoules of laser pulse could be introduced due to the limited aperture of the hollow fiber [11.2294].

Energy Scaling

For the development of a variety of applications of high harmonics (HH), one of the most important issues is energy scaling. High-energy HH is expected to boost new physics in the soft-x-ray region. *Takahashi* et al. report energy scaling of HH in Ar under the optimized phase-matched condition [11.2290, 2295]. Their scaling method demonstrated a linear increase of harmonic energy with respect to the geometrical focusing area of the pump pulse, while keeping an almost perfect spatial profile of the harmonic output. The maximum energy of the 27th harmonic attained was 0.33 nJ with a conversion efficiency of 1.5×10^{-5}. The evolution of HH intensities in the spectral region from the 23rd- to 27th-order harmonics was also measured as a function of medium length. The result is shown in Fig. 11.260. The solid line shows theoretically fitted intensities for the 23rd, 25th and 27th harmonics. The coherence length was estimated to be ≈ 15 cm by fitting the theoretical curves. As was pointed out by *Constant* et al. [11.2289], the optimizing conditions for the medium, coherence and absorption lengths are given by $L_{\mathrm{med}} > 3L_{\mathrm{abs}}$ and $L_{\mathrm{c}} > 5L_{\mathrm{abs}}$, where L_{med}, L_{c}, and L_{abs} are the medium length, the coherence length, and the absorption length, respectively. The 23rd- and 25th-order harmonics satis-

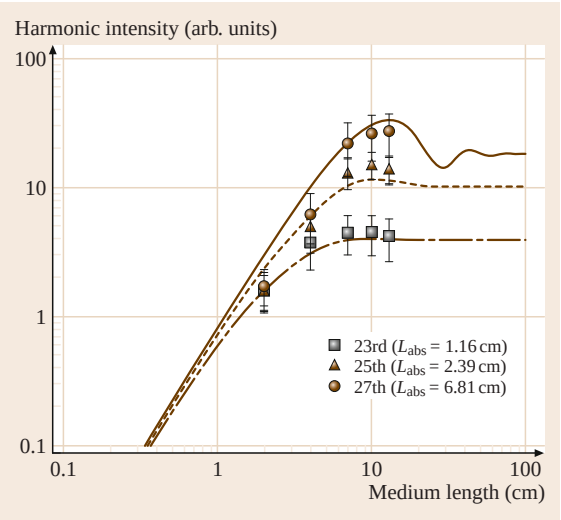

Fig. 11.260 Emitted photon number of the harmonics in argon as a function of the medium length. The *solid line* corresponds to the calculated photon number for $L_c \approx 15$ cm with 1.8 torr argon in free space

fied the optimized condition for this relation. Therefore, those orders were saturated under the experimental conditions. On the other hand, the 27th-order harmonic did not yet satisfy the above conditions, because of low absorption. It was reported that a loosely focused geometry becomes a waveguide geometry in the long focus limit [11.2296].

Spatial Coherence

Since HHG is based on nonlinear frequency conversion, the spatial and temporal coherences of high-order harmonics are inherently expected to succeed to those of the fundamental laser pulse. However, HHG conducted by use of a tight-focusing geometry in thin gas media did not allow full phase matching to enhance the coherence. Typically, multimode components are observed as broadened peaks in the spectrum or the pedestal of the spatial profiles. Recent studies have revealed that macroscopic phase matching can realize highly efficient and spatially well-characterized (nearly Gaussian profile) high-order harmonic light [11.2295]. Several groups have reported the interferometric measurement of the spatial coherence of high harmonics [11.2297–2301]. When macroscopic phase matching is achieved in a hollow fiber or loosely focused geometry, the measurements show that the harmonic beams have almost perfect spatial coherence. Figure 11.261 shows the interferogram of the 27th-harmonic beam gener-

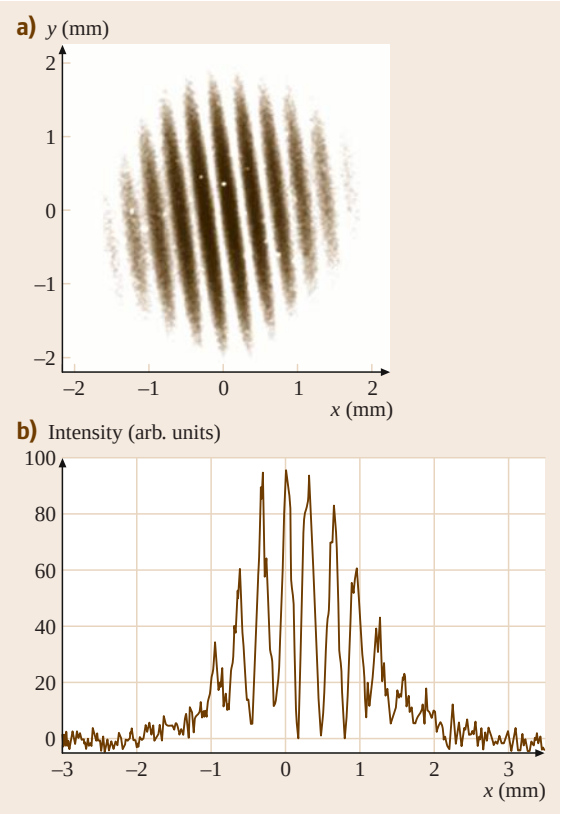

Fig. 11.261a,b Interferogram of a harmonic beam diffracted by double pinholes separated by 100 μm: **(a)** fringe image, **(b)** intensity profile of the interferogram along a horizontal line passing through the center

ated with an Ar-filled hollow fiber pumped with 20 fs, 0.35 mJ Ti:sapphire laser pulses [11.2299]. This interferogram was obtained with two pinholes separated by 100 μm, while the harmonic-beam diameter was measured to be 130 μm. A similar result at 13.5 nm using the 59th-harmonic beam was obtained by the single-shot spatial double-slit interference technique [11.2301]. This 13 nm harmonic source is useful for wavelength inspection of optics and masks for EUV lithography. Figure 11.262 also shows the interferogram recorded by point-diffraction interferometry, which indicates that the harmonic beam can be considered as a spherical wave within a phase error of $\lambda/15$ [11.2300].

Applications

In addition to applications in atomic physics [11.2302], solid-state spectroscopy [11.2303] and plasma diagnostics [11.2304], high harmonics hold the promise

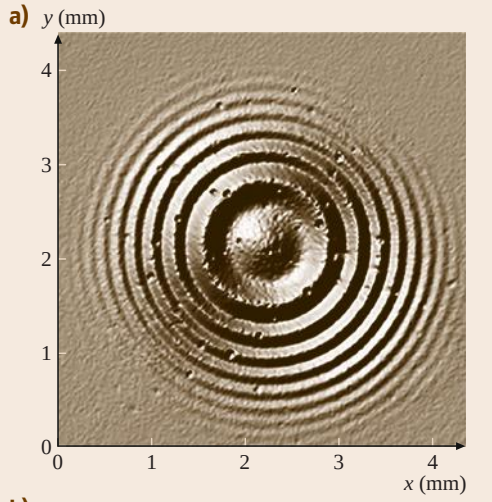

Fig. 11.262 (**a**) Interferogram recorded with a PDI plate with a 10 μm pinhole. (**b**) Intensity profile of the interferogram along a horizontal line passing through the center

of achieving a tabletop source for coherent diffractive imaging. *Sandberg* et al. reported lensless diffractive imaging [11.2305] and Fourier transform holography [11.2306] using 29 nm harmonic beam generated by a tabletop high harmonic source. By increasing high harmonic energy up to 1 mJ at 32 nm, single-shot diffractive imaging was demonstrated recently [11.2307]. High intensity of high harmonics is also expected to give rise to nonlinear phenomena in the XUV region. *Takahashi* et al. [11.2290, 2308] generated a peak power of 130 MW at 62.3 nm in 0.6 torr Xe and 10 MW at 30 nm in 2 torr Ar by phase matching technique and loosely focused geometry. When these harmonic pulses are focused with multilayer mirrors, the focused intensity reaches 10^{14} W/cm^2 [11.2309], which is high enough to cause nonlinear interactions. Among various phenomena of nonlinear interactions between soft x-rays and matter, two-photon double ionization of He atom has attracted much attention and has been studied theoretically in a number of papers because it provides insight into the electron–electron interaction (that is, electron correlation) and can pave the wave for unexplored aspects of the three-body problem [11.2310–2312]. On the other hand, nonlinear phenomena are indispensable for the progress of ultrafast optics and spectroscopy, because the direct measurement of ultrafast soft x-ray pulses by means of autocorrelation method gives us intuitive information about their temporal shapes [11.2313]. *Nabekawa* et al. reported the first observation of two-photon double ionization in He with 29.6 nm harmonic photons and used it to measure the pulse duration of the 29.6 nm harmonic pulse by autocorrelation method [11.2314]. When instantaneous double ionization occurs in molecules, the ionized molecules explode due to the static Coulomb repulsion force. This molecular Coulomb explosion was also observed using a train of attosecond pulses from high harmonic source [11.2315].

Furthermore, coherent XUV and x-ray pulses are not only useful owing to their short wavelengths, but are also important due to their potential to produce electromagnetic radiation in the range of attoseconds. High-order harmonics are now recognized as the only source of attosecond pulses [11.2316, 2317]. Excellent special and temporal coherence of high harmonics are also useful as a seed pulse for plasma x-ray lasers [11.2316, 2318] and x-ray-free electron lasers [11.2319], which are operated in self-amplified spontaneous emission mode.

11.13 Generation of Ultrahigh Light Intensities and Relativistic Laser–Matter Interaction

Modern laser technologies allow the amplification of short laser pulses to energies of some tens of kJ. Additionally, ultrashort pulses containing only a few optical cycles can be generated. By merging these techniques

nowadays focused laser beams can reach unprecedented intensities in the range of 10^{21} W/cm^2 and will reach even higher values in the near future. At these intensities the electric and magnetic field strength is many orders of magnitude higher than those that will ever be possible in a static generation scheme. By applying these fields to a target it becomes possible to gain access to a new interaction regime of light and matter: relativistic optics. This opens a new wide area in experimental science where classical optics meets plasma dynamics, relativistic quantum mechanics, and high-energy physics.

11.13.1 Laser Systems for the Generation of Ultrahigh Intensities

Amplification of Ultrashort Pulses to High Energies

For ultrashort pulses the energy density of light at the surface and in the volume of all the optical elements is limited by the onset of nonlinear effects and laser damage due to the high peak power. Moreover, in a laser amplifier the energy extraction efficiency is a function of the ratio of the energy density and the saturation fluence of the laser material. Hence, a short pulse cannot be amplified efficiently. The chirped pulse amplification (CPA) technique [11.2320] circumvents this difficulty. The principle of CPA is depicted in Fig. 11.263. Ultrashort pulses contain a broad spectral bandwidth according to their Fourier transformation. This fact enable the possibility to add a phase shift to different frequencies or wavelengths of the laser pulse just after its generation in a mode-locked laser cavity. The result is a stretched pulse containing a chirp, i. e., the pulse duration is no longer bandwidth limited. The lengthened pulse has accordingly a lower peak power. It can be amplified much more efficiently and compressed to a very short pulse afterwards by adding a spectral phase with an opposite sign to that introduced by the stretcher.

After the invention of the CPA technique tremendous progress in the development of ultrashort pulse lasers towards higher peak power has been witnessed. Nowadays, terawatt (TW) laser pulses can be produced using tabletop laboratory-scale laser systems that operate at repetition rates of 10 Hz or higher. Whereas, even higher power up to the petawatt (PW) can be generated by flashlamp-pumped lasers that have factory-building sizes, like the first PW laser, that was realized in 1999 [11.2321]. The CPA technique is common to all of these devices.

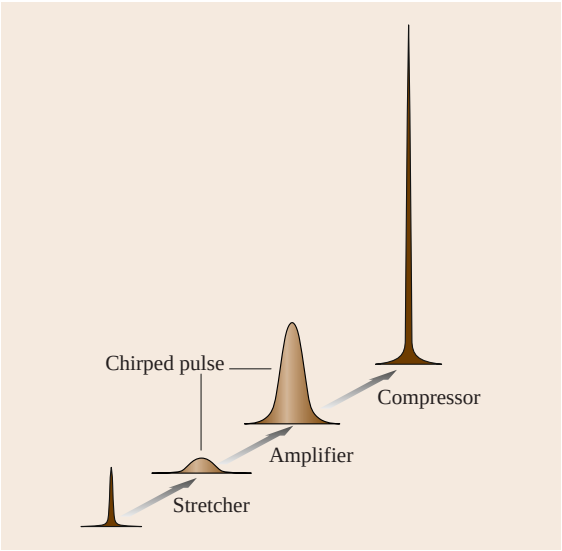

Fig. 11.263 The CPA principle. An ultrashort pulse generated in a mode-locked laser is stretched by adding a spectral phase that group delay different wavelengths of the pulse. After amplification retaining the pulse spectrum and chirp the pulse is recompressed to its original length, resulting in ultrahigh peak power

Because pulse stretching and compression are related to each other and are normally based on the same principle, the stretcher and compressor are treated here as a stretcher–compressor pair (SCP). Pulse stretching naturally occurs in the vicinity of dispersion. Hence, the propagation of pulses in dispersive media always leads to pulse stretching. In order to keep the required space and size of optical elements as small as possible highly dispersive optics, i. e., gratings will be used. Nevertheless other elements such as prisms, grating prisms (so called grisms), fibers and chirped fiber Bragg gratings as well as chirped mirrors can be applied. Here we limit ourselves to the simplest case of flat reflective phase gratings, because these offer the largest group delay.

The principle of pulse compression with identical parallel gratings was first described by *Treacy* [11.2322]. A pulse is diffracted by a grating, angularly split into its different wavelengths and propagated to the second parallel-aligned grating. The second grating removes the angular modulation, i. e., redirects all wavevectors of the different wavelets into the same direction. If all the waves are treated as plane waves, the introduced lateral shift can be neglected. For a real, limited beam size the same device of parallel gratings has to be used

once more in order to combine the wavelets again spatially. As a side effect this doubles the stretching factor of the arrangement. Section 12.1.3 contains a detailed description of these devices.

For ultrahigh-peak-power lasers a maximum stretching/compression factor, i. e., the ratio of stretched pulse length to bandwidth limited pulse length is required in order to maximize the fluence in the amplifier chain. The stretching factor depends on the line density of the gratings, the center wavelength, and the bandwidth of the pulse. Very long stretching factors of 10 000 or more are required for most broadband rare-earth-doped laser materials in order to allow fluences in the amplifier close to or above the gain-saturation fluence.

If the grating distance is chosen in this way, such that the unclipped spectral bandwidth is twice the spectral full width at half maximum (FWHM) of the pulse, the maximum stretched pulse length τ_{max} is only a function of the grating size L

$$\tau_{max} = 2\frac{L}{c}\cos(\alpha)\,, \qquad (11.237)$$

where $\cos\alpha$ is a factor according to the diffraction angle α of the grating and has a maximum of unity in the unrealistic case of a diffracted beam parallel to the grating surface. The factor of 2 refers to the Littrow case, i. e., the input and diffraction angle being equal. The latter normally maximizes the grating diffraction efficiency. For holographic metal-coated diffraction gratings with near-rectangular groove shapes it has been shown that an optimum diffraction efficiency of a metal grating at wavelength λ can be achieved for a grating constant of about $\sqrt{2\lambda}$ [11.2323], which results in a Littrow angle of 45°. This leads to a minimum grating size for an SCP of about 24 cm if a femtosecond pulse has to be stretched to 1 ns. Passing a stretcher or compressor setup again can, in principle, increase the stretching factor, but introduces losses that are most often acceptable for the stretcher but not for the pulse compressor.

Very large grating distances and hence long stretched pulses require a similar accuracy for the compensation of dispersion by a well-matched stretcher and compressor as in the case of ultra-broadband fs pulses, because higher-order dispersion terms increase together with the second-order term. Because most often aberrations of the telescope optics cannot be tolerated, aberration-free all-reflective designs like the Öffner triplet are applied [11.2324]. In special cases aberrations introduced by the stretcher may help to compensate for laser-material dispersion in the amplifier chain [11.2325].

The required grating sizes for the compressor of a high-energy laser system is ruled by the generated group delay in order recompress the pulse and the size required to fit the compressor to the beam diameter. Before compression the laser beam has to be expanded to reduce the fluence in the beam to an amount well below the damage threshold of the compressor optics, particularly the gratings. For a metal-coated grating damage thresholds may reach the $0.5\,J/cm^2$ level [11.2323] for half-ps pulses, but will normally be less than $0.25\,J/cm^2$. In the compressor setup these fluences result in intensities that are well above the onset of nonlinear effects in air at normal pressures. In order to prevent the pulse from self-focusing and self-splitting into white-light filaments, pulse compression has to be performed in a vacuum vessel.

In the region of fs to ps pulses the damage threshold for metal coatings is nearly independent of pulse duration, in contrast to dielectrics where the main damage mechanism is linked to nonlinear absorption effects. For pulses longer than 100 fs dielectric gratings may substantially improve overall performance [11.2326]. Damage thresholds two to four times that of gold-coated gratings are reported. These dielectric phase gratings on top of a multilayer mirror can, in principle, show a 100% diffraction efficiency to the minus-first order [11.2327]. Therefore they are favored in high-energy high-peak-power laser systems.

The peak power of a laser system is limited mainly by the possible sizes of the diffraction gratings. A workaround is to add identical smaller gratings to a mosaic grating or tiled grating. The smaller grating tiles have to be coherently phased together in order to make them work like a single one. Using this technique to build a compressor opens the way to further power scaling of high-peak-intensity lasers. Compression of pulses to 650 fs with a tiled grating replacing a meter-sized grating in a high-energy laser system has already been demonstrated [11.2328], as well as pulse compression of a chirped 2 ns pulse down to 150 fs [11.2329] by phasing two 350 mm-wide gold-coated gratings with the help of a six-axis piezo-driven mount.

Laser Materials for High Peak Power

A crucial issue conceiving a high-peak-power laser system is the choice of the gain material. Broad band width and a high cross section for stimulated emission are required. Due to the limited peak power of the pump source a long fluorescence lifetime for energy storage is desired. At higher fluorescence lifetimes either the emission cross section, or the gain bandwidth, or both

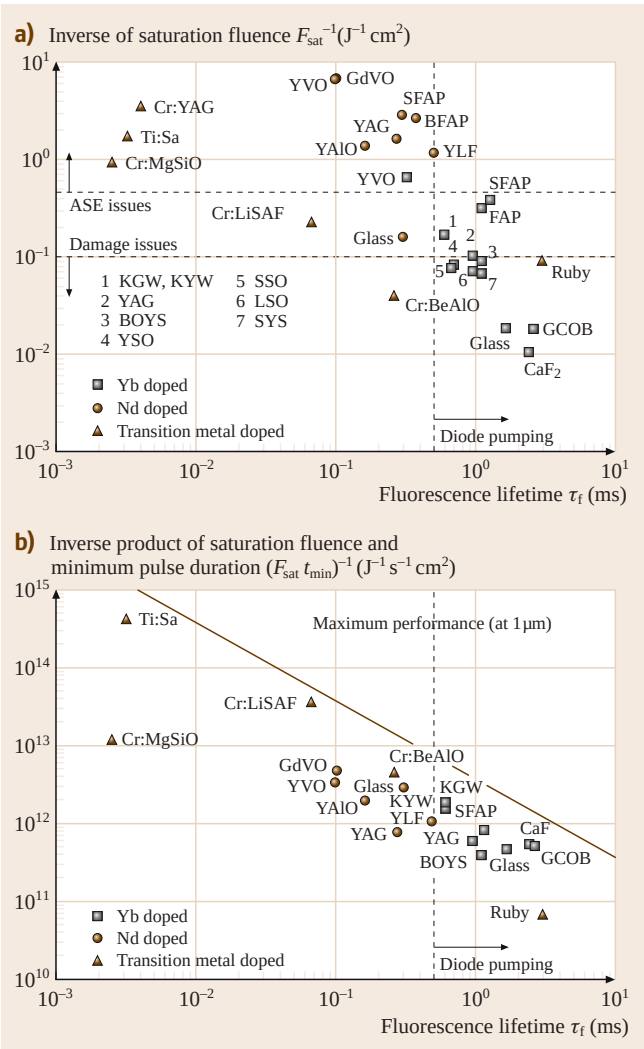

Fig. 11.264 **(a)** Capability of laser materials for energy storage and generation of high energy pulses. The inverse saturation fluence is plotted against the fluorescence lifetime. For a higher gain amplified spontaneous emission (ASE) become an issue whereas for lower gain damage limits efficient energy extraction. Effective pumping will be useful if the fluorescence lifetime exceeds a certain limit. The limits are marked with *dashed lines*. **(b)** Capability of laser materials for energy storage and generation of high peak power. The inverse saturation fluence multiplied by minimum possible pulse width plotted against fluorescence lifetime τ. Differently doped materials are marked with *different colors* ▶

decrease. For efficient amplification the extracted laser pulse energy density has to be close to the saturation fluence of the gain medium.

Figure 11.264 illustrates the possibility of generating high peak power out of some established laser materials. The inverse of the product of the saturation fluence and the shortest pulse duration indicates the capability of a laser material for high amplification at maximum bandwidth. Assuming Gaussian-shaped gain spectra the correlation between the emission cross section, bandwidth and fluorescence lifetime of a laser material is given by

$$\sigma_{em} = \frac{c_0^2}{4\pi n^2 \nu^2} \frac{1}{\tau_f} \frac{\sqrt{\ln 2}}{\Delta\nu\sqrt{\pi}} \qquad (11.238)$$

with c_0 the velocity of light in vacuum, n the refractive index, h Planck's constant, ν the center frequency, τ_f the fluorescence lifetime, and $\Delta\nu$ the bandwidth (FWHM). Applying the time–bandwidth product for Gaussian line-shape a criteria for the generation of high peak power at a corresponding fluorescence lifetime depending on the laser wavelength lambda and the refractive index n is obtained

$$\frac{\tau_f}{t_p F_{sat}} \leq 4.26 \times 10^9 \frac{(\lambda[\mu m])^3}{n^2} \frac{[cm^2]}{[J]} . \qquad (11.239)$$

Here the saturation fluence F_{sat} is given by $F_{sat} = h\nu/\sigma_{em}$.

In Fig. 11.264 suitable materials for amplification to a high energy level are mapped. Furthermore, there is an optimum region between high gain and low gain, where amplified stimulated emission and damage issues, respectively, are likely to occur.

Recently, it was observed that cryogenic laser materials may show enhanced performance. Either spectroscopic parameters and thermal behavior can be improved by cooling to liquid-nitrogen temperatures [11.2330]. Ti:sapphire for instance gain, higher efficiency and thermal conductivity. Quasi-three-level systems represented by the Yb-level system show higher emission cross sections and additionally reduced absorption at the laser wavelength, because population of the low laser level is suppressed [11.2331, 2332]. It could be shown that using cryogenic cooled Yb:YAG a 100% photon slope efficiency is possible in a CW laser [11.2333], this means that above laser threshold every pump photon is converted into laser radiation. This is of course not possible in short-pulse amplifiers because of the energy loss as spontaneous and amplified spontaneous fluorescence.

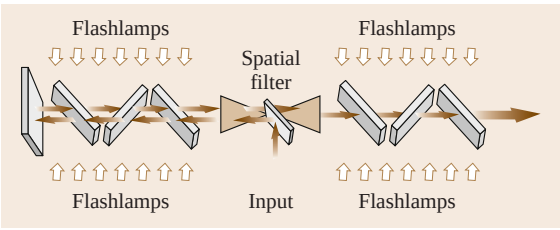

Fig. 11.265 Typical flashlamp pumped slab amplifier configuration. The seed pulse is injected at the spatial filter between a double-pass section and a single-pass booster amplifier

Laser Amplifier Schemes for High Peak Power

Except some examples of high-energy excimer lasers and upcoming free-electron lasers for the generation of high peak power at very short wavelengths typical scientific lasers are based on solid-state lasing materials as presented above, all of which are pumped optically. Because a high flux of pump photons is needed to invert the energy-level population significantly only three options for pumping exist: flashlamps, lasers, and diode lasers. Diode lasers are treated separately because no enhanced additional pumping is required for them, providing a stabilized current is sufficient.

So far the flashlamp is the cheapest generator for a high pump photon flux. In the past flashlamp-pumped solid-state lasers have been scaled to 20 kJ pulse energy in a single beam. Such systems are based on schemes where bundles of meter-size flashlamps pumping several Nd-doped glass discs arranged at Brewster's angle in the laser beam path as sketched in Fig. 11.265. For fusion lasers like the National Ignition Facility in the US (NIF) [11.2334, 2335], Laser Megajoule in France (LMJ) [11.2336] or Gekko in Japan [11.2337] several such beam lines are bundled together to form megajoule laser facilities. Such beam lines were the first with the capability to generate petawatt laser pulses [11.2321]. Typical for this kind of lasers are a double-pass main amplifier and a single-pass booster amplifier section.

The drawback of flashlamp pumping is the low efficiency of this scheme. Pump photons are not only generated at the absorption wavelength of the laser material but also at wavelengths not involved in the lasing process. This low efficiency results in substantial heat left inside the laser materials, which are themselves poor heat conductors. The maximum repetition rate of this disc configuration scales with the inverse square of the beam diameter. Amplifiers with beam diameters of some 10 cm can be operated at repetition rates of some shots per day only. With these systems scientific investigations of plasma effects are extremely difficult and expensive. For Nd-doped glasses the gain bandwidth limits the shortest pulses to about 400 fs if simply a single type of glass is deployed. Furthermore, mixed Nd:glass systems are able to provide a broader band width and pulses of about 150 fs can be amplified to the petawatt level [11.2338, 2339]. To generate 100 TW to PW peak power pulses, energies in the 10–100 J range are needed, which require large amplifiers that are typically not operated at high repetition rates. Nevertheless, using these lasers for pumping an OPCPA (see later) opens the door for ultra-broadband amplification of few-cycle pulses to the 10 J level [11.2340].

Using laser diodes as the pump source helps to relieve some of these difficulties because their emission spectrum is much narrower and can be fitted to the absorption line of the laser-active medium. Consequently less energy is wasted and less heat is left inside the laser active medium. However, high-power diodes with energy-conversion efficiencies up to 75% and continuous-wave output in the 100 W range are only available in the red and near-infrared spectrum. These diodes are based on double heterostructures of ternary and quaternary semiconductors incorporating GaAs. This spectral range is preferred for pumping rare-earth-doped laser materials, where Nd and Yb are most favored. Broadband gain materials including transition metals such as Cr:LiSAF will attract more interest if suitable diodes providing high brightness are developed. Today diode-pumped infrared frequency-doubled lasers are used to pump Ti:sapphire, the laser material able to amplify the widest spectrum and hence the shortest pulses. By this route, pulses with petawatt peak power are possible at a reasonable repetition rate [11.2341].

The direct diode-pumped amplification of 150 fs pulses to the joule and 10 J level has already been shown by pumping an Yb-doped fluoride-phosphate glass at 940 nm [11.2342, 2343] with the edge-cooled disc arrangement shown in Fig. 11.266a. Because of its high thermal conductivity crystals are prefered against glasses. A promising material for direct diode-pumped high intensity laser systems is Yb:CaF_2. Terawatt peak power was already achieved [11.2344, 2345]. Since the efficiency of the amplifiers are of main interest in such diode-pumped systems, cryogenic cooling is applied also for amplification of ultra-short pulses with this material [11.2346, 2347].

To accomplish experimentalists' demands for higher repetition rates advanced cooling technologies have to be developed even for diode-pumped solid-

state lasers (DPSSL). Figure 11.266 shows a variety of DPSSL pumping schemes with different cooling architectures.

In slab lasers, where the various pump schemes depicted in Fig. 11.266b–d are employed, one dimension is used to provide a small distance for heat removal. They differ in the way in which pump light is provided. Expanding this idea to two dimensions results in the cladding pumped fiber amplifier (Fig. 11.266g), which is not or only radiatively cooled like the heat capacity lasers (Fig. 11.266f), which are able to run as long as the temperature does not reach a certain level [11.2348]. These lasers provide bursts of pulses. Thin disc lasers (Fig. 11.266e) allow a very high average power and can produce very good beam profiles but are difficult to scale to larger beam diameters and higher pulse energies. A compromise is the use of a thicker disc at a moderate repetition rate in the same configuration. The thicker disc does not require multiple pump-beam passes for full absorption and provides a larger single-pass amplification than the thin-disc amplifier. Nonetheless, multi-pass pumping is an approach to increase the efficiency of three-level lasers without cryogenic cooling [11.2349].

By putting several thin discs together and using the amplifier slab interspace for gas cooling, as in the architecture sketched in Fig. 11.266h, the gain and absorption equals that of the thick disc but efficient cooling is enabled. A diode-pumped laser of this type was developed at the Lawrence Livermore National Laboratory in the US. It was called Mercury [11.2350] and allowed an output of 65 J, the highest ns pulse energy from a single DPSSL at a repetition rate of 10 Hz so far reported.

A combination of the schemes in Fig. 11.234d,e was successfully used with the help of a cryogenic cooled thin layer of ceramic Yb:YAG on a white YAG prism for highly efficient amplification of nanosecond pulses [11.2331, 2332].

The long propagation length in a fiber that confines the laser light field to the doped and amplifying core allows high amplification factors in a single pass and optical-to-optical efficiencies close to the theoretical limit given by the quantum efficiency. For TEM_{00}-mode radiation the maximum pulse energy is limited to some mJ for CPA. Nevertheless, average powers from several 100 W to the kW region are possible. To reach a high extraction efficiency for the low-energy seed pulses provided by fs oscillators multipass amplifiers or regenerative amplifiers are adopted. Multipass amplifiers can be found with a variety of geometries. All pulse

parameters, such as the polarization or propagation direction, can be used to separate pulses from successive passes and finally for out-coupling.

The regenerative amplifier is a seeded oscillator with an active element, in most cases a fast switching Pockels cell, that allows the extraction of the amplified pulse when the gain of the active medium is saturated. It benefits from a stability that stems from gain saturation and beam quality that is ensured by successive spatial filtering in the laser cavity. The drawbacks of

regenerative amplifiers are pre-pulses produced by leakage from the cavity in round-trips before extraction and long path lengths in dispersive material that has to be compensated by the SCP of a CPA system.

The last section of a high-power laser amplifier system is a booster amplifier with a low number of passes or one pass only. In order to extract the energy with high-efficiency, saturation fluence has to be reached across the full beam diameter. The result is a so-called top-hat beam profile with a uniform fluence in the center and a steep fluence rise at the edge. In gain media with a long propagation distance this may be achieved automatically after some distance and the length were uniform aperture filling is not guaranteed hardly affects the overall efficiency of the amplifier. For amplifiers with short propagation distances of the pulse in the active medium the seed pulse itself has to be converted into a top-hat profile starting from a Gaussian. A simple method to implement this is by diffraction at a serrated aperture [11.2351].

Because a top-hat beam unlike the Gaussian changes its profile while propagating it has to be relay imaged to successive optical elements of the laser system to avoid hot spots and laser damage. In high-power laser systems relay imaging is often combined with beam expanders and spatial filters [11.2352].

Broadband Optical Parametric Chirped Pulse Amplification

Alternatively instead of conventional laser amplifiers a parametric amplification process (OPA) can be used for the generation of high-energy broadband pulses. In this second-order nonlinear interaction a pump photon is split into a signal and an idler photon. This process is the reverse of sum-frequency generation. Energy-conservation demands that the sum of the signal and idler frequencies equals the pump frequency. Additionally, fulfilling momentum conservation ensures coherence of the involved waves while propagating through the nonlinear medium. The latter is known as phase matching. The nonlinear medium has to be a crystal in order to show second-order nonlinearity and achieve phase matching. The phase-matching condition also determines the wavelengths of the signal and idler waves.

For a certain direction of pump, signal, and idler waves only one combination of wavelengths can be generated. In order to allow broadband amplification of a signal input wave using a narrow-band pump the different idler wavelengths should have different directions in the crystal. This principle is illustrated in Fig. 11.267 and is called optical chirped pulse amplification (OPCPA) if the signal beam is a chirped stretched pulse [11.2353–2356].

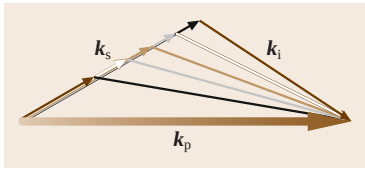

Fig. 11.267 Scheme to achieve broadband optical parametric amplification. In order to achieve broadband signal amplification in a parametric nonlinear optical process using a narrow-band pump different idler wavelengths have different propagating directions in a crystal to fulfill the phase-matching condition while all signal waves propagate collinearly

With the OPCPA scheme, energy can be transferred from a narrow-band nanosecond pulse to a stretched broadband signal pulse [11.2357–2360]. The problem of amplification of ultrashort pulses is thereby split into the task of amplification of high-energy laser pulses and the task of implementation of broadband OPA. Comparing the OPCPA with a conventional laser-pumped CPA several advantages can be realized. Firstly no energy is stored in the nonlinear crystal and, except parasitic absorption, no energy is lost in the crystal, which results in no heat being produced in the process. This fact allow easy high-repetition-rate scaling of the amplifiers without phase distortions by thermal effects. Because no resonance to energy levels of a dielectric medium is required, very large band widths at any center wave length can be generated. It was shown that pulses shorter than 10 fs can be amplified. Using crystals with high nonlinear optical coefficients like the most prominent crystal BBO and at sufficient intensities a single pass can provide an amplification of the signal by many orders of magnitude. Regenerative amplifiers are not needed and the problem of pulse leakage from them disappears. Amplification lasts only as long as the pump passes the crystal and therefore pre-pulses and post-pulses as well as back-reflected pulses are not amplified any more and higher pulse contrasts are possible with the OPCPA technique. Lastly the amplified signal beam is an analog of the input signal and unwanted phase distortions of the high-energy pump are carried away with the idler beam like the different $\boldsymbol{k}$ vectors in Fig. 11.268.

In order to use all of these advantages a careful design of OPCPA is required. For instance if an OPCPA stage is driven to its maximum amplification and the

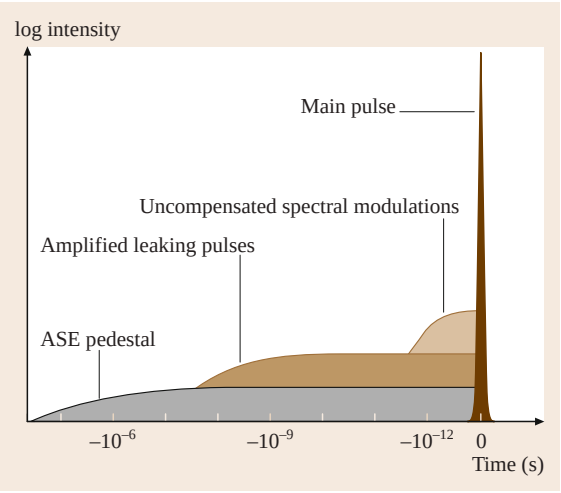

Fig. 11.268 Typical pulse contrast characteristics. The main femtosecond laser pulse is typically preceded by amplified stimulated emission (ASE), amplified pre-pulses and uncompressed chirp

process starts to saturate, the impact of intensity variations of the signal to the output is reduced but intensity variations of the pump are transferred to the amplified beam. Additionally, signal and idler waves are generated starting from noise, a problem similar to the amplified spontaneous emission (ASE) in a conventional laser amplifier. To minimize this effect a pump pulse length no longer than the seeding signal pulse and their perfect synchronization is required, which is challenging for ps pulses. Contrariwise ps pulses offer higher intensities at a fixed fluence, which reduces the required crystal length, with the advantage of increasing the amplification bandwidth without changing the crystal orientation. More requirements may arise at different wavelengths involved, like absorption, or second-harmonic generation from the signal or idler beams, amongst others.

Nevertheless, OPCPA is the technique that allows the implementation of an ultrashort pulse option to all coherent high-energy light sources that emit pulses in the nanosecond and picosecond range and transfers them to an ultrahigh-peak-power laser system. A 0.56 PW 43 fs laser system was recently demonstrated [11.2361] based on OPCPA in a large-aperture KDP crystal. These crystals are used for Pockels cells and frequency converters in fusion laser systems and can be grown with meter-size apertures. This in principle allows multi-petawatt power scaling [11.2362, 2363].

High Demands on Pulse Preparation for Advanced Experiments

The acceleration of electrons and protons by a laser requires light intensities on the order of $10^{20}\,\mathrm{W/cm^2}$, which is many orders of magnitude above the onset of nonlinear effects and atom ionization, which results in Coulomb explosion even in low-density targets such as gases, triggered by lower intensity background radiation of the laser. Experiments are strongly affected by this pre-pulse laser-target interaction [11.2364]. To prevent the target from being destroyed before the main part of the laser pulse arrives, laser output has to be cleaned from its leading pedestal. A typical laser pulse characteristic is shown in Figure 11.268. The long-term pre-pulse pedestal results from ASE of the laser active material, whose duration is closely linked to its fluorescence lifetime. Additionally, regenerative amplifiers that are often used as the first devices in the amplifier chain, always have a certain leakage of pulses from preceding round-trips. The pulses are again amplified in successive multipass and booster amplifiers, generating high-energy pre-pulses on target. Finally, non-bandwidth-limited pulse recompression based on material dispersion, wavelength clipping, aberrations in stretcher and compressor setups and uncompensated higher-order dispersion terms result in pre-pulses and pedestals as shown in Sect. 12.1 for frequency-domain-filtered short pulses.

Numerous methods are used to remove this unwanted pre-pulse laser light. Primarily, the total amplification is split into stepwise amplification with additional possibilities for time-domain and spatial pulse filtering. For this purpose fast Pockels cells [11.2365] and spatial filters, which are often combined with beam expanders, are applied. Spatial filters and apertures prevent spontaneously emitted fluorescence light from propagation to the subsequent amplifiers. These measures can often improve pulse contrast ratios considerably [11.2366].

Nonlinear optical effects that favor high intensities can be used as well. Examples of the latter case are saturable absorbers and laser pulse switched gates. The OPCPA inherently embodies such a gate if a rectangular-shaped pump pulse is used. Therefore pre-pulse suppression in the OPCPA [11.2367] can be as high as its gain.

Saturable absorbers and self-phase-conjugating mirrors are used for nanosecond laser systems. In the case of a chirped pulse amplification system these techniques require pulse compression before and stretching after filtering. This limits their application to low-energy

pulses or prohibits their use if very long stretching factors are needed. Nevertheless, cross polarized wave generation, a variant of nonlinear optical self switching, has recently attracted most interest in high power lasers systems for contrast enhancement [11.2368, 2369], because its potential for application on even few-cycle pulses [11.2370]. The effect of this method is twofold: the spectrum of the pulse is shortened and the contrast between pulse and ASE background is increased.

Nonlinear effects can also be used after final pulse recompression. One possibility is frequency conversion by second-harmonic generation. Another pre-pulse suppression method with high efficiency and low loss is the usage of a plasma mirror [11.2371]. Because the laser has to be focused anyway a perfectly transmitting dielectric medium is placed near the focus of the beam. The leading edge of the pulse is transmitted until the intensity reaches the ionization threshold. At this step a plasma is generated with increasing electron density. The plasma occurs on a time scale that does not allow it to expand. If the plasma frequency matches the laser frequency this plasma acts as a perfect mirror and the main pulse is reflected to the target. With a single plasma mirror the contrast ratio for petawatt-class lasers can be improved by factors of about 100 [11.2321].

Experiments with lasers at ultrahigh intensities require the focusing of a high-peak-power laser onto a very small spot. Phase distortions in the beam line can increase the minimum spot size in the focal plane considerably. Adaptive mirrors are used to correct phase fronts [11.2372]. Closed-loop systems allow near-diffraction-limited focusing of ultrashort pulses [11.2373, 2374]. These techniques today allow intensities in the range of $10^{20}\,\mathrm{W/cm^2}$ with terawatt and petawatt laser systems.

11.13.2 Relativistic Optics and Laser Particle Acceleration

The interaction of light and matter at intensities of $10^{20}\,\mathrm{W/cm^2}$ changes considerably when compared to classical, even classical nonlinear optics. At intensities of 10^{13}–$10^{15}\,\mathrm{W/cm^2}$ matter becomes ionized and the high intensity laser pulse interacts with a dynamically evolving plasma where the dominant mechanism for the interaction of light and matter is the interaction with free electrons.

In classical optics the interaction of light and matter is described in the following way: the electric field of an electromagnetic wave exerts a force on the bound or free electrons, which then oscillate with the frequency of the wave. The dependence of the oscillating polarization induced in the material by the motion of the electrons on the driving electric field then yields the linear and nonlinear optical constants of the material. Although this picture is inherently classical it also provides the general idea of a quantum-mechanical description of light–matter interaction.

This classical description of light–matter interaction is based on two assumptions, which are valid for sufficiently low light intensities:

1. The force exerted on the electrons by the magnetic field of the electromagnetic wave may be neglected.
2. The speed of the oscillating motion of the electron is small compared to the speed of light.

The breakdown of these two approximations marks the onset of relativistic optics, which is based on a fully relativistic description of the interaction of an electromagnetic wave with matter.

Relativistic Motion of an Electron in an Electromagnetic Wave

We first consider the equation of motion of a free electron in the field of an electromagnetic wave

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\gamma m\dot{\boldsymbol{r}}\right) = -e\left(\boldsymbol{E}+\dot{\boldsymbol{r}}\times\boldsymbol{B}\right), \tag{11.240}$$

where t is the time, m the electron rest mass, $\dot{\boldsymbol{r}}$ the velocity of the electron, e the elementary charge, $\boldsymbol{E}$ the electric, $\boldsymbol{B}$ the magnetic field of the electromagnetic wave, and

$$\gamma = \left(1-\left|\dot{\boldsymbol{r}}\right|^2/c^2\right)^{-\frac{1}{2}},$$

where c is the speed of light in vacuum. For a plane electromagnetic wave of frequency ω and wavenumber $k=\omega/(c)$ propagating in the z-direction we insert $\boldsymbol{E}=\boldsymbol{E}_0\cos(\omega t-kz)$. Since $\nabla\times\boldsymbol{E}=-\partial\boldsymbol{B}/\partial t$ we obtain: $|\boldsymbol{B}|=|\boldsymbol{E}|/c$. Before solving (11.240) we introduce the normalized quantities: $\hat{t}=\omega t$, $\hat{z}=z\omega/c$, $\boldsymbol{\beta}=\dot{\boldsymbol{r}}/c$ and $a_0=eE_0/(m\omega c)$. Then we rewrite (11.240) in components assuming linear polarization of the electric field in the x-direction

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}\hat{t}}\left(\gamma\beta_x\right) &= a_0\left(1-\beta_z\right)\cos\left(\hat{t}-\hat{z}\right),\\
\frac{\mathrm{d}}{\mathrm{d}\hat{t}}\left(\gamma\beta_y\right) &= 0,\\
\frac{\mathrm{d}}{\mathrm{d}\hat{t}}\left(\gamma\beta_z\right) &= a_0\beta_x\cos\left(\hat{t}-\hat{z}\right).
\end{aligned} \tag{11.241}$$

Although (11.241) may be solved for more-general initial conditions we give here the solution for an electron

initially at rest in the origin of our coordinate system, i. e., $\boldsymbol{r}(0) = 0$ and $\dot{\boldsymbol{r}}(0) = 0$, with the phase parameter $\Theta = \hat{t} - \hat{z}$

$$\begin{aligned} \hat{x} &= a_0\,(1 - \cos\Theta)\,, \\ \hat{y} &= 0\,, \\ \hat{z} &= \frac{a_0^2}{4}\left(\Theta - \frac{1}{2}\sin 2\Theta\right), \text{ and} \\ \gamma^2 &= 1 + \frac{a_0^2}{2}\sin^2\Theta\,. \end{aligned} \tag{11.242}$$

The motion of the electron is displayed in Fig. 11.269 in two different coordinate systems:

1. The laboratory frame
2. The *average rest frame* of the electron, which is a coordinate system co-moving with the electron in the $\hat{z}'$-direction, where the coordinate $\hat{z}'$ is given by $\hat{z}' = \hat{z} - a_0^2/4\Theta$.

It is immediately apparent that the motion of the electron in the fully relativistic case is quite different from the classical picture, where a solution of (11.240) is obtained for $\gamma = 1$ and $\boldsymbol{B} = 0$.

The electron oscillates, as in the classical case, periodically in the $\tilde{x}$-direction, the direction of polarization of the oscillating electric field. However, unlike in the classical case the electron is also accelerated in the $\hat{z}$-direction, the propagation direction of the electromagnetic wave. The magnitude of the electron motion is governed by the parameter a_0, the dimensionless electric field strength [11.2375]. In the classical picture $\gamma = 1$, $\boldsymbol{B} = 0$ which of course becomes incorrect at high velocities; the condition $a_0 = 1$ would correspond to an electron that acquires a maximum oscillation velocity of $\dot{\boldsymbol{r}} = c$. The condition $a_0 \ll 1$, therefore corresponds to the classical case of $|\dot{\boldsymbol{r}}| \ll c$ while $a_0 \gg 1$ describes the extreme relativistic motion of the electron. In practical units a_0 is given by

$$a_0^2 = \frac{I\lambda^2}{1.37 \times 10^{18}\,\mathrm{W\,cm^{-2}\,\mu m^2}} \tag{11.243}$$

where I is the light intensity and λ its wavelength. For optical wavelength where $\lambda \approx 1\,\mu\mathrm{m}$ intensities above $I \approx 10^{18}\,\mathrm{W/cm^2}$ are therefore called relativistic intensities. In the extreme relativistic case $a_0 \gg 1$ the distance the electron travels in $\hat{z}$-direction during one electric field oscillation is much larger than its excursion in the $\hat{x}$-direction, and a complete reversal of the conditions found in the weakly relativistic case $a_0 \leq 1$ occurs. The acceleration of electrons in the propagation direction of

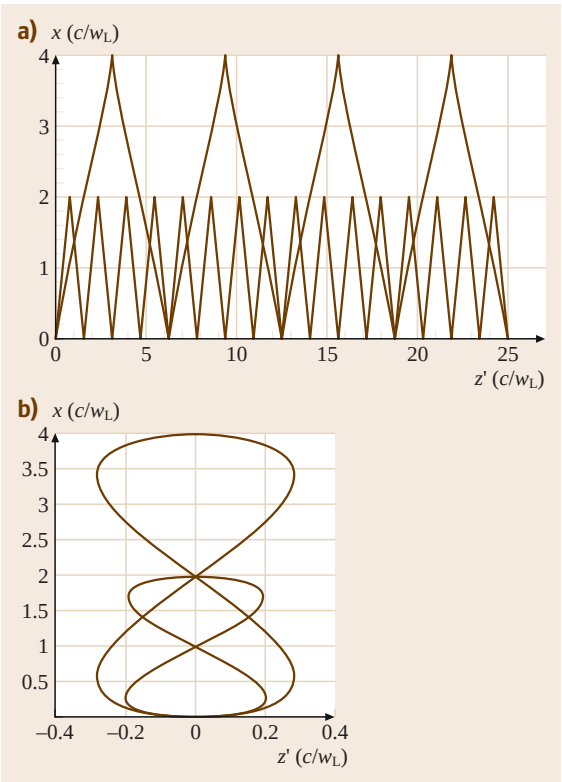

Fig. 11.269 **(a)** Trajectories of a free electron in a traveling electromagnetic wave for different laser field strengths $a_0 = 1$ and $a_0 = 2$ calculated for the initial conditions $\theta_{\mathrm{in}} = 0$ and $\beta_{z0} = 0$ in the laboratory frame. **(b)** The trajectories in the moving frame of the electron (indicated by the *primed coordinate*) exhibit the characteristic figure-of-eight movement. Laser field strength and initial conditions corresponding to **(a)** were used

the electromagnetic wave appears to be in contradiction to the well-known fact derived from energy and momentum conversation that free photons cannot accelerate free electrons. In fact if a light pulse is considered the electron acquires kinetic energy in the rising part of the pulse and looses it again to the electromagnetic wave in the falling part of the pulse. After the pulse has left, the electron experiences a shift in the propagation direction of the pulse but has not acquired a net energy in agreement with the conservation laws for energy and momentum. If, however, the field of the electromagnetic wave is suddenly switched off while the electron moves in the propagation direction the electron cannot give its energy back to the field and maintains its energy acquired from the field. The switching of the field may be

achieved, i. e., by shielding the field in a steep plasma gradient or by a guiding channel.

The second interesting feature of the solution of the equation of motion (11.241) is the anharmonic oscillating motion of the electron in the $\hat{x}$- and $\hat{z}$-direction best seen in the co-moving frame (Fig. 11.269b). This means that the electron radiates not only at the frequency of the diving electromagnetic wave but also emits other frequencies. While for $a_0 \leq 1$ the spectrum contains essentially the even (polarized in the $\hat{z}$-direction) and odd (polarized in the $\hat{x}$-direction) harmonics, the spatial and spectral emission pattern becomes very complex for higher intensities ($a_0 \geq 1$). This phenomenon is called nonlinear Thomson scattering and has been observed experimentally.

The Ponderomotive Force

The total energy of the electrons driven by the electromagnetic field of a laser is given by

$$E(\boldsymbol{r}, t) = \gamma(\boldsymbol{r}, t) mc^2 \,. \tag{11.244}$$

Due to the dependence of γ on the electron velocity $|\dot{\boldsymbol{r}}|$ the energy will vary widely on the length scale of the laser wavelength and the time scale given by the laser frequency. If one is not interested in the fast, mostly oscillatory motion of the electrons one may average over time, yielding

$$\langle \gamma(r) \rangle = \sqrt{1 + \frac{a_0^2(\boldsymbol{r})}{2}} \,. \tag{11.245}$$

The slow spatial dependence indicated in $a_0^2(\boldsymbol{r})$ may, for example, be due to the intensity variation over the focus of the laser beam, which usually occurs over much larger length scales than a wavelength.

The spatial dependence of the time-averaged energy gives rise to a force called the ponderomotive force

$$\boldsymbol{F}_\mathrm{p} = -\nabla \langle E(\boldsymbol{r}) \rangle = -mc^2 \nabla \langle \gamma(r) \rangle \,. \tag{11.246}$$

This force will act on particles that oscillate in spatial regions where the laser intensity is high and push them into regions of lower laser intensity. It is instructive to consider the weakly relativistic limit of the ponderomotive force. With the definition of a_0 we find for $\langle \gamma \rangle - 1 \ll 1$

$$F_\mathrm{p} = -\frac{e^2}{4m\omega^2} \nabla E_0^2(\boldsymbol{r}) \,. \tag{11.247}$$

In the classical limit this constitutes the gradient of the time-averaged kinetic energy of the electron oscillating in the laser field [11.2376].

Another way to look at the ponderomotive force is to view regions of high laser intensity as regions of high electromagnetic energy density $W = \varepsilon_0 \boldsymbol{E}^2(\boldsymbol{r}, t)/2$, which represents a pressure pushing the electrons from regions of high pressure to those of low pressure.

The Optical Properties of a Relativistic Laser Plasma and Relativistic Channeling

When an intense laser pulse at relativistic intensities propagates through a gas consisting of atoms with low atomic number, such as hydrogen or helium, the rising part of the laser pulse fully ionizes the gas and the laser pulse interacts with a fully ionized plasma. For example helium is fully ionized already at an intensity of a few times $10^{16}\,\mathrm{W/cm^2}$ while relativistic intensities usually exceed $10^{18}\,\mathrm{W/cm^2}$. The dielectric constant of a fully ionized plasma is given by

$$\varepsilon_\mathrm{r} = 1 - \frac{\omega_\mathrm{p}^2}{\omega^2} \,, \tag{11.248}$$

where $\omega_\mathrm{p}^2 = e^2 n_\mathrm{e}/(\varepsilon_0 \gamma m)$ and n_e is the electron density.

Collisions have been neglected here which is a reasonable assumption for laser pulses of durations of less than 1 ps and electron densities of $n_\mathrm{e} \leq 10^{22}\,\mathrm{cm^{-3}}$. It should be noted that in a relativistic plasma the plasma frequency ω_p depends on γ and therefore on the laser intensity. The dielectric constant becomes negative for electron densities where the plasma frequency ω_p exceeds the laser frequency ω. In the nonrelativistic case ($\gamma = 1$) an critical electron density n_crit is defined through the condition $\omega_\mathrm{p}^2 = \omega^2$ yielding [11.2376]

$$n_\mathrm{crit} = \frac{\varepsilon_0 m \omega^2}{e^2} \,. \tag{11.249}$$

For electron densities $n_\mathrm{e} \geq n_\mathrm{crit}$ the plasma is called dense while it is underdense for $n_\mathrm{e} \leq n_\mathrm{crit}$. In practical units the critical electron density is given by $n_\mathrm{crit} = 1.1 \times 10^{21}\,(1\,\mu\mathrm{m}/\lambda)^2\,\mathrm{cm^{-3}}$. With this definition the dielectric constant may be rewritten

$$\varepsilon_\mathrm{r} = 1 - \frac{n_\mathrm{e}}{\gamma n_\mathrm{crit}} \,. \tag{11.250}$$

Electromagnetic radiation propagates in a medium where $\varepsilon_\mathrm{r} \geq 0$ and is reflected from a medium with $\varepsilon_\mathrm{r} \leq 0$. The condition for light propagation is therefore $n_\mathrm{e}/\gamma \leq n_\mathrm{crit}$.

The index of refraction of the plasma is given by $n = \sqrt{\varepsilon_\mathrm{r}}$. In an underdense plasma n is real and the laser pulse propagates. But n is a complicated function of intensity for two reasons:

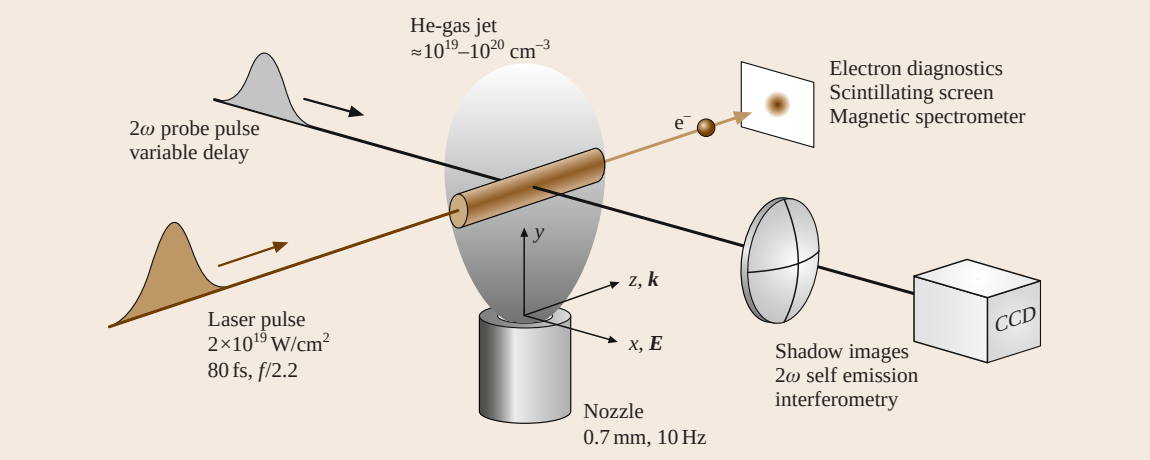

Fig. 11.270 Experimental setup. The main pulse is focused to an intensity of a few $19\,\mathrm{W/cm^2}$ into a pulsed He-gas jet, where a relativistic channel due to relativistic self-focusing is forming. By splitting and frequency doubling part of the main pulse a probe pulse is generated. This probe pulse is used for imaging and observing the laser–plasma interaction on a time scale determined by the probe pulse duration of $\approx 100\,\mathrm{fs}$. The electrons that are accelerated in the relativistic channel are characterized by magnetic spectroscopy and nuclear reactions

1. At the center of the propagating laser pulse the intensity is high. Therefore the ponderomotive force pushes the electrons away from the center and the electron density in the center decreases, increasing the index of refraction.
2. The remaining electrons in the center gain higher energies in the laser field than those sitting at the edges of the laser beam. This increases γ further and thus increases the index of refraction at the center of the laser beam.

This means that a relativistic laser pulse self-modulates the index of refraction in such a way that self-focusing of the laser occurs. As in other self-focusing phenomena known from nonlinear optics self-focusing is countered by diffraction and therefore self-focusing depends on a critical power rather than on intensity. A laser pulse interacting with a fully ionized plasma will therefore undergo self-focusing if its total power P exceeds the critical power P_{crit} [11.2377]

$$P \geq P_{\mathrm{crit}} = \frac{8\pi\varepsilon_0 m^2 c^5}{e^2}\frac{n_{\mathrm{crit}}}{n_{\mathrm{e}}} = 17.4\,\mathrm{GW}\frac{n_{\mathrm{crit}}}{n_{\mathrm{e}}}\,. \tag{11.251}$$

The dynamic equilibrium of defocusing because of diffraction and self-focusing due to nonlinear effects leads to a guiding effect for the high-intensity laser pulse in a plasma called relativistic channeling. This phenomenon has been observed experimentally. A typical experimental arrangement is shown in Fig. 11.270.

A Ti:sapphire laser ($\lambda = 800\,\mathrm{nm}$) with a total power of 8 TW is focused to an intensity of about $2\times10^{19}\,\mathrm{W/cm^2}$ into a helium gas jet from a nozzle with a very well-characterized gas density profile (Fig. 11.271).

Figure 11.271 shows the relativistic channel which extends over a length of about 300 μm, corresponding to about 15 Rayleigh lengths of the laser focusing optics. At the onset of the channel the electron density amounts to $5\times10^{19}\,\mathrm{cm^{-3}}$. The critical density is $1.7\times10^{21}\,\mathrm{cm^{-3}}$ at $\lambda = 800\,\mathrm{nm}$. Therefore the total laser power of 8 TW exceeds the critical power of $P_{\mathrm{crit}} \approx 0.6\,\mathrm{TW}$ obtained from (11.251) substantially and relativistic channeling is expected and observed. In addition a probe pulse at $\lambda = 400\,\mathrm{nm}$ was used to measure the electron density in the channel interferometrically (Fig. 11.270). The result shown in Fig. 11.272 gives the electron density profile across the channel at the onset of the channel. It is apparent that the electron density at the channel center is depressed, due to the expulsion of electrons because of the ponderomotive force. This result also provides direct evidence for the guiding structure of a relativistic channel.

Finally it should be noted that optics in the relativistic regime is always nonlinear. The index of refraction is always intensity dependent due to the ponderomotive force and the intensity dependence of the electron mass.

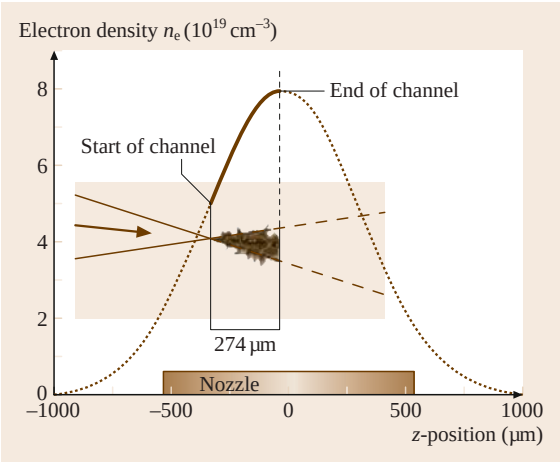

Fig. 11.271 The lateral plasma density profile above the nozzle has a Gaussian shape (*dotted line*). The density along the channel and its position is indicated by the *bold line*. The *inset* shows the corresponding observed channel of the same spatial region. The extension of the emission indicates a channel length of 274 μm, about 12 times the Rayleigh length of the laser. The relativistic channel starts near the steepest density gradient and ends close to the maximum density (grad $n_e = 0$)

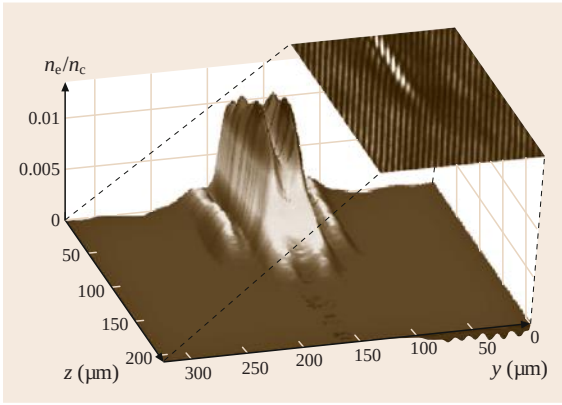

Fig. 11.272 Plasma density at the start of the channel determined by interferometry. The electron density in the walls of the channel rose up to values of $n_e(\text{wall}) = 6 \times 10^{19}$ cm^{-3}. The image in the *upper right corner* shows the interferogram from which the plasma density was obtained

Electron Acceleration

Since in the relativistic regime of laser–plasma interaction charged particles may be accelerated to high energies, it has been recognized for some time that laser plasmas are an ideal medium for high-field compact accelerators. The plasma as an ionized medium may sustain much higher fields than it is possible to generate with conventional accelerator technology, where material breakdown imposes a limit at less than 100 MV/m. Electric fields in the TV/m range may however be generated in laser plasmas.

In many experiments over the past two decades a variety of acceleration mechanisms have been identified. A selection of these mechanisms will briefly be described in the following with focus on schemes where only a single laser pulse is needed to accelerate initially resting electrons to relativistic energies. All these schemes have in common that a laser pulse is focused into a gas jet, generating an underdense plasma (Fig. 11.270).

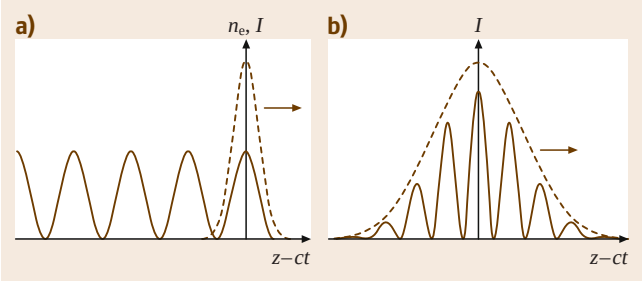

Fig. 11.273 **(a)** LWFA: a short laser pulse ($c\tau \leq p$) shown as a *dashed line* drives a plasma wave. **(b)** SM-LWFA: an initially long laser pulse (*dashed line*) breaks up into a train of shorter pulses that match the condition of LWFA and resonantly drive a plasma wave (after [11.2377])

Laser Wakefield Acceleration. When a relativistic laser pulse impinges on a plasma the ponderomotive force expels electrons in both the transverse and longitudinal directions. The electrons expelled from the laser pulse in the backward direction lead to a plasma wave called the laser wakefield (Fig. 11.273) [11.2378].

The plasma wave follows the driving laser pulse with a phase velocity determined by the laser pulse group velocity. The electric fields associated with the plasma wave are now longitudinal. An electron can *ride* on the plasma wave and be accelerated to relativistic energies in the direction of laser propagation. This process is called laser wakefield acceleration (LWFA).

This process is most efficient when the laser pulse length $c\tau$, where τ is the pulse duration, is shorter than the plasma wavelength $\lambda_p = 2\pi c/\omega_p$.

This condition is depicted in Fig. 11.273a. When a large number of electrons acquire a velocity close to

the phase velocity of the plasma wave, wave-breaking occurs. The fast electrons are *surfing* on the wake of the plasma wave.

Self-Modulated Laser Wakefield Acceleration. If the laser pulse length is longer than the plasma wavelength $c\tau \geq \lambda_p$ the laser pulse undergoes a self-modulation instability. The leading edge of the laser pulse drives a plasma wave. The electron density modulation of the plasma wave in turn represents a periodic modulation of the refractive index. It acts on the long laser pulse such that the pulse is self-modulated and breaks up into a train of short pulses (Fig. 11.273b). These shorter pulses now match the conditions for LWFA and can resonantly drive a plasma wave. This self-modulated laser wakefield acceleration (SM-LWFA) is not as efficient as pure LWFA, but still high-energy even quasi-monoenergetic electron beams may be generated.

Direct Laser Acceleration. Another acceleration process which is quite different in nature to wakefield acceleration is direct laser acceleration (DLA) which is closely related to the formation of a relativistic channel. The ponderomotive force expels electrons from the laser beam axis and generates a radial quasistatic electric field. Electrons that are accelerated along the laser propagation generate an azimuthal magnetic field. The combination of these two fields results in an effective potential well for relativistic electrons. Electrons trapped in this well will oscillate at the frequency $\omega_\beta = \omega_p/(2\sqrt{\gamma})$, the betatron frequency. If the trapped electron is moving fast enough along the laser propagation, the laser oscillations may be in phase with the betatron oscillations in the frame of the electron.

In this case, an efficient energy coupling is possible. The energy gained by the electron in this process directly results from the laser field and therefore the name direct laser acceleration is appropriate.

Bubble Acceleration. The most important regime of laser wakefield acceleration is *bubble acceleration*, which was proposed in 2002 on the basis of particle-in-cell (PIC) simulations [11.2379]. Short ($\tau \leq 7$ fs) and intense ($a_0 \geq 1$) laser pulses were predicted to produce quasi-monoenergetic electrons with energies in the GeV range.

The ponderomotive force also plays an important role for this acceleration mechanism. In a frame moving with an intensive laser pulse propagating through a plasma the electrons are expelled from the center of the pulse in both the longitudinal and transverse directions. It turns out that behind the laser pulse an electron density depression, called a bubble, is generated and electrons the stream around this bubble and enter it again from the back side. In this way a strong electric field in longitudinal direction reaching TV/m is generated, which leads to efficient electron acceleration.

Experiments. Numerous laser acceleration experiments have been carried out, mostly using experimental setups like the one shown in Fig. 11.270. Initially always quasi-exponential electron spectra were obtained with electron temperatures that follow the scaling law

$$kT_e \approx mc^2 \left(\sqrt{1 + \frac{a_0^2}{2}} - 1 \right) , \qquad (11.252)$$

which corresponds to the kinetic energy of the electron in the laser field. These exponential spectra are not only observed in underdense plasmas but also in the overdense plasmas encountered in laser–solid interactions [11.2380]. For a typical intensity of $I = 10^{20}\,\mathrm{W/cm^2}$ and $\lambda = 1\,\mu\mathrm{m}$, $a_0 = 8.5$ we obtain $kT_e \approx 2.6\,\mathrm{MeV}$ from (11.252).

It is, however, also possible to generate monoenergetic electron spectra. As predicted by numerical simulations the bubble regime may be reached for high-power, gently focused laser pulses of short pulse duration. Although the requirements of the pure bubble regime have not yet quite been reached experimentally the experiments show that in the transition regime between LWFA and bubble acceleration monoenergetic electron spectra may be generated [11.2381–2383]. A typical early result is shown in Fig. 11.274.

In the last decade this approach has been developed both experimentally and theoretically. For the guidance of the laser pulse in the plasma not only relativistic self-channeling of the laser pulse is used, but it is supported by additional guiding in an artificially created plasma channel in a discharge tube. In this way much longer acceleration lengths for the electrons beam possible and electron energies of about 1 GeV have been generated [11.2384].

In a recent experiment [11.2385] self guiding of the laser beam at very low gas densities of $\gg 10^{18}\,\mathrm{cm^{-3}}$ lead to electron injection into the bubble in a He/CO_2 gas mixture. In this way a 1.45 GeV electron beam was generated.

Like in conventional accelerators it will be important to build successive stages of laser wakefield accelerators to reach ultimatively the TeV energy

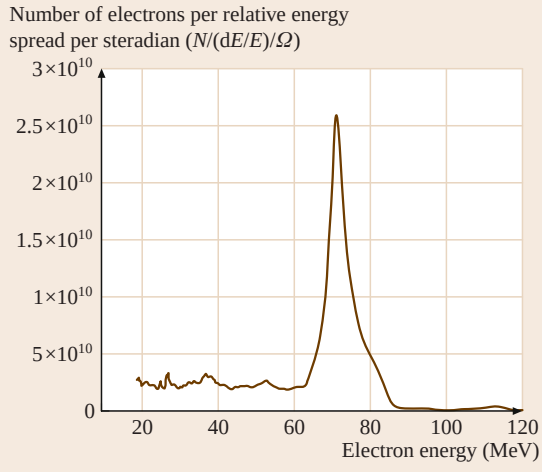

Fig. 11.274 Monoenergetic electron spectrum generated in an experimental setup similar to the one shown in Fig. 11.264 (after [11.2383])

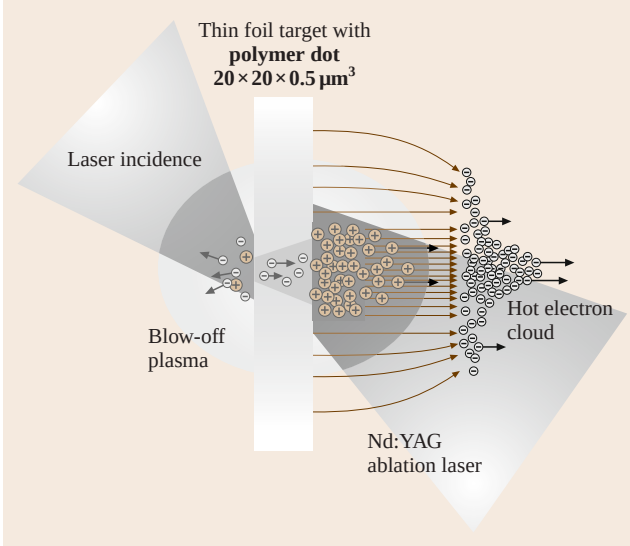
regime. First progress in this direction was recently reported [11.2386], where a two-stage electron accelerator was demonstrated which reached a total energy of 0.5 GeV at a relative energy spread of about 5%.

Ion Acceleration

Relativistic laser–matter interaction also leads to the generation of monoenergetic beam of ions of MeV energies by a mechanism quite different from the mechanism involved in electron acceleration.



As discussed earlier the interaction of an intense light field with matter yields the generation of a hot plasma and the subsequent acceleration of electrons up to relativistic energies. Protons and ions are accelerated by a well-controlled mechanism known as *target normal sheath acceleration* (TNSA) following the initial electron acceleration (Fig. 11.275). Fast electrons are accelerated by an intense laser pulse (intensity $I \geq 10^{19}\,W/cm^2$) from the surface of a thin metal foil in the forward direction. They penetrate the foil and ionize atoms along their paths. Within about a picosecond, those electrons leaving the target at the rear surface (that is, the back surface with respect to the laser irradiation) build up a quasistatic electric field. The field acts normally to the target surface, has cylindrical symmetry and decreases in the transverse direction. Owing to the ultrashort duration of the electron bunch and its high charge, this field may reach values of several TV/m close to the axis and thus the potential can attain several tens of MeV. Protons and positively charged ions present on the back surface of the foil may be accelerated by this field until they compensate the electron charge. In most cases, the origin of these parasitic protons has been identified to be a hydrocarbon contamination layer on the target surface.

As the duration of the acceleration is ultrashort and the protons (as well as the ions) are at rest before acceleration, comprising a very small phase-space volume, the transverse emittance of the proton beam reaches values as low as a few 10^{-3} mm mrad for 10 MeV protons. However, laser-accelerated ion beams still show an energy spectrum exhibiting a quasi-exponential shape with a distinct cut-off energy. This can be explained by the inhomogeneous distribution of electrons in the sheath, which causes an accelerating field that is inhomogeneous in the transverse direction. For a plane and unstructured target, the transverse dimension of the

Fig. 11.275 Laser acceleration of protons from the back side of a microstructured target. A terawatt (TW) laser pulse is focused onto the front side of the target foil, where it generates a blow-off plasma and subsequently accelerates electrons. The electrons penetrate the foil, ionize hydrogen and other atoms at the back surface and set up a Debye sheath. The inhomogeneous distribution of the hot electron cloud causes a transversely inhomogeneous accelerating field (target normal sheath acceleration (TNSA)). Applying a small hydrogen-rich dot on the back surface enhances the proton yield in the central part of the accelerating field, where it is nearly homogenous. These protons constitute the quasi-monoenergetic bunch ◀

electric field and hence the source size of the accelerated protons is much larger than the laser's focal spot. Therefore, different parasitic protons experience a range of potentials, resulting in a broad distribution of energies.

Following this understanding of the mechanism of laser acceleration of protons, it was pointed out that the resulting proton energy spectrum has a strong correlation to the spatial distribution of the protons on the target surface. In order to generate high-quality proton beams with monoenergetic features, a bilayered, microstructured target, consisting of a thin high-Z metal foil and a small proton-rich dot on the back surface was proposed. The transverse dimension of such dots is smaller than that of the acceleration sheath, and hence the protons will only be subject to the central – that is, homogeneous – part of the acceleration field. In this configuration, the protons all experience the same electric field and are accelerated in the same potential (Fig. 11.275). The resulting proton beam has a spectrum with a strong monoenergetic peak [11.2387].

Recent experiments with a 10 TW, 600 mJ laser showed that in this way quasi-monoenergetic proton beams containing 10^8 protons with energies of a few MeV and a relative width of $\Delta E/E \approx 10\%$ and a total charge of about 100 pC were generated.

In a different experiment quasi-monoenergetic carbon ions of 4 MeV energy were generated from a very thin carbon layer on a metal target.

Applications and Future Developments

Relativistic optics leads to laser particle accelerators that are considerably more compact than classical accelerators. Presently laser accelerators reach maximum energies for monoenergetic electron beams exceeding 1 GeV and almost 100 MeV for ion beams with a total charge of up to 1 nC per bunch. The scaling for both electron and ion acceleration with laser and target parameters appears to be sufficiently well understood that electron energies significantly exceeding 1 GeV and ion energies of a few hundred MeV in a single acceleration stage appear to be possible in the near future. There are however at least two challenges laser accelerators that have to overcome before widespread applications will become attractive.

In order to reach energies in the TeV range multistaging of both electron and ion accelerators appears necessary. For laser electron accelerators first staging experiments have been tried and were partially successful. Although energy, beam quality and charge per bunch are already attractive for low-energy applications of laser accelerators their average power presently remains orders of magnitude below the average power of conventional accelerators. This is solely due to limitations in laser technology and may be overcome in the future when high-average-power high-intensity lasers become available.

Laser accelerators have already been used for a number of demonstration experiments. Low-energy nuclear reactions have been induced using high-intensity lasers [11.2377] and nuclear transmutation scenarios employing lasers have been discussed [11.2388]. Laser-generated ion beams carry enough dose for radiation therapy using ion beams, a very promising application because the average power of a laser accelerator is already sufficient for this innovative method of cancer treatment. There are now several programs worldwide pursuing this technological approach. First experiments irradiating human cancer cells with laser accelerated protons show that the biological effectiveness of such beams is not significantly different from ion beams from classical ion accelerators although laser accelerators operate in a quite different regime of peak dose power as compared to conventional accelerators [11.2389].

With ever-increasing laser intensities other areas of physics such as gravitational physics, elementary particle physics or nonlinear quantum electrodynamics (QED) effects [11.2377] also come into the focus of high-intensity lasers.

11.14 Frequency Stabilization of Lasers

Soon after the development of the first HeNe laser, it was realized that the radiation of a continuous-wave laser would be ideally suited as a measurement tool, provided its frequency was stable and reproducible. Applications of frequency-stabilized lasers include high-resolution laser spectroscopy, quantum optics, optical frequency standards, the determination of fundamental constants, and the detection of gravitational waves. In these various cases, the requirements on frequency-stabilized lasers are quite different. For example, optical frequency standards and optical clocks need the smallest possible uncertainty in the knowledge of the absolute laser frequency, whereas gravity-wave detectors need lasers of extremely low frequency noise

while the absolute laser frequency is less important. Hence, different stabilization methods have been developed to address the various tasks. The purpose of this chapter is to review the general methods of laser frequency stabilization and to describe some representative examples of frequency-stabilized lasers. The radiations of a variety of stabilized lasers are recommended as optical reference frequencies [11.2390–2392].

Basically, the frequency of any laser is determined within the bandwidth of its amplifying medium by the optical length of the resonator. This optical length in turn is a function not only of its actual geometrical length but also of the refractive index of the gain medium itself, which may depend on several different parameters. The width of the gain profile may vary between a few $10^{-6}\nu$ for gas lasers up to approximately 10% for, e.g., dye lasers or laser diodes. Different types of lasers have different noise characteristics. In most cases, the dominant frequency noise is of technical nature and is far above the Schawlow–Townes limit [11.2393]. Since such technical frequency fluctuations are relatively slow they can be controlled by a suitable electronic servo system even if the frequency excursions of the free-running laser are large. Different laser types and the specific requirements on these lasers have led to a variety of stabilization methods. Within the limited space of this article, it is impossible to present a comprehensive and detailed description of all these stabilization schemes. Hence, we concentrate on the description of the basic principles of laser frequency stabilization. For a deeper understanding, the reader is encouraged to study the references given in this article as well as textbooks on laser spectroscopy and optical clocks [11.2394–2397].

We start with a brief discussion of the terms characterizing the frequency behavior of a laser. These are noise, stability, line width, reproducibility, and the uncertainty of the laser frequency. Section 11.14.2 describes the basics of laser frequency stabilization. Examples of stabilized lasers are presented in Sect. 11.14.3. Section 11.14.4 explains a universal method of optical frequency measurements by means of mode-locked femtosecond lasers.

11.14.1 Characterization of Noise, Stability, Linewidth, Reproducibility, and Uncertainty of the Laser Frequency

Noise, stability, linewidth, reproducibility, and the uncertainty of the frequency are important parameters of any frequency-stabilized laser. In general, the laser frequency fluctuates about a mean value which itself may drift and walk randomly. Such variations may be caused, e.g., by changes in the temperature, air pressure, vibrations, acoustics, or by fluctuations within the active laser medium itself.

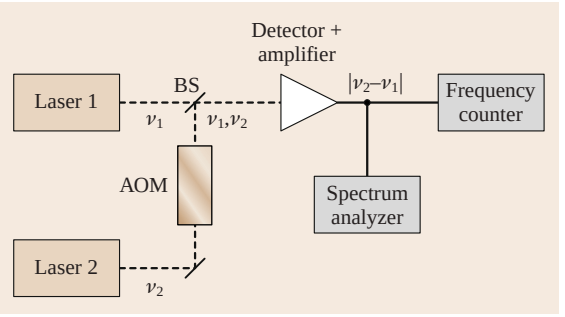


Fig. 11.276 Schematics of a beat-frequency measurement

The variations in the laser frequency can be investigated, e.g., by measuring the beat frequency $\nu_B = |\nu_1 - \nu_2|$ between two identical but independently stabilized lasers 1 and 2 (Fig. 11.276). For this purpose, the beams of two lasers are coaxially combined by a beam splitter and focused onto a fast photodetector. The *beat frequency* ν_B shows up as an oscillation in the power of the combined laser beams. The photodetector transforms it to an oscillation of the photocurrent, provided ν_B is small enough that it can be processed by state-of-the-art electronics. To avoid any zero crossings it may be advantageous to shift the frequency of one of the two laser beams, e.g., by an acousto-optical modulator (AOM).

Frequency fluctuations of a laser can be measured in both the frequency and time domain. Measurements in the frequency domain are often used at higher fluctuation (Fourier) frequencies whereas slower-frequency fluctuations and drifts can be measured conveniently in the time domain (see below).

Spectral Density of Frequency Noise

In the frequency domain, fluctuations $\delta\nu$ at the Fourier frequency f can be detected by a frequency discriminator, which converts frequency fluctuations to proportional voltage fluctuations. Since the noise components are not correlated, it is convenient to describe the fluctuations $\delta\nu(f)$ by the mean square $\langle\delta\nu(f)^2\rangle$, which occurs within a bandwidth B at the Fourier frequency f. This value is equivalent to the spectral noise power. The power spectral density is then defined as $S_f = \langle\delta\nu^2\rangle/B$ and the integration of S_f over B results in the total power of the frequency noise within the band-

width B. For the *relative* power spectral density S_y we obtain $S_y = \langle(\delta\nu/\nu)^2\rangle/B$.

To a good approximation, the frequency noise of any oscillator can be modeled by a power series of the Fourier frequency

$$S_y = \sum_{\alpha=-2}^{2} c_\alpha f^\alpha \,. \tag{11.253}$$

Depending on the exponent α the five terms of (11.253) describe:

- A random frequency walk for $\alpha = -2$
- Flicker $(1/f)$ frequency noise for $\alpha = -1$
- White frequency noise for $\alpha = 0$
- Flicker $(1/f)$ phase noise for $\alpha = 1$
- White phase noise for $\alpha = 2$.

Superimposed on the noise given in (11.253), we may also find peculiarities in the noise spectrum that are generated by noise sources specific to the individual laser. Such noise may be generated, e.g., by environmental sources such as the excitation of mechanical resonances in the laser resonator, by instabilities of the mechanical setup, or by fluctuations in the refractive index of the laser medium. Furthermore, the laser frequency is sensitive to optical feedback and careful isolation of the laser system from back-scattered light is important for successful operation of stabilized lasers. Usually, the different noise components show up at different Fourier frequencies. Hence, the detection of these noise components helps us to identify the various noise sources and to reduce their influence. In addition, the knowledge of the frequency noise spectrum of a free-running laser is also important for the design and optimization of the frequency control system.

The noise spectra of various types of lasers may be quite different. For example, most of the frequency noise in gas lasers such as HeNe or CO_2 lasers occurs at low Fourier frequencies. It is generated in part by mechanical instabilities of the laser setup. The corresponding frequency excursions $\delta\nu$ may amount to a few MHz at Fourier frequencies up to about 10 kHz. In addition, random-walk and flicker $(1/f)$ frequency noise shows up at these low frequencies. Neglecting further possible noise sources originating from plasma resonances of the discharge, the noise spectrum at higher Fourier frequencies may be approximated by white frequency noise. In tunable CW dye lasers, on the other hand, the frequency noise is much larger than in gas lasers. It is generated mostly by variations in the thickness and the refractive index of the dye jet, which flows at high speed through the small active volume of the laser. Hence, rather strong frequency fluctuations are observed at Fourier frequencies around 50 kHz. At higher Fourier frequencies the influence of the dye jet decreases and hence the noise also decreases, eventually reaching the photon shot-noise level.

Allan Standard Deviation

Slow variations, in particular drifts and random walk of the laser frequency can be measured conveniently in the time domain by counting the mean frequency ν within a time interval τ. Such measurements are advantageous if changes in the frequency within time intervals between seconds and several hours are of interest. The relative frequency instability in the time domain is characterized by the Allan deviation [11.2398, 2399]

$$\sigma_y(\tau) = \frac{1}{\nu}\left[\frac{1}{2(N-1)}\sum_{n=1}^{N-1}(\nu_{n+1}-\nu_n)^2\right]^{1/2}, \tag{11.254}$$

where the root mean square of the difference between two consecutive frequency measurements $(\nu_{n+1}-\nu_n)$ is used as a measure of the stability. The frequency values ν_{n+1} in (11.254)

$$\nu_{n+1} = \frac{1}{\tau}\int_{i=n\tau}^{(n+1)\tau} \nu_i(t)\,\mathrm{d}t \tag{11.255}$$

represent the mean frequency averaged during the nth interval of duration τ. Since it is difficult to measure the optical frequency directly, it can be down-converted by beating the laser radiation against the radiation of a second laser such that the beat frequency arrives in the radio-frequency range, where it can be counted directly. In this case, the measurement contains the instabilities of both lasers. If the two lasers are identical but independent, we can assume that both lasers contribute equally to the standard deviation and consequently, the measured value corresponds to $\sqrt{2}$ times the Allan deviation $\sigma_y(\tau)$ of a single laser.

The dependence of $\sigma_y(\tau)$ on the averaging time τ contains information about the frequency noise spectrum of the laser. If the relative power spectral density of the noise S_y is known, $\sigma_y(\tau)$ can be calculated by the relation [11.2399]

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)\frac{(\sin\pi f\tau)^4}{(\pi f\tau)^2}\,\mathrm{d}f \,. \tag{11.256}$$

Table 11.58 Dependence of the Allan deviation on τ for the different noise processes discussed in (11.258)

Noise category	α	β	$\sigma_y^2(2,\tau)$
White frequency noise	0	−1	$\propto 1/\tau$
White phase noise	2	−2	$\propto 1/\tau^2$
$1/f$ (frequency noise)	−1	0	Constant
$1/f$ (phase noise)	1	−2	$\propto 1/\tau^2$
Random frequency noise	−2	1	$\propto \tau$

For the different models of the noise process given in (11.253), we can describe the Allan variance $\sigma_y^2(\tau)$ by the relation

$$\sigma_y^2(\tau) = d_\alpha \tau^\beta \,, \tag{11.257}$$

where β is determined by the relation [11.2399]

$$\beta = \begin{cases} -\alpha - 1 & \text{for} \quad \alpha \le 1 \\ -2 & \text{for} \quad \alpha > 1 \end{cases} \tag{11.258}$$

and d_α is a constant. The dependence of $\sigma_y^2(\tau)$ on τ is listed for the noise processes of (11.258) in Table 11.58.

Of course, any frequency modulation will also show up in the Allan standard deviation. In the case that the gate time τ is an integer multiple of the modulation period $\tau_m = 1/f_m$, where f_m is the modulation frequency, the influence of the modulation is eliminated. It will be maximum for $\tau_m = (2n+1)/(2f_m)$. With increasing integration times τ, the influence of the modulation washes out and can be neglected, eventually.

As a result of (11.257), we find that the noise process can be estimated from the slope of a log–log $\sigma_y(\tau)$ plot. For example, in a HeNe laser that is frequency stabilized to an absorption line of molecular iodine, $\sigma_y(\tau)$ decreases in a wide range of τ with the square root of τ corresponding to a slope of $-1/2$, (Fig. 11.277) indicating white frequency noise within the corresponding time interval τ. At longer integration times, $\sigma_y(\tau)$ flattens out due to flicker frequency noise and in some cases eventually increases again due to drifts and random frequency walks. For practical applications, the $\sigma_y(\tau)$ plot indicates the minimum integration time τ necessary to achieve a given statistical frequency uncertainty.

Linewidth of Laser Radiation

In incoherent light sources such as spectral lamps, where the radiation consists of uncorrelated photons emitted within a certain narrow frequency band, the linewidth is determined by a superposition of the natural width of the transition and Doppler broadening. It can

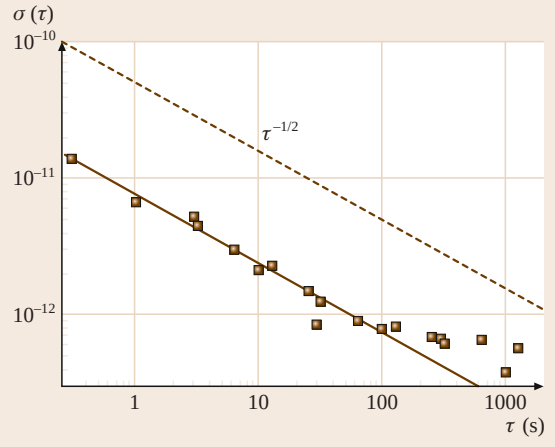

Fig. 11.277 Allan deviation $\sigma_y(\tau)$ versus integration time τ of an iodine-stabilized HeNe laser

be measured, for example, by a high-resolution scanning Fabry–Pérot interferometer. In the case of laser radiation, the line broadening is caused by frequency fluctuations of the continuously emitted coherent laser radiation. The frequency fluctuations generate noise sidebands that cause broadening of the laser spectrum. The linewidth is then determined by the size and spectral extension of these sidebands. In the case of pure harmonic phase modulation, the field E of the laser radiation is given by the relation

$$\begin{aligned} E(t) &= E \sin\left[\Omega_0 t + \delta\Phi \sin(\omega t)\right] \\ &= E\Big\{ J_0(\delta\Phi)\sin(\Omega_0 t) \\ &\quad + \sum_{n=1}^{\infty} J_n(\delta\Phi)\exp[\mathrm{i}(\Omega_0 + n\omega)t] \\ &\quad + \sum_{n=1}^{\infty} J_n(-\delta\Phi)\exp[\mathrm{i}(\Omega_0 - n\omega)t]\Big\} \,, \end{aligned} \tag{11.259}$$

where $\Omega_0 = 2\pi\nu_0$ and $\omega = 2\pi f$ represent the carrier and modulation frequency, respectively; $\delta\Phi = \delta\nu/f$ is the modulation index with $\delta\nu$ the amplitude of the frequency deviation. The amplitude of the nth sideband given by the nth order of the Bessel function $J_n(\delta\Phi)$ decreases strongly with n for $n > \delta\Phi$. Basically, we can distinguish between the two limiting cases of:

1. Large frequency fluctuations $\delta\nu$ at low Fourier frequencies f

2. Small, fast frequency fluctuations δf in a broad band.

Case 1 is frequently observed with laser resonators, which pick up environmental acoustic or mechanical noise. The mean amplitudes $\langle \delta\nu^2 \rangle^{1/2}$ of such fluctuations may be in the range between a few 10 kHz up to several megahertz, whereas they usually occur at Fourier frequencies in a range below 1 kHz. Hence the modulation index $\delta\Phi \gg 1$. In this case, the linewidth is given by [11.2400]

$$\Delta\nu_{\mathrm{FWHM}} = \left[8\ln(2)\langle\delta\nu^2\rangle\right]^{1/2} \cong 2.355\langle\delta\nu^2\rangle^{1/2} \quad (11.260)$$

close to the frequency excursions between the peaks.

If the servo gain of the frequency stabilization is high enough to reduce the frequency fluctuations at low Fourier frequencies, we may observe case 2. Under the assumption that we can neglect frequency drifts and frequency changes at very low Fourier frequencies, we arrive at frequency fluctuations $(\langle\delta\nu\rangle^2)^{1/2} \ll B$ and correspondingly to a small modulation index. In this case, only the amplitudes of the first-order sidebands $J_n(\delta\Phi)$ and $J_{-n}(\delta\Phi)$ contribute significantly to the linewidth. If the spectral density S_f is constant, the line profile is Lorentzian and the linewidth is given by the relation [11.2400]

$$\Delta\nu_{\mathrm{FWHM}} = \pi S_\mathrm{f} \,. \quad (11.261)$$

Frequency Reproducibility and Uncertainty of Laser Radiation

Whenever the laser frequency is needed as a precise reference, knowledge of the *reproducibility* and *uncertainty* is essential. Since the frequency of the stabilized laser depends on various operational and environmental parameters it is necessary to analyze this dependence and to control these parameters carefully. The *frequency reproducibility* is a measure of the scatter in the frequency values of an ensemble of differently designed laser systems of the same kind, developed for example in different laboratories. The reproducibility can then be investigated by frequency inter-comparisons between such differently designed lasers. Alternatively, the term *frequency reproducibility* is also used to describe the scatter in the frequency of a single laser caused by the uncertainty in the precise control and optimization of the operation parameters.

The *frequency uncertainty* is a measure of how accurately we can realize the reference frequency and determine its value. Basically, the total uncertainty contains two contributions. The first represents the uncertainty to which the transition frequency of an unperturbed atomic or molecular absorber at rest can be realized. This part contains all values in the uncertainty of frequency shifts caused by environmental and/or operational conditions. Such shifts may be generated, e.g., by a residual Doppler effect, by collisions, and by external fields. The second term in the total uncertainty is linked to the determination of the frequency value. Such frequency measurements have to be referenced to the primary standard of time and frequency, the Cs atomic clock. If the frequency measurement is phase-coherent, the measurement itself does not contribute to the total uncertainty. Under this condition, the uncertainty of the optical frequency is determined only by the uncertainty of the standard itself and that of the Cs reference.

11.14.2 Basics of Laser Frequency Stabilization

In any active frequency control system, the laser frequency is servo controlled to a reference frequency. This may be provided by an eigenfrequency of a stable optical (Fabry–Pérot) resonator, by the gain profile of the laser itself, or by a suitable atomic or molecular transition. The first case has the advantage that it provides a good signal-to-noise ratio, allowing a fast servo lock. However, since the laser frequency is coupled to the length of an artifact, it may change in time. Stabilization to such artifacts is often applied as an intermediate step to reduce the linewidth of the laser emission and to allow for high spectral resolution. In a second step, the frequency can then be stabilized to an absolute frequency reference provided by a suitable atomic or molecular absorption line.

The following sections give an introduction to basic methods of laser frequency stabilization. We start with the generation of the error signal and review four prominent examples. The first two methods – the *side-of-the-fringe stabilization* and the *phase-modulation (Pound–Drever–Hall) technique* are used to stabilize the laser frequency to a resonance of a stable optical cavity. Absolute frequency stabilization to an atomic reference is then reviewed and the fundamentals of the electronic servo control system are described.

Generation of the Error Signal

Basically, the frequency stabilization of a laser converts the frequency deviation $\delta\nu = \nu_\mathrm{l} - \nu_0$ between the laser frequency ν_l and the reference frequency ν_0 to an

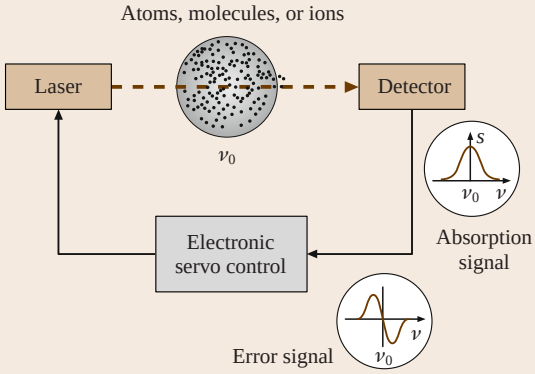

Fig. 11.278 Schematic of a laser frequency stabilization to the center of an absorption line

error signal that is proportional to $\delta\nu$. This signal is amplified by a servo amplifier and used to control the laser frequency such that the error signal vanishes. Figure 11.278 shows the basic scheme of a stabilization to an atomic reference frequency.

Side-of-the-Fringe Stabilization. In commercial stabilized lasers such as tunable dye lasers, it is a well-established practice to stabilize the frequency to a resonance of a stable optical cavity. The frequency discriminator is provided by the side of a transmission fringe [11.2401]. The basic idea is that the sloping side of the fringe converts the laser frequency fluctuations to amplitude fluctuations with high conversion efficiency and a good signal-to-noise ratio. To prevent laser amplitude noise from entering the discriminator channel, two balanced photodetectors are used (Fig. 11.279a). One looks at the frequency-selective transmission of the resonator and the other views an attenuated portion of the input beam.

The attenuation is adjusted such that the resulting difference of the two photodetector signals crosses zero at the half-point of the maximum transmission. In a frequency interval close to the zero crossing, the signal depends almost linearly on the frequency deviation $\delta\nu$ and can be used as an error signal for stabilization. This side-of-the-fringe method is quite simple and very useful for many applications. However, if high spectral resolution and low drift rates are required, it turns out that the reference frequency is not defined precisely enough. For example, if the direction of the laser beam incident to the resonator changes, the transmission will also change whereas the power in the other reference beam stays constant. Hence, the zero crossing of the

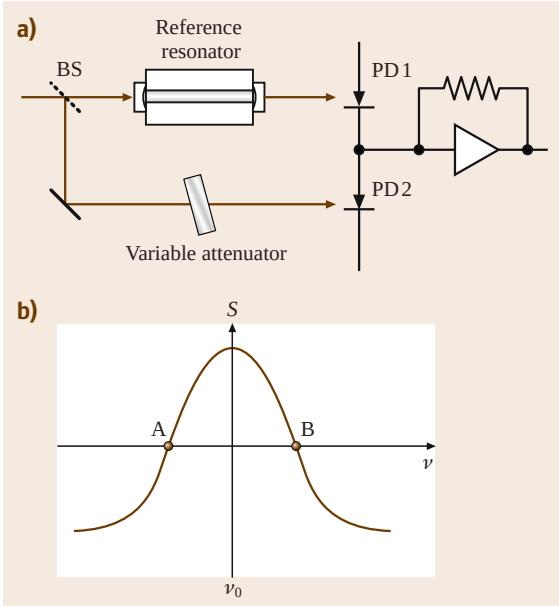

Fig. 11.279a,b Frequency stabilization to the side of a fringe. **(a)** Experimental setup, **(b)** either point A or point B can be selected as the reference

error signal changes, leading to a shift of the stabilized laser frequency. A further difficulty arises from the fact that the speed of the servo control is ultimately limited by the response time of the cavity [11.2402]. Furthermore, the locking range of the servo control is asymmetric. For example, if the laser frequency is locked to point A (Fig. 11.279b), the locking range towards lower frequencies corresponds almost to the total free spectral range of the cavity, whereas for higher frequencies it corresponds only to approximately one full width at half-maximum. Hence, spontaneous and fast excursions towards higher frequencies exceeding the half-width may force the laser to fall out of lock and relock at the next-higher interference order. To increase the locking range and to avoid such unwanted frequency jumps, commercial lasers usually apply reference resonators of rather low finesse at the cost of a strongly reduced sensitivity. Nevertheless, side-of-the-fringe stabilization has been used very successfully in many stabilized lasers.

Phase-Modulation Technique. Many of the shortcomings of the side-of-the-fringe method are avoided if the laser frequency is locked to the *center* of a symmetric resonance. This can be achieved in transmission or reflection. In the latter case, the amplitude of the return

beam is a superposition of the beam reflected directly at the entrance mirror and a small part of the light stored inside, which leaks out of the cavity. At resonance, the two beams interfere destructively and the intensity of the return beam has a minimum at the line center. It follows that an abrupt change of the laser frequency shows up instantaneously in the interference signal between these two beams and the transient behavior of the resonator does not limit the bandwidth of the servo control [11.2403, 2404]. Hence, a servo bandwidth up to a few megahertz can be achieved even with ultrahigh-finesse cavities with linewidths in the low kilohertz range.

Fast stabilization techniques to line center have been developed [11.2405–2407] utilizing either DC or radio-frequency (RF) methods. In the following, we describe an RF method where the signal is detected in reflection. This method was introduced by *Pound* [11.2408] to stabilize the frequency of a microwave oscillator and later applied in the optical range by *Drever* et al. (the PDH technique) [11.2406]. To generate the error signal, the phase of the laser radiation is modulated at a radio frequency. For an optimum signal size, the modulation frequency should be larger than the width of the cavity resonance. A high modulation frequency is also advantageous, since the influence of $1/f$ noise decreases and can eventually be neglected, leading to a signal-to-noise level close to the shot-noise limit.

The basic experimental setup of the PDH stabilization scheme is shown in Fig. 11.280. A small fraction of the laser power ($< 10\%$) is split off the main laser beam and used for the stabilization. It is phase modulated by an electrooptic modulator (EOM). The modulation frequency (typically ≈ 15 MHz) is several times larger than the width of the resonance. The modulation index $\delta\nu/f_{\mathrm{m}}$ is in the range 10–30%. After passing a polarizing beam splitter (PBS) and a 45° Faraday polarization rotator (FR), the incident beam is mode-matched into the reference resonator. The polarization of the returning beam is rotated by another 45°. Hence, the incident and the returning beam are polarized perpendicular to each other and separated by the PBS. The return beam is sent to a photodetector (PD).

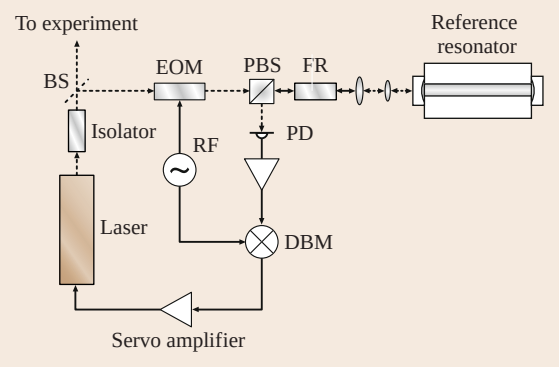

Fig. 11.280 Schematic of the PDH frequency stabilization technique (see text) (BS: beam splitter, PBS: polarizing beam splitter, EOM: electrooptic modulator, RF: modulation-frequency generator, PD: photodetector, DBM: double balanced mixer)

If the laser frequency is tuned far from resonance, the carrier and the sidebands of the modulated beam are promptly reflected and no intensity modulation is observed by the photodetector. If the carrier or either sideband approaches the cavity resonance, its amplitude and phase changes depending on the detuning of the corresponding frequency component from the cavity resonance. The other frequency components which are off-resonance are promptly reflected. Hence, in the returning beam, the balance between the carrier and the sidebands is broken and power modulation is generated. The corresponding amplitude modulation of the photocurrent is phase-sensitively detected by the PD followed by a double-balanced mixer, which is driven at the modulation frequency. The corresponding demodulated signals – after passing a low-pass filter – are shown for different modulation frequencies G versus the laser frequency in Fig. 11.281a in phase and Fig. 11.281b in quadrature with the modulation voltage at the EOM.

In the first case (Fig. 11.281a), we observe a dispersive signal $D(\Delta)$ with zero crossings at the resonance of the carrier and close to the resonances of the sidebands. It is given by the relation [11.2396].

$$D(\Delta) \propto \frac{\Omega^2\Gamma\Delta(\Gamma^2+\Omega^2-\Delta^2)}{(\Delta^2+\Gamma^2)[(\Delta+\Omega)^2+\Gamma^2][(\Delta-\Omega)^2+\Gamma^2]} \,. \tag{11.262a}$$

The absorptive signal $A(\Delta)$ (Fig. 11.281b) is given by

$$A(\Delta) \propto \frac{\Omega\Gamma\Delta(\Gamma^2+\Omega^2+\Delta^2)}{(\Delta^2+\Gamma^2)[(\Delta+\Omega)^2+\Gamma^2][(\Delta-\Omega)^2+\Gamma^2]} \,. \tag{11.262b}$$

In (11.262), $\Gamma/2\pi = \nu_{\mathrm{h}}$ is the half-width at half-maximum of the cavity resonance, $\Omega/2\pi$ is the modulation frequency, and $\Delta/2\pi = (\nu - \nu_0)$ is the frequency detuning.

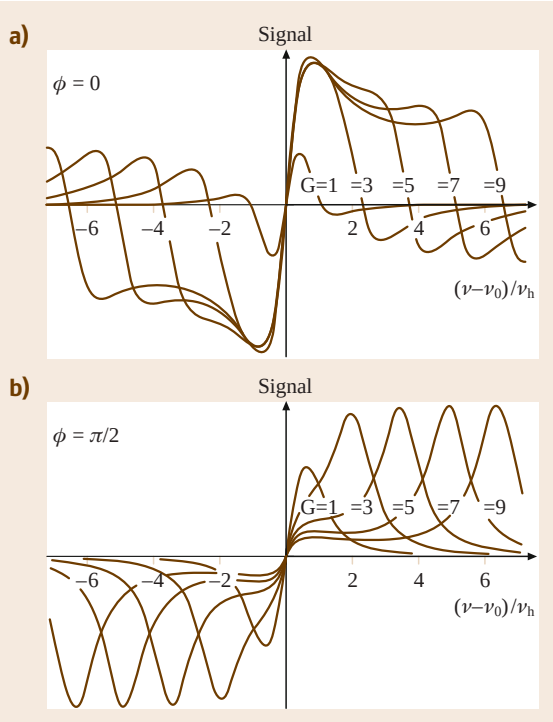

Fig. 11.281a,b Demodulated signals versus detuning observed with the PDH technique, **(a)** in phase ($\varphi = 0$) and **(b)** in quadrature ($\varphi = \pi/2$) with the modulation. $G = (\nu_m/\nu_h)$ corresponds to the ratio between the modulation frequency ν_m and the half-width ν_h of the resonance

The central zero crossing of the dispersion signal $D(\Delta)$ (Fig. 11.281a) is used as the error signal for the frequency control. The signal detected in quadrature (Fig. 11.281b) shows a resonance feature when either of the sidebands coincides with the cavity resonance. The different polarities of the two features are caused by the phase difference π between the carrier and the upper sideband and that between the carrier and the lower sideband. Independent of the detection phase, the demodulated signal is always antisymmetric with respect to the central zero crossing. Consequently, a small phase deviation from zero does not change the frequency of the central zero crossing. However, it will slightly change the slope of the frequency discriminator and thereby the gain of the servo loop.

Since the returning beam results from an interference between the frequency components promptly reflected at the entrance mirror and part of the stored radiation leaking out of the cavity, any fast frequency change shows up as a change in the interference signal instantaneously even if the response time of the cavity is much longer. At low Fourier frequencies f, smaller than the half-width $\Gamma/2\pi (2\pi f \ll \Gamma)$, the transient response of the cavity can be neglected and the demodulated signal acts as a *frequency* discriminator. With increasing Fourier frequency, the signal turns to a *phase* discriminator for $2\pi f \gg \Gamma$. Hence, the amplitude $A(f)$ and the phase $\phi(f)$ of the error signal have a low-pass characteristic, which rolls off with $1/f$ for frequencies f above the cut-off frequency $\Gamma/2\pi$ [11.2403]

$$A(f) = A(0)\frac{1}{\sqrt{1+(2\pi f/\Gamma)^2}}\,,$$
$$\varphi(f) = -\arctan(2\pi f/\Gamma)\,. \qquad (11.263)$$

If this integrating behavior for $\Gamma > 2\pi f$ is taken into account in the design of the servo amplifier, a servo bandwidth much larger than $\Gamma/2\pi$ can be envisaged. Basically, the servo bandwidth is limited to a few megahertz by residual delays in the servo system.

If the frequency of the laser is stabilized, the size of the residual error signal provides us with information about the quality of the servo electronics. However, this error signal is by no means a measure of the actually achieved frequency stability or laser linewidth. There may be still frequency fluctuations that are not detected by the electronic servo. In particular, at very high spectral resolution, small variations of the optical length in the cavity can no longer be neglected. The true linewidth of the laser can be estimated only by methods independent of the actual servo loop, e.g., by beat-frequency comparisons with a second laser or by the use of a second independent frequency discriminator.

To achieve a narrow linewidth, it is important to isolate the cavity from any distortions, e.g., from vibrations, acoustics, and temperature changes caused by the environment. For this reason, the resonator is frequently vibration isolated and supported in a temperature-controlled vacuum chamber [11.2403, 2409].

The long-standing problem to set up Fabry–Pérot resonators that are highly immune against vibrations was solved recently by different approaches [11.2410–2413]. These approaches employ mounting arrangements where the forces that act on the resonator due to the vibrations are coupled into the resonator at well defined points; e.g. due to symmetry of the resonator, points can be found where perturbations do not lead (to first order) to a length change of the resonator and hence not to a frequency change. With different techniques the lasers stabilized to such optical resonators achieve

stabilities that are ultimately limited by the thermomechanical noise [11.2414]. This noise limit is due to the Brownian motion in the spacer, mirror substrates, and the mirror coatings of the resonator that lead to fluctuations of the optical length. Current attempts to reduce this limit rely, e.g., on mirror substrates with increased mechanical quality factors, longer spacers that separate the mirrors, or large-area laser modes [11.2415].

A further cause of possible frequency offsets is a spurious residual amplitude modulation (RAM) of the intrinsic laser beam. Such RAM may be generated, e.g., by an imperfect phase modulator itself. Very often, RAM is also introduced by spurious interferences in the optical setup caused, for example, by light backscattered at the surfaces of optical elements. The servo cannot distinguish between the true error signal and the RAM. Hence, the total of the superimposed signals are servo controlled to zero, leading to a nonzero error signal and consequently to a frequency shift. Usually, this spurious RAM varies with time and we experience frequency fluctuations that are not identified by the error signal of the servo loop. At high spectral resolution, these fluctuations may be orders of magnitude larger than those estimated from the noise in the error signal. Hence, it is important to isolate the cavity from environmental perturbations and to minimize the RAM very carefully.

The narrowest linewidth achieved with the PDH method in a dye laser was as low as 0.5 Hz [11.2416] and even with diode lasers a linewidth in the range of approximately 1 Hz was achieved [11.2404, 2417, 2418]. The PDH stabilization technique is now used almost exclusively, if a precision stabilization to a cavity resonance is required combined with extremely high spectral resolution.

Stabilization to a Doppler-Free Atomic Reference. The stabilization methods discussed above describe methods to stabilize the laser frequency to a reference provided by the length of an artifact. An *absolute* stabilization requires that the frequency is traced back to a natural constant, e.g., to the center of a suitable atomic or molecular absorption line. Ideally, the frequency of such transition should not depend on environmental or operational parameters such as external fields, atomic collisions, laser power, etc. The atomic reference line should be narrow and provide us with a sufficient signal-to-noise ratio. The atoms may be contained in an absorption cell, in an atomic beam or stored in a trap. At room temperature, the thermal velocity distribution of the atomic absorbers cause a Doppler broadening of the line, which is in the range of $\delta\nu/\nu \approx 10^{-6}$ and which is usually much larger than the natural linewidth of the reference transition. An atom moving with a velocity component v_z in the direction of the laser beam sees a Doppler-shifted frequency

$$\nu_D = \nu_l \left[1 \pm v_z/c + v^2/(2c^2)\right] , \qquad (11.264)$$

where ν_l is the laser frequency and v_z is the velocity component in the direction of the laser beam. In (11.264), the term $\nu_l v_z/c$ represents the first-order Doppler effect. The positive sign is valid for atoms counter-propagating to the laser beam, whereas the minus sign belongs to the co-propagating ones. The third term $\nu_l v^2/(2c^2)$ corresponds to the (relativistic) second-order Doppler effect. Whereas the first-order Doppler effect can be strongly suppressed by the application of nonlinear Doppler-free spectroscopic methods such as, e.g., *saturated absorption* [11.2419, 2420] or Doppler-free *two-photon excitation* [11.2421, 2422], the second-order effect can be reduced only by cooling the absorbers.

As a typical example of Doppler-free spectroscopy, we concentrate on the saturated absorption and give a brief description of this method. For simplicity, we neglect the influence of the second order Doppler effect. Let us consider an atomic ensemble that is excited by two counter-propagating laser beams of the same frequency ν_l. If ν_l does not coincide with the line center ν_0 of the transition, the two beams will excite and saturate *two* groups of atoms with velocity components v_z and $-v_z$, of which the Doppler-shifted frequencies ν_D coincide with the laser frequency ν_l. Consequently, two saturation holes are burned into the velocity distribution of the ground state. If we tune the laser frequency closer to the center of the line, $|v_z|$ decreases and the holes approach each other until they overlap for $v_z = 0$ when the laser frequency is tuned to line center. In this singular case, the number of atoms contributing to the absorption decreases and hence less laser power is absorbed, resulting in a narrow Doppler-free absorption dip, which is used as a reference for the stabilization. Hence, (first-order) Doppler broadening is suppressed and the width of this dip is determined by the natural width of the transition, by power and collision broadening of the line, and ultimately by the limited interaction time of the atoms moving across the laser beam. To first order, the profile of this dip can be approximated by a Lorentzian line shape.

As a practical example, let us consider an absorbing gas contained in a cell at low pressure. It can be placed inside or outside the laser cavity. If the cell is

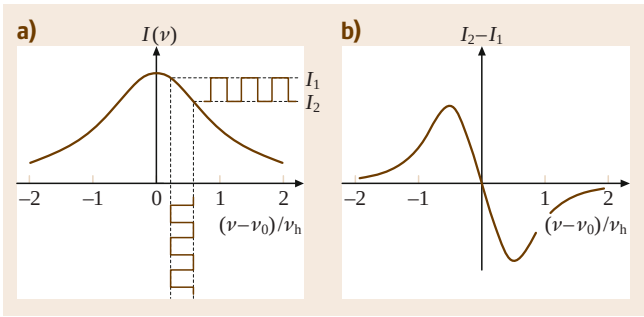

Fig. 11.282a,b Generation of the error signal by a square-wave frequency modulation

placed inside, a Doppler-free feature caused by saturated absorption will show up as a small symmetric dip in the tuning curve of the laser at the center of the reference transition. This feature must be converted to an error signal that is antisymmetric with respect to the detuning $\Delta\nu = \nu_l - \nu_0$. A simple concept to generate the error signal is to switch the laser frequency between two discrete values (Fig. 11.282a). The difference in the corresponding two absorption signals $I_2 - I_1$ leads to an antisymmetric error signal with a zero crossing at the line center (Fig. 11.282b). For small modulation amplitudes, the error signal is proportional to the first derivative of the absorption signal.

Instead of a square-wave modulation, most lasers use a harmonic frequency modulation. Consequently, the laser power will contain harmonics of the modulation frequency. The amplitudes of these harmonics depend on the modulation width and on the detuning. The amplitude of a particular harmonic signal in the laser power can be detected by a photodetector followed by a phase-sensitive detector, which is gated by the corresponding harmonic of the modulation frequency. For a symmetric absorption line, the amplitudes of the odd harmonics are antisymmetric and have a zero crossing at $\Delta\nu = 0$. Hence, these odd harmonics are suitable as error signals for frequency stabilization. In many cases, third-harmonic detection is applied in order to suppress a residual slope [11.2423,2424]. If the modulation width is small compared to the linewidth, the derived signal represents the corresponding derivative of the saturation signal, e.g., the first derivative for the first harmonic and the third derivative for the third harmonic.

If we approximate the Doppler-free saturation feature by a Lorentzian line profile $I(\nu)$.

$$I(\nu) = \frac{A}{1 + \left[(\nu - \nu_0)/\nu_{1/2}\right]^2} \qquad (11.265)$$

we can estimate the amplitudes of the harmonics versus the detuning for various modulation widths [11.2425]. In (11.265), A and $\nu_{1/2}$ are the height and the half-width (HWHM) of the saturated absorption feature, respectively. The modulated laser frequency $\nu(t)$ can be written as

$$\nu(t) = \nu_0 + \Delta\nu + \delta\nu A\cos(\omega t)\,, \qquad (11.266)$$

where $\Delta\nu$ is the detuning of the mean laser frequency from the line center ν_0 and $\delta\nu_A$ is the modulation amplitude. If the modulation frequency $\omega/2\pi$ is small compared to the linewidth, the detected signal follows the laser frequency $\nu(t)$ closely and we can replace ν in (11.265) by $\nu(t)$ of (11.266), leading to a time-dependent absorption signal

$$I(t) = \frac{A}{1 + \left\{\left[\Delta\nu + \delta\nu_A\cos(\omega t)\right]/\nu_{1/2}\right\}^2}\,.$$

If we relate $\Delta\nu$ and $\delta\nu_A$ to the half-width (HWHM) $\nu_{1/2}$ we obtain with the reduced detuning $d_D = \Delta\nu/\nu_{1/2}$ and the reduced modulation amplitude $d_A = \delta\nu_A/\nu_{1/2}$

$$I(t) = \frac{A}{1 + [d_D + d_A\cos(\omega t)]^2}\,. \qquad (11.267)$$

The signal $I(t)$ is periodic in time and can be expressed by a Fourier series

$$I(t) = \frac{A_0}{2} + \sum_{m=1}^{\infty} A_m\cos(m\omega t)\,, \qquad (11.268)$$

where the Fourier coefficient A_m represents the signal amplitude of the mth harmonic of the modulation frequency $\omega/(2\pi)$. It can be calculated by the relation

$$A_m = \frac{2}{\pi}\int_0^{\pi} I(\tau)\cos(m\tau)\,\mathrm{d}\tau\,.$$

For the coefficients A_1 and A_3 we obtain [11.2425]

$$A_1 = \frac{1}{d_A}\left[(\mathrm{sign}\,d_D)\,P_- - d_D P_+\right] \qquad (11.269a)$$

and

$$A_3 = \frac{1}{d_A^3}\left\{(\mathrm{sign}\,d_D)\left[4\left(1 - 3d_D^2\right) + 3d_A^2\right]P_- + \left[4\left(3 - d_D^2\right) + 3d_A^2\right]d_D P_+ - 16 d_D\right\}\,, \qquad (11.269b)$$

with

$$P_\pm = \frac{1}{\rho}\sqrt{2(\rho \pm \alpha)}\,,$$

$$\rho = \sqrt{\alpha^2 + 4d_D^2}\,,$$

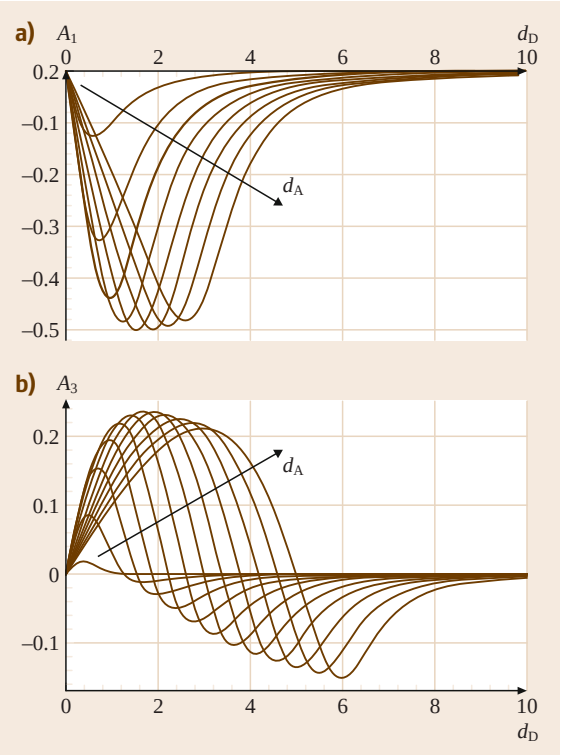

Fig. 11.283 Amplitudes of the first harmonic (A_1) and the third harmonic (A_3) versus the detuning $d_D = \Delta\nu/\nu_{1/2}$. The modulation amplitude was chosen as $d_A = 0.2, 0.6, 1.0, \ldots, 3.0$ for A_1, and $d_A = 0.5, 1.0, 1.5, \ldots, 6.0$ for A_3

and

$$\alpha = 1 + d_A^2 - d_D^2 \,.$$

A_1 and A_3 are shown versus the detuning d_D for various modulation amplitudes d_A in Fig. 11.283a,b, respectively. Both curves have zero crossings at $d_D = 0$. In the central part, their amplitudes depend linearly on the detuning d_D. Hence, both signals A_1 and A_3 can be used as discriminator signals for frequency control. Their slope depends on the modulation width d_A. For small amplitudes $d_A \ll 1$, the slope of the first-harmonic signal depends linearly on d_A and that of the third harmonic increases with the third power of d_A. The largest slope and consequently the highest sensitivity can be obtained with the first harmonic $A_1(d_D)$. In many cases, however, the saturation signal $I(d_D)$ is superimposed on a frequency-dependent (sloping) background. Consequently, a signal is added to the first-harmonic signal $A_1(d_D)$ and the zero crossing is shifted, leading to a frequency offset of the stabilized laser frequency. This shift can be strongly reduced if the third or a higher odd harmonic is applied for the stabilization. A typical example of a laser utilizing the third-harmonic detection technique is the iodine-stabilized HeNe laser (Sect. 11.14.3).

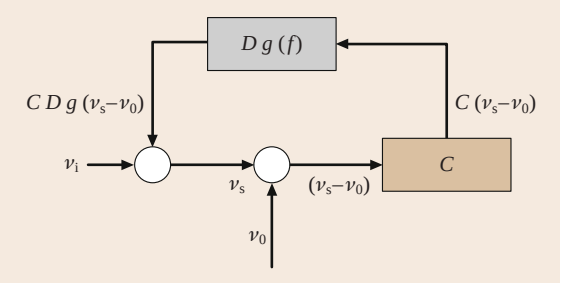

Fig. 11.284 Equivalent circuit of a laser frequency stabilization

Servo Amplifier and Filter

This subsection describes how the error signal is used to control the laser frequency. If the servo control is operating, the initial frequency ν_i of the free-running laser is corrected by the servo loop to ν_s, which is close to the reference frequency ν_0 (Fig. 11.284). The difference $\delta\nu = \nu_s - \nu_0$ represents the residual frequency deviation from the line center ν_0 of the stabilized laser. This deviation $\delta\nu$ is converted to an amplitude $U = C\delta\nu$ by the error signal, where the constant C is proportional to the sensitivity of the frequency discriminator. The signal $C\delta\nu$ is amplified in the following servo amplifier by a factor $g(f)$ and is then transferred to a frequency transducer, which corrects the laser frequency ν_i by $-CDg(f)\delta\nu$. Here D is the sensitivity of the transducer, which transforms the control voltage to a corresponding frequency shift of the laser. The term $g(f)$ characterizes the frequency-dependent gain of the electronic servo amplifier. The servo loop provides a negative feedback to the laser frequency and the corrected value ν_s can be written as

$$\nu_s = \nu_i - CDg(f)\delta\nu \,, \tag{11.270}$$

which can be transformed to

$$\frac{\delta\nu}{\Delta\nu} = \frac{1}{1 + CDg(f)} \,, \tag{11.271}$$

where $\Delta\nu = \nu_i - \nu_0$ is the initial frequency offset of the free-running laser.

We see that the servo control circuit reduces the frequency deviation $\Delta\nu$ of the free-running laser by

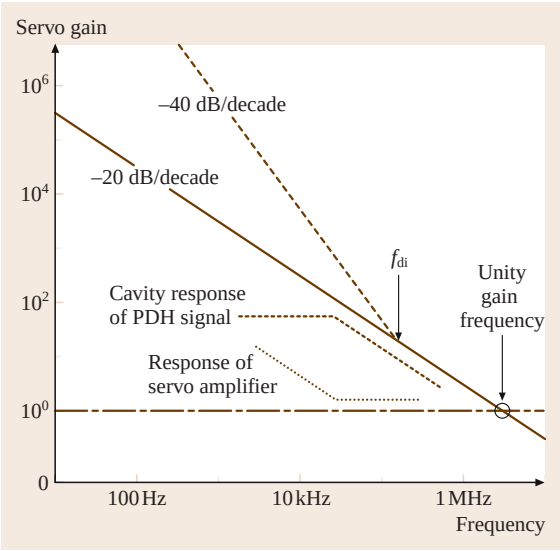

Fig. 11.285 Typical servo gain versus Fourier frequency of a PDH frequency stabilization to a cavity resonance (see text)

a factor of $1/[1+CDg(f)]$, where $CDg(f)$ represents the gain of the open servo loop. To achieve a negligibly small value of the residual frequency deviation $\delta\nu$, the servo gain should be as high as possible. In particular, the deviation of the mean frequency averaged over long times should be close to zero. This requires that $g(f \to 0) \to \infty$. In any servo control system, phase shifts and time delays of the servo loop put limitations on the maximum gain and the bandwidth of the servo control. A simple technique to provide high servo gain at low frequencies and to reduce the influence of phase shifts and time delays at high frequencies is to reduce the servo gain with increasing Fourier frequency f. Such a characteristic can be obtained by an integrating behavior of the servo gain, i. e., if $CDg(f)$ decreases with $1/f$ for increasing frequencies. In this case, the total transfer function of the control system can be characterized by a unity-gain frequency f_C, the frequency at which the gain of the open servo loop $CDg(f_C) = 1$. At low fluctuation frequencies $f \ll f_C$, the frequency deviations $\Delta\nu(f)$ will be reduced by a factor of f/f_C and an increase of the servo gain corresponds to a proportional increase of the unity-gain frequency f_C. Consequently, in an integrating servo loop a high servo gain requires a large servo bandwidth f_C. In cases where the servo bandwidth f_C is limited and where large frequency fluctuations at low frequencies must be suppressed, an additional integration can be introduced, leading to a double integrating behavior and consequently to a higher servo gain at low frequencies. The stability of the servo loop requires that this double integration is effective only at frequencies well below the unity-gain frequency f_C. In practice, the maximum crossover frequency f_{di} between single and double integration should be smaller than $f_C/4$. Figure 11.285 shows a typical dependence of servo gain on the fluctuation frequency of a frequency stabilization to a narrow cavity resonance using the PHD technique.

11.14.3 Examples of Frequency-Stabilized Lasers

This section describes a few examples of stabilized lasers. Some of their radiations are recommended as reference frequencies for the realization of the length unit *meter* and as references for scientific applications [11.2390]. Frequency-stabilized lasers have been developed that cover a wide range of wavelengths from the near UV to the far IR. Of these examples, HeNe lasers are of great practical importance since they are often employed in many applications, e.g., as wavelength standards in interferometers for dimensional metrology. Most of these lasers utilize the frequency of their gain profile itself as the reference for the stabilization. In these cases, the stabilized frequency depends on the discharge parameters, the gas pressure, and gas mixture inside the laser tube, and the relative reproducibility is limited to some 10^{-7}. Hence, if the absolute value of the laser frequency is important, it should be compared from time to time with a superior standard, e.g., a HeNe laser of which the frequency is stabilized to an absorption line of molecular iodine.

With increasing requirements on reproducibility and accuracy, the laser frequency needs to be stabilized to suitable references such as the narrow absorption lines of atoms, molecules, or ions, and line broadening caused by the movement of the absorbers needs to be reduced by Doppler-free techniques such as saturated absorption or two-photon excitation. Ultimately, any frequency shifts caused by a residual Doppler effect can be strongly reduced if the laser radiation interacts with cold atomic absorbers only.

This section is organized as follows. In the first part, we explain as a typical example the stabilization of a tunable diode laser to the resonance of a stable optical cavity. We then continue with HeNe lasers stabilized to their gain profile. The next section represents laser radiations that are stabilized to suitable absorption lines of atoms, molecules, or ions. In view of their practical

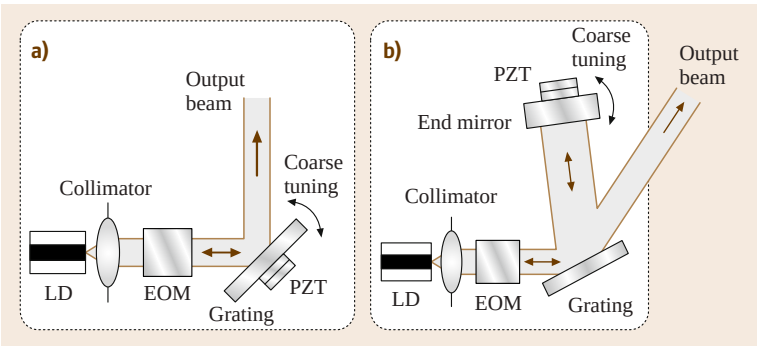

Fig. 11.286a,b Typical setups of extended-cavity diode lasers (ECDLs). **(a)** Littrow configuration, **(b)** Littman configuration (see text)

importance, we focus on HeNe lasers, which can be stabilized to the absorption lines of molecular iodine. The absorbing particles of these lasers are contained in an absorption cell. In the next step, laser stabilization systems based on atomic or molecular beams are discussed. The last part of this section presents a brief description of lasers stabilized to cold ions and atoms.

Frequency Stabilization of Diode Lasers

Tunable lasers are important tools in the field of precision laser spectroscopy. Whereas in the past the visible spectrum was covered mostly by dye lasers, diode lasers are increasingly taking over due to their small size, high efficiency, high power, and reliability. They are available in a wide range of the visible and infrared spectrum. However, if high spectral resolution is required, the linewidth of most solitary laser diodes, which ranges from 10–300 MHz, is orders of magnitude too large. Several methods have been developed to improve the spectral purity of these lasers. Most of them apply optical feedback [11.2426, 2427]. This section discusses a typical example, where the length of the laser resonator is increased by an external reflector [11.2428, 2429]. Compared to solitary laser diodes, the linewidth of such extended-cavity diode lasers (ECDL) can be reduced to some 100 kHz. Figure 11.286 shows two typical setups of ECDLs in the Littrow and Littman configurations. In both configurations, the beam leaving the antireflection-coated facet of the laser diode (LD) is collimated and directed onto a reflection grating. In the Littrow configuration (Fig. 11.286a), the laser grating acts as the end mirror of the extended laser resonator where the beam is back-reflected into the laser diode in the first diffraction order. The zeroth-order beam is coupled out. Coarse frequency tuning can be performed by rotating the grating, whereas a piezoelectric transducer (PZT) and/or an electrooptic modulator (EOM) can be used to fine-tune and control the laser frequency by changing the optical length of the cavity. Frequency tuning can also be achieved by changing the injection current of the laser diode; this method, however, will also change the laser power. The Littrow configuration can be designed to be very compact. Unfortunately, the direction of its output beam changes with any rotation of the grating. This shortcoming is avoided in the Littman configuration [11.2430] where the ECDL contains an additional mirror (Fig. 11.286b). In this configuration the beam deflected in the first diffraction order is directed onto this extra mirror and back-reflected from there into the laser diode. In the Littman configuration, the laser beam passes the grating twice and hence the wavelength selectivity is increased compared to the Littrow configuration. The output beam leaves the grating in the zeroth order. In this configuration, a coarse frequency setting is achieved by rotating the end mirror, with the consequence that the direction of the output beam does not change. Fine-tuning of the frequency can be performed in the same way as with the Littrow configuration by means of a PZT or an EOM.

The frequency noise of ECDLs occurs at Fourier frequencies low enough that a further linewidth reduction below 100 kHz can be achieved by active frequency stabilization to the resonance of an optical cavity [11.2431], as described in Sect. 11.14.2. Precise frequency tuning can be performed, e.g., by changing the length of the optical reference cavity. This method, however, strongly perturbs the stability of the cavity. To achieve the highest possible resolution, it is better to introduce a variable frequency difference between the laser output beam and the cavity resonance. Since the frequency-shifted beam is locked to the cavity resonance, which is not affected, the stabilization circuit will shift the laser frequency, with the consequence that it can be tuned very precisely relative to the stable cavity resonance. Such a shift can be achieved,

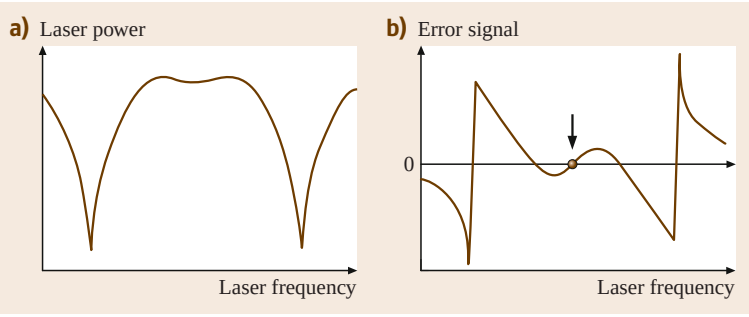

Fig. 11.287a,b Tuning curve (**a**) and error signal (**b**) of a Lamb-dip stabilized HeNe laser

e.g., by an acoustooptic modulator or an electrooptic modulator. Using the PDH technique and a carefully designed and isolated reference cavity of ultrahigh finesse, a linewidth as narrow as 1 Hz and below was recently observed, demonstrating the great potential of diode lasers for applications in precision spectroscopy and optical frequency standards [11.2404, 2417, 2418].

Frequency Stabilization of HeNe Lasers

HeNe lasers can operate at several different wavelengths within the spectral range between the green ($\lambda = 543$ nm) and the infrared ($\lambda = 3.39\,\mu$m). Regarding the various wavelengths, the emission at $\lambda = 633$ nm is probably most important. HeNe lasers are advantageous since their operation is simple, the intrinsic frequency noise is small, and the output power in the range between 100 μW and some 3 mW is sufficient for many applications in metrology. Provided the neon gas inside the laser tube consists of a single isotope, the width of the Doppler-broadened gain profile is in the range of approximately 1.5 GHz and single or two-frequency operation can easily be achieved by choosing a sufficiently short length of the laser resonator. Owing to these favored properties and their simplicity, frequency-stabilized HeNe lasers were developed very early [11.2432]. The first stabilization systems – which are still used in many laboratories – apply the gain profile itself as the frequency reference.

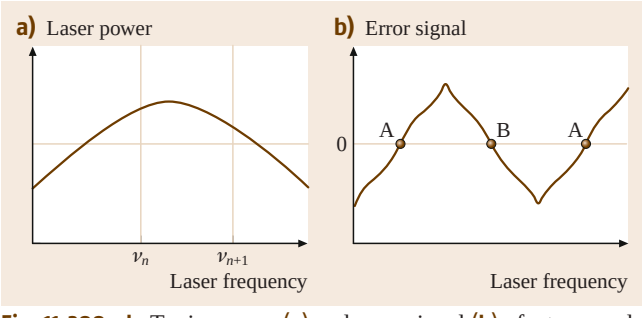

Fig. 11.288a,b Tuning curve (**a**) and error signal (**b**) of a two-mode stabilized HeNe laser

Lamb-Dip Stabilization. The Lamb-dip-stabilized laser was one of the first frequency-stabilized lasers [11.2433]. It makes use of the fact that the output power passes through a local minimum – the *Lamb dip* – when the laser frequency is tuned across the center of the gain curve (Fig. 11.287a). Similar to the Doppler-free minimum of saturated absorption, the Lamb dip is caused by an increased saturation of the gain at the line center when both the forward- and backward-running waves inside the resonator interact with the same velocity group ($v_z = 0$) of atoms. Hence the number of atoms contributing to the laser action is decreased, leading to a reduced laser power at line center. To generate the error signal (Fig. 11.287b), the laser frequency is modulated and the first harmonic in the output power is detected.

Two-Mode Stabilization. A simple stabilization system can easily be set up, if the HeNe laser operates at two adjacent longitudinal modes (Fig. 11.288a) and if these modes are polarized perpendicular to each other. These conditions are provided, e.g., in commercial HeNe laser tubes of 30 cm length with internal mirrors. Perpendicular polarization is observed since it minimizes the gain competition of two modes. Frequently, the plane of polarization of each mode is fixed within the tube. These properties allow us to separate the two modes by a polarization divider, e.g., a Wollaston prism, and to monitor the power in each mode by a separate photodetector. The difference between the photocurrents of the two detectors $I_1 - I_2$ depends on the frequencies of the two modes (Fig. 11.288b). It crosses zero when they are distributed symmetrically with respect to the center of the gain curve and the powers in the two modes are identical. Hence, the difference in the photocurrents is used as the error signal for frequency stabilization and no

frequency modulation is necessary [11.2434]. Several means can be applied to transfer the control signal to the length of laser tube, such as heating the tube via the discharge current or a separate external heater. With this simple laser stabilization technique, a relative reproducibility of better than 10^{-7} has been demonstrated. During a time interval of 5 days relative frequency variations as low as 10^{-9} were demonstrated under favored laboratory conditions [11.2435].

Zeeman Stabilization. Another method of frequency stabilization widely applied in commercial HeNe lasers and laser interferometers utilizes the Zeeman effect in a short (≈ 10 cm) single-mode laser. If we apply a longitudinal magnetic field, the Zeeman effect causes a splitting of the laser mode into two submodes ν_+ and ν_- of opposite circular polarization and slightly different frequencies. Depending on the size of the magnetic field, the frequency difference $\nu_+ - \nu_-$ is in the range between 300 kHz and 2 MHz. The two submodes can be separated by a quarter-wave plate followed by a polarizing beam splitter. Similar to two-mode stabilization, the difference of the output powers at ν_+ and ν_- can be utilized as the error signal [11.2436].

Alternatively, the error signal can also be generated by utilizing the frequency difference $\delta\nu = \nu_+ - \nu_-$. It has been shown that $\delta\nu$ changes with the mean laser frequency and that it has a minimum at the line center. This dependence is caused by nonlinear mode-pulling effects in the gain medium. The error signal to find this minimum is generated by modulating the laser frequency and monitoring the beat frequency between the two Zeeman modes by means of a reversible counter [11.2437]. To derive the error signal, the direction of counting is reversed at every half period of the modulation. The accumulated counter content, which corresponds to the integrated error signal, is then fed into a digital-to-analog converter after each period. Its output is used to control the frequency of the laser so that the mean laser frequency coincides with the minimum of the beat frequency. With such lasers a relative frequency reproducibility of 10^{-8} can be achieved over a period of 5 months under laboratory conditions [11.2437].

Absolute Frequency Stabilization Utilizing Separate Absorption Cells

As indicated above, the frequency of HeNe lasers stabilized to their gain profile may change with time. Such frequency shifts can be reduced by several orders of magnitude if the frequency reference is provided by a suitable narrow absorption line of which the transition frequency is largely independent on the parameters of operation. There are now several different laser systems available in a wide range of the optical spectrum that are stabilized to such frequency references. Some of these have been recommended by the Comité International des Poids et Mesures (CIPM) [11.2390]. Their radiations are listed together with the values of their frequencies, wavelengths, and their relative uncertainties in Table 11.59. Six of the recommended reference frequencies are stabilized to hyperfine-structure components of molecular iodine, which has a rich spectrum of narrow absorption lines in the visible range. They belong to the transition between the electronic B level and the ground state (X level). Since the iodine molecule is heavy, its velocity – and hence the Doppler broadening – is rather low at room temperature. Furthermore, the vapor pressure – causing a pressure-induced shift and broadening – can be controlled conveniently via the temperature of a cooling finger attached to the iodine absorption cell. Four of the iodine references are used to stabilize HeNe lasers at $\lambda \approx 543$, 612, 633, and 640 nm. From this group, the one operating at 633 nm is of particular importance since it is used in many standard laboratories as a reference for interferometric length measurements, laser wavelength calibrations, and applications in precision laser spectroscopy. It can also act as a reference to calibrate HeNe lasers that are stabilized to their gain profile utilizing beat-frequency comparisons. Hence, the I_2-stabilized HeNe laser at $\lambda = 633$ nm can be regarded as the workhorse in many laboratories.

The iodine molecules are contained at low vapor pressure in a cell. Depending on the laser system, the length of the cell may range from a few centimeters up to several meters. In either case, the content of impurities must be low in order to prevent any frequency shifts caused by collisions with impurities. For example, in the case of iodine-stabilized lasers, the quality of the iodine filling limits the uncertainty ultimately achievable. Nevertheless, as a result of its rich spectrum, I_2 is often used as the frequency reference for different types of lasers operating within the visible spectrum. Two types of I_2-stabilized lasers, the HeNe laser ($\lambda = 633$ nm) and the frequency-doubled Nd:YAG laser ($\lambda = 532$ nm) will be discussed in the following.

Iodine-Stabilized HeNe Laser ($\lambda = 633$ nm). Figure 11.289 schematically shows the typical setup of an iodine-stabilized HeNe laser. The laser head consists of a HeNe discharge tube and an iodine absorption cell mounted inside the laser resonator. The lengths of the discharge tube and the absorption cell are typically

Table 11.59 Selected recommended reference wavelengths/frequencies generated by stabilized lasers [11.2390]

20 and 10 cm, respectively, corresponding to a minimum length of the resonator of approximately 35 cm and a free spectral range of ≈ 430 MHz. Despite of the rather long resonator the laser emits only one single frequency, owing to the loss in the absorption cell. In order to reduce the influence of acoustics and vibrations, the resonator should be made as rugged as possible. The spacers should consist of a material of low thermal expansion. The radii of curvature of the laser mirrors r are usually in the range 0.6–4 m and a radius of $r=1$ m is most commonly used. Both mirrors have a reflectivity of approximately 98%, allowing single-frequency operation over most of the free spectral range. Output powers of up to 300 μW were achieved, which is sufficient for most applications in laser spectroscopy and interferometry. The two mirrors are mounted on PZT actuators, allowing one to change the resonator length and thereby the laser frequency by applying a voltage to the PZTs.

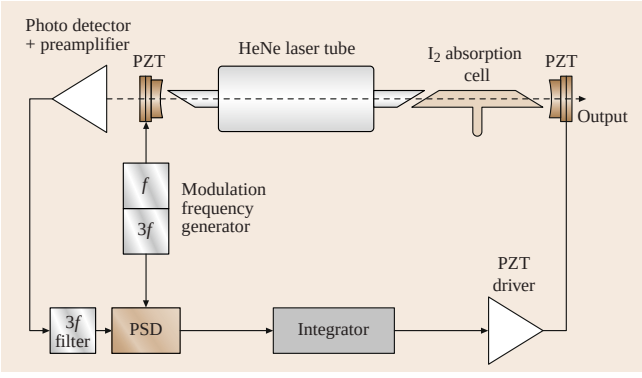

Fig. 11.289 Experimental scheme of an iodine stabilized HeNe laser

Figure 11.290a shows four absorption features in the tuning curve of the laser. They belong to the hyperfine-structure (HFS) components d, e, f, and g (a_{18}, a_{17}, a_{16}, and a_{15}, respectively) of the transition R(127), $\nu'=5$, $\nu''=11$ of $^{127}I_2$. The separation between the components d, e, f, and g is approximately 13 MHz, and the full width at half-maximum of each line is in the range of 5 MHz, corresponding to a quality factor of $Q=\nu/\delta\nu\approx10^8$. The height is approximately 0.1% of the laser power. To generate the error signal for the stabilization, the length and thereby the frequency of the laser is modulated harmonically by applying a sine-wave voltage to the left PZT (Fig. 11.289). For the stabilization, third-harmonic detection is used. The third-harmonic signal in the output power is filtered out, demodulated by a phase-sensitive detector (PSD) and passed through a low-pass filter. It then serves as error signal for the stabilization. A typical third-harmonic spectrum of molecular iodine containing seven HFS components within the tuning range of the laser is shown in Fig. 11.290b. Each absorption feature is suitable as a reference for the stabilization.

With the servo loop operating, the length of the laser is stabilized such that the third-harmonic signal of the corresponding HFS component vanishes at its central zero crossing.

The stability and the reproducibility of the I_2-stabilized HeNe laser can be investigated by beat-frequency measurements of two independent laser systems. Figure 11.277 shows the measured Allan standard deviation $\sigma(\tau)$ of an iodine-stabilized HeNe laser versus the integrating time τ. In the range between $\tau = 10\,\text{ms}$ and $\tau = 100\,\text{s}$, $\sigma(\tau)$ decreases approximately with the square root of τ, corresponding to white frequency noise. The minimum instability of about 2×10^{-13} is observed at an integrating time $\tau \approx 1000\,\text{s}$.

The reproducibility of the iodine-stabilized HeNe laser was investigated by measuring the dependence of the laser frequency on the various operation parameters and by frequency inter-comparisons between lasers of different institutes. The laser frequency depends on the modulation width, the iodine vapor pressure, and slightly on the laser power. The coefficients are approximately $-6\,\text{kHz/Pa}$ and $-10\,\text{kHz/MHz}$ for the pressure and modulation dependence, respectively. International frequency comparisons between iodine-stabilized lasers have shown that the stabilized frequencies of the majority of iodine-stabilized HeNe lasers coincide within a range of approximately 12 kHz, corresponding to $2.5 \times 10^{-11}\nu$. For specified operation parameters (temperature of the cell: (25±5) °C, temperature of the cold point: (15 ± 0.2) °C, width of frequency modulation between the peaks: (6 ± 0.3) MHz, one-way intracavity beam power: (10±5) mW) a relative standard uncertainty of the recommended frequency value of 2.5×10^{-11} can be achieved [11.2390].

Iodine-Stabilized Frequency-Doubled Nd:YAG Lasers ($\lambda = 532\,\text{nm}$). Frequency-doubled YAG lasers pumped by diode lasers are of particular interest in applications as optical frequency standards for the following reasons. Small lasers providing us with high output powers of 100 mW at 532 nm are commercially available. The intrinsic frequency noise of YAG lasers can be very low. Part of the emission range coincides with strong absorption lines of molecular iodine (Fig. 11.291a) that are suitable as reference frequencies for the stabilization. Figure 11.291b shows the Doppler-free absorption spectrum observed within the continuous tuning range of 5 GHz of a commercial laser. The observed absorption lines represent two sets of hyperfine components belonging to the 32-0, R(57) and the 32-0, P(54) ro-vibrational lines labeled # 1104 and # 1105, respectively [11.2438]. Any of these transitions is suitable as a frequency reference. Since the frequency difference to the recommended a_{10} component of the 32-0, R(56) transition is known to about 2 kHz an accurate optical frequency can be attributed to each HFS component.

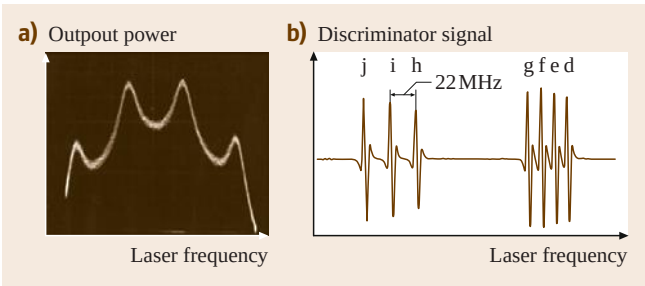

Fig. 11.290a,b Saturation dips **(a)** and error signals **(b)** of an iodine-stabilized HeNe laser ($\lambda = 633\,\text{nm}$) for the components d–j (also referred to as a_{18}–a_{12}, respectively)

Various methods have been used in different laboratories to generate the error signal. The methods of modulation transfer spectroscopy [11.2439, 2440] and phase-modulation spectroscopy [11.2441, 2442] are very powerful to achieve a discriminant signal with a high signal-to-noise ratio.

International frequency comparisons show that the frequency reproducibility of these lasers is in the range of 5 kHz [11.2443, 2444], mostly limited by potential impurities in the absorption cell. Regarding its high power, its compactness, and its high frequency reproducibility, the iodine-stabilized frequency-doubled Nd:YAG laser represents an optical frequency standard with important applications in precision length metrology, interferometry, and spectroscopy.

Laser Stabilized to a Two-Photon Transition in Rubidium. The radiation of a laser stabilized to the two-photon transition $5S_{1/2}$–$5D_{5/2}$ in rubidium (Fig. 11.292) [11.2445] represents a reference in the near infrared at a wavelength of 778 nm. In this spectral range, easy-to-handle laser diodes of low frequency noise are available, allowing the development of a transportable optical frequency standard of high precision. Furthermore, the laser may provide a precise frequency reference for optical communication systems since twice its wavelength coincides with the transmission band at 1.55 µm. Its optical frequency has been determined [11.2446].

In a simple setup [11.2445], the collimated beam of an extended-cavity diode laser passes through an

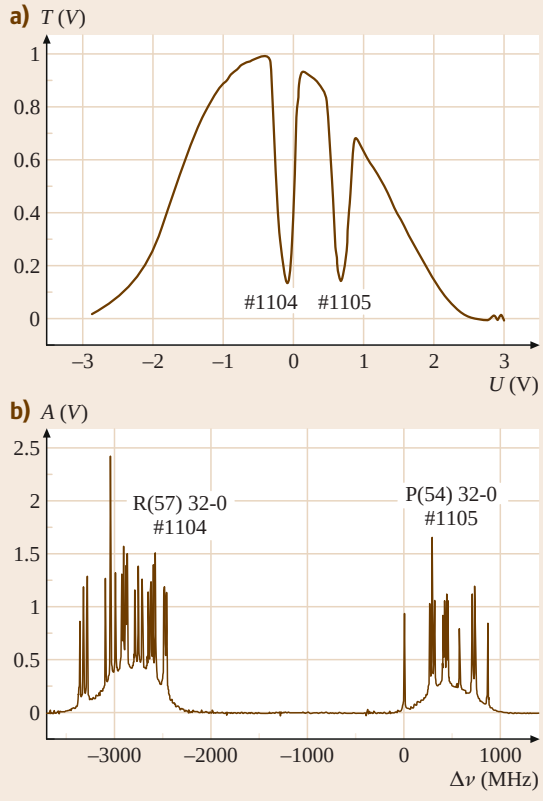

Fig. 11.291a,b Absorption lines of molecular iodine within the emission profile of a commercial frequency-doubled Nd:YAG laser. **(a)** Doppler-limited, **(b)** with Doppler-free excitation, the hyperfine structure is resolved

absorption cell filled with rubidium vapor. The cell is sealed with Brewster windows at its ends and filled with natural rubidium (73% ^{85}Rb and 27% ^{87}Rb). The beam is retro-reflected by a mirror or a cat's eye in order to allow Doppler-free two-photon excitation. Optical feedback into the diode laser is avoided by Faraday isolators. When the laser frequency is scanned through the two-photon resonance, the excitation of the upper level ($5^2D_{5/2}$) is observed via the blue fluorescence (420 nm) of the 6P–5S transition in the cascade of the spontaneous decay 5D → 6P → 5S. With this setup, a relative frequency stability of $\sigma(\tau) = 3\times10^{-13}\tau^{-1/2}$ has been achieved for integrating times τ up to 2000 s.

It is known that the stabilized frequencies of standards based on two-photon transitions suffer from light shifts. Their magnitude depends linearly on the intensity. Therefore, it is important to control the laser power and to prepare a well-defined laser beam geometry for

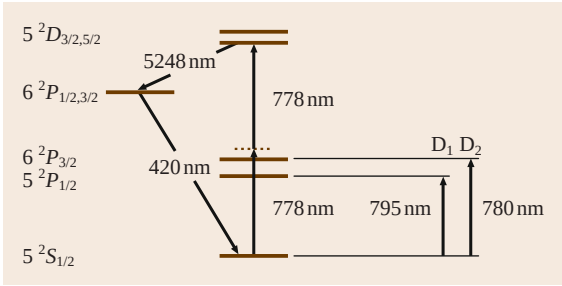

Fig. 11.292 Energy levels of Rb relevant for a two-photon stabilized diode laser

the excitation. This requirement can be fulfilled if the absorption cell is mounted inside a nondegenerate optical resonator. The use of a resonator also allows a power buildup of the radiation and, therefore, an increase of the two-photon excitation. Furthermore, it provides exact retro-reflection of the laser beam, which is necessary to suppress residual first-order Doppler shifts. In the experiments [11.2445], the laser frequency was prestabilized in a first step to a resonance of this cavity. It could then be tuned through the two-photon resonance by changing the length of the resonator via a PZT actuator to which one of the mirrors is mounted. Compared to the results of the simple setup described before, the observed frequency stability was approximately the same. However, the light shift could be better controlled and consequently the frequency of the transition can be extrapolated more precisely to zero laser power.

Laser-cooled ensembles of Rb atoms have also been used for frequency stabilization to reduce the influence of the second-order Doppler effect [11.2447]. Further evaluations will show if a standard based on cold Rb atoms leads to a significant reduction of the relative frequency uncertainty. Nevertheless, in its present state, the Rb-stabilized laser represents an interesting precision frequency reference.

Stabilized Lasers Based on Atomic or Molecular Beams

Atomic and molecular absorbers are often prepared in beams rather than in absorption cells for various reasons. First, some gases such as hydrogen are not stable as atomic species and need to be prepared just shortly before excitation. Vapors of metals would soon coat the cell windows and strongly decrease their transparency. Second, the use of a collimated beam allows us to utilize an excitation geometry in which the laser beam crosses the atomic beam at a right angle. In the case of single-photon transitions, this may reduce the first-

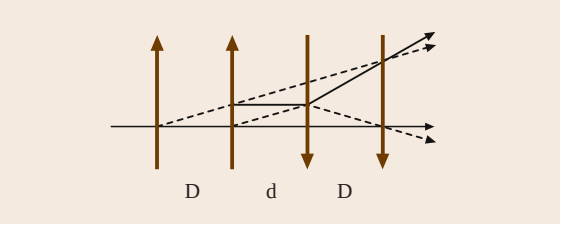

Fig. 11.293 Ramsey–Bordé matter–wave interferometer (the figure shows only those partial beams that lead to an interference structure)

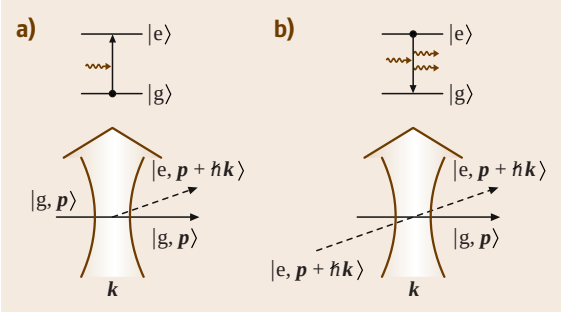

Fig. 11.294 Laser beams as beam splitters for an atomic wave

order Doppler effect by several orders of magnitude. Furthermore, for long-lived atomic states, the excitation and detection zones can be separated, leading to an increased signal-to-noise ratio since scattered light from the excitation beam can be better suppressed.

The mean velocity of molecules or atoms at room temperature ranges from approximately 100 m/s to more than 2000 m/s. At this velocity, the interaction time of the particles crossing the laser beam at a right angle, is typically less than 10^{-5} s for beam diameters of a few millimeters. Hence, the corresponding line broadening is more than 0.1 MHz. This broadening can be reduced by applying Ramsey's method of separated field excitation first introduced in the microwave range [11.2448]. For single-photon transitions in the optical regime, where the wavelength of the radiation is typically much smaller than the diameter of the atomic beam, additional steps need to be taken to use separated field excitation. This can be achieved either by blocking well-defined trajectories of the atomic beam [11.2449] or by using three [11.2450] or more [11.2451] spatially separated excitation zones.

An alternative method is a longitudinal excitation where the atoms fly parallel or anti-parallel to the laser beam. This method is suitable in the case of two-photon transitions. For example, one of the recommended radiations (Table 11.59) corresponds to the 1S–2S two-photon transition of atomic hydrogen. In the experiment, a beam of cold atomic hydrogen is formed by guiding hydrogen molecules through a gas discharge and reflecting the atomic particles at a plate which is cooled by liquid helium. The reflector directs the hydrogen atoms on the optical axis of an optical resonator which is tuned close to the 1S–2S two-photon transition. The *longitudinal* excitation inside a resonator allows the strong power buildup necessary for a two-photon excitation, precise mode-matching of the forward- and backward-running waves inside the resonator, and an increased interaction time of the atoms with the laser beam, leading to increased spectral resolution. The relative uncertainty of the transition frequency recommended by the CIPM is as low as 2.0×10^{-13} [11.2390].

In the case of single-photon transitions, the transverse excitation by separated laser fields (Fig. 11.293) is frequently applied to achieve high spectral resolution and a good signal-to-noise ratio. It was shown by Bordé that this method leads to an atom interferometer (Ramsey–Bordé interferometer) where the laser beams act as coherent beam splitters for the atomic beam [11.2452–2454]. The prominent advantage of optical Ramsey excitation with separated fields results from the fact that the transit-time broadening and the resolution can be adjusted independently. The former can be increased by choosing short interaction times in each zone, thereby allowing a large fraction of the atoms to contribute to the signal. The resolution, however, is mainly determined by the time of flight between the interaction zones. In the following, we give a brief description of the Ramsey–Bordé interferometer. Utilizing the internal energy structure of the atoms, absorption and induced emission processes can be used to split or deflect atomic beams. If an atom absorbs a photon from a traveling wave, it also absorbs the photon momentum $\hbar\boldsymbol{k}$ (Fig. 11.294a). Hence, the excited atom suffers a photon recoil. If the atomic wave was in the excited state before interaction with the laser radiation, the inverse process (induced emission) will occur (Fig. 11.294b). The probability ρ of observing such excitation or emission process depends on the intensity, the frequency of the light field, and the duration of the interaction. In general, the atom will be left in a coherent superposition of the ground and the excited state (Fig. 11.294). Since the atoms have different momenta in both states, it is more appropriate to use the picture of atomic wave packets. The interaction can act, e.g., as a 50% beam splitter ($\rho = 0.5$, $\pi/2$ pulse) or as a mirror

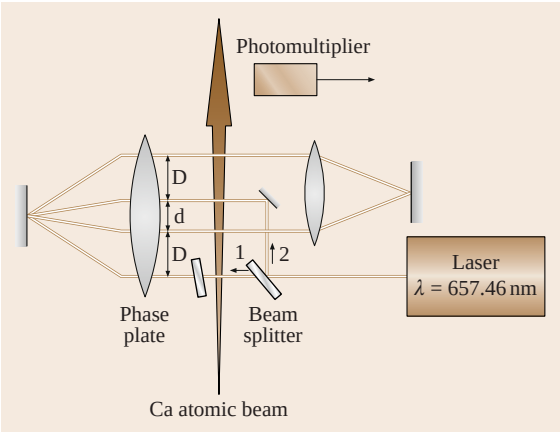

Fig. 11.295 Scheme of a transportable diode-laser frequency stabilized to the $^1S_0$–$^3P_1$ inter-combination transition by means of separated field excitation of a ^{40}Ca beam (after [11.2455])

($\rho = 1, \pi$ pulse). In any case, the phase of the light beam is transferred to the deflected partial atomic wave. If the light field is slightly detuned from the atomic resonance, the corresponding energy difference $\hbar\delta\omega$ is also transferred to the deflected partial wave as kinetic energy, and consequently the de Broglie wavelength is changed.

The combination of such beam splitters may lead to atom interferometers that are similar to an optical Mach–Zehnder interferometer (Fig. 11.293). During the first and each subsequent interaction, the matter wave is coherently split into partial waves with the internal states $|g\rangle$ and $|e\rangle$, which are represented by the solid and the dashed lines in Figs. 11.294 and 11.293. If an absorption or emission is induced, the momentum of the corresponding wave packet is changed by the photon momentum $\hbar\boldsymbol{k}$. At the final interaction, the loop of the trajectories closes and the laser field superimposes the partial waves, resulting in an atom interference. Since the atomic wave packets leave the two outputs of each interferometer in different internal states, the interference structure can be observed by monitoring the population either in the excited or the ground state.

The inter-combination transitions $^1S_0$–$^3P_1$ of the alkaline-earth atoms are well known to represent excellent references for optical frequency standards [11.2456]. They exhibit narrow natural linewidths of about 0.04 kHz (Mg), 0.3 kHz (Ca), and 6 kHz (Sr). In all three cases the frequencies of the $\Delta m_J = 0$ transitions are almost insensitive to electric and magnetic fields.

The inter-combination lines have been investigated in effusive beams of magnesium [11.2457], strontium [11.2458, 2459], and barium atoms [11.2460]. Most work for optical frequency standard applications has probably been performed with Ca atomic beams [11.2461, 2462]. This transition was investigated by various groups [11.2455, 2463–2465]. The radiation of a Ca-stabilized laser is also recommended as a reference frequency by the CIPM [11.2390]. As a typical example let us discuss the layout of a transportable Ca-atomic-beam standard (Fig. 11.295) [11.2455].

A few milliwatts of the available output power of an ECDL – pre-stabilized to a reference frequency of an optical cavity – is sent through a polarization-preserving single-mode fiber to a beam splitter/mirror configuration and is split into two beams 1 and 2 of equal power. From each one of the beams (1 or 2) crossing the atomic beam perpendicularly an excitation geometry with two pairs of counter-propagating laser beams is obtained by the help of two cat's-eye retro-reflectors. The co-propagating beams are separated by the distance $D = 10$ mm and the distance between the two innermost counter-propagating beams is $d = 13$ mm. The optical layout with the fused silica block is designed in such a way that the part 2 leads to the same excitation geometry as part 1, but its direction with respect to the atomic beam is reversed (Fig. 11.295). During the experiment, the laser beams propagate either in direction 1 or 2 and the beams propagating in the opposite direction are blocked.

The excited atoms are detected by measuring the fluorescence intensity from the decay of the excited atoms by a photomultiplier. The detected fluorescence intensity of the $\Delta m_j = 0$ transition versus laser frequency detuning $\Delta\Omega/2\pi = (\omega - \omega_g)/2\pi$, representing the frequency difference between the laser frequency $\omega/2\pi$ and the frequency $\omega_0/2\pi$ of the Ca inter-combination line, can be derived simplifying the expression given in [11.2451, (16), (17)] and integrating over the total velocity v.

I(\Delta_0) &= \int_0^\infty A(P, v, \Delta_0)\, f(v) \\
&\quad \times \left\{ \cos\left[2T \left(\Delta_0 + \delta_{\mathrm{rec}} + \frac{\omega_0 v^2}{2c^2} \right) + \Phi_{\mathrm{L}} \right] \right. \\
&\quad \left. + \cos\left[2T \left(\Delta_0 - \delta_{\mathrm{rec}} + \frac{\omega_0 v^2}{2c^2} \right) + \Phi_{\mathrm{L}} \right] \right\} \mathrm{d}v \\
&\quad + B(P, v, \Delta_0)\,. \qquad (11.272)
\end{aligned}
$$

In (11.272), $A(P, v, \Delta_0)$ describes the contribution of a particular atom with velocity v to the signal, and $B(P, v, \Delta_0)$ describes the amplitude of the background of the Doppler-broadened line including the saturation dip, both depending on the laser power P and weakly on the detuning $\delta\nu = \Delta_0/2\pi$ of the laser frequency. The factor $f(v)$ represents the velocity distribution, where we have neglected the influence of the velocity components perpendicular to the atomic beam.

$$\Phi_L = \Phi_2 - \Phi_1 + \Phi_4 - \Phi_3 \qquad (11.273)$$

is a residual phase between the four exciting laser beams having the phases Φ_i in the interaction zone, and $T = D/v$ is the flight time of the atoms between two co-propagating beams. The phase Φ_L – which shifts the frequency of the interference structure – can be detected by reversing the directions of the laser beams (from 1 to 2 or vice versa, Fig. 11.295) and compensated by rotating the phase plate [11.2455].

The phase of each cosine function in (11.272) contains three contributions. Besides Φ_L there are the terms Δ_0 resulting from the detuning, $\delta_{rec} = \hbar k^2/(2m_{Ca}c^2)$ from the photon recoil, where $\boldsymbol{k}$ is the wavevector of the laser field and m_{Ca} the mass of a Ca atom, and $\omega_0 v^2/(2c^2)$ from the second-order Doppler effect.

The signal for each velocity group v consists of two cosine functions with a period $1/(2T)$ that is determined by the distance D and the atomic velocity. The two components are separated by the recoil splitting $2\delta_{rec} = 2\pi 23.1\,\text{kHz}$. For an optimum superposition of the two cosines, the period should be an integer fraction of the recoil splitting. The FWHM linewidth of the signal is approximately given by $1/(4T)$.

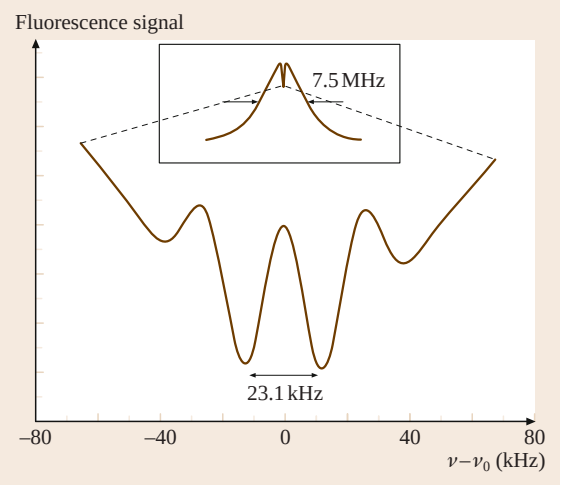

Fig. 11.296 Atom interference structures observed in a thermal beam of Ca atoms (after [11.2455])

From the measured fluorescence signal versus detuning $\delta\nu = \nu - \nu_0$ (Fig. 11.296) one clearly recognizes in the central part of the saturation dip the two central minima of the two cosine terms separated by the recoil splitting. With increasing detuning the cosine structure is washed out, since all velocity groups v of the atomic beam contribute with a slightly different period. The inset of Fig. 11.296 shows the total detected signal where the Doppler broadening is determined by the degree of collimation and the velocity distribution of the atomic beam, leading to a FWHM of the structure of 7.5 MHz. With an evaluated relative uncertainty of 1.3×10^{-12} combined with a relative stability of $\sigma(\tau) = 9\times10^{-13}$ at $\tau = 1\,\text{s}$, the transportable Ca frequency standard is one order of magnitude superior to the widely used transportable iodine-stabilized HeNe laser at $\lambda = 633\,\text{nm}$.

Optical Frequency Standards Based on Laser-Cooled Absorbers

In the case of frequency-stabilized lasers utilizing *thermal* absorbers, the uncertainty in the center of the reference line is ultimately limited by frequency shifts caused by residual phase errors in the optical excitation and by the second-order Doppler shift $\delta\nu/\nu = -v^2/(2c^2)$. Both frequency shifts scale with the velocity of the absorbers and can be reduced by orders of magnitude if the control signal is only generated by slow absorbers. In addition, the increased interaction time of the atoms with the laser beam leads to reduced broadening of the reference line. Hence, the most accurate optical frequency standards are based on cold absorbers. Two typical examples are described in the following sections. The first describes a standard utilizing a single trapped Yb^+ ion, whereas the second part presents a frequency standard based on an ensemble of cold Ca atoms.

Optical Frequency Standards Based on Cold, Stored Ions. The ideal reference for an optical frequency standard would consist of an ensemble of identical but independent atoms at rest in free space. This condition can be approximated in part by a single ion confined in a small volume inside an axially symmetric configuration of electrodes shown schematically in Fig. 11.297 (Paul trap) [11.2466]. Trapping is performed by applying a suitable RF voltage to the electrodes. Such traps allow us to store and cool *single* ions in the field-free region of the trap center. Linear ion traps [11.2467] al-

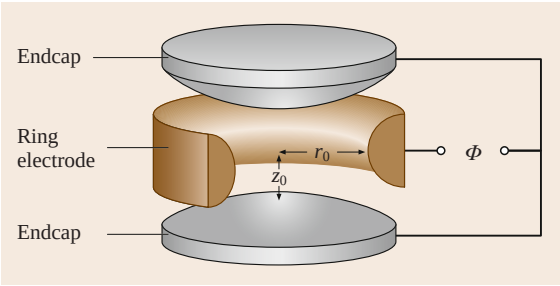

Fig. 11.297 Electrode configuration of an RF ion trap (Paul trap) (after [11.2466])

low us to store more than a single ion and microtraps might be [11.2468] used in future for laser frequency stabilization as well.

Ions suitable for precision frequency standards provide a closed transition for cooling and a reference (clock) transition. Cooling of the ion is performed by irradiating it with laser radiation which is tuned slightly below resonance and the cooling occurs by repeated absorption and emission [11.2469, 2470]. When the *clock* transition is probed, the cooling radiation has to be turned off in order to suppress light shifts and strong line broadening. The RF trapping field, however, may stay unchanged, allowing ideally unlimited interrogation times. If several ions are confined in a trap, their repelling forces will lead to an *ion cloud*, extending into the nonvanishing RF field and kinetic energy from the oscillating trapping field will be picked up. Such heating can be avoided if only a single ion is trapped in the center of the trap, where the trapping field vanishes. Since only *one* ion can contribute to the stabilization, it is important to detect the excitation of the reference transition with high efficiency. An efficiency close to 100% can be accomplished by the method of *electron shelving* [11.2471], which utilizes the fact that the strong fluorescence on the cooling transition is interrupted if the ion is excited to the upper state of the reference transition.

Several different ions are being investigated for applications in frequency-stabilized lasers. Very promising results have been observed with standards based on the ions of mercury [11.2472], strontium [11.2473, 2474], indium [11.2475], and ytterbium [11.2476, 2477]. As a typical example, we consider an optical standard based on a single ^{171}Yb ion (Fig. 11.298). There are three different clock transitions that can be accessed by the frequency-doubled radiation of diode lasers. The 435 nm clock transition has recently been observed with a linewidth as narrow as

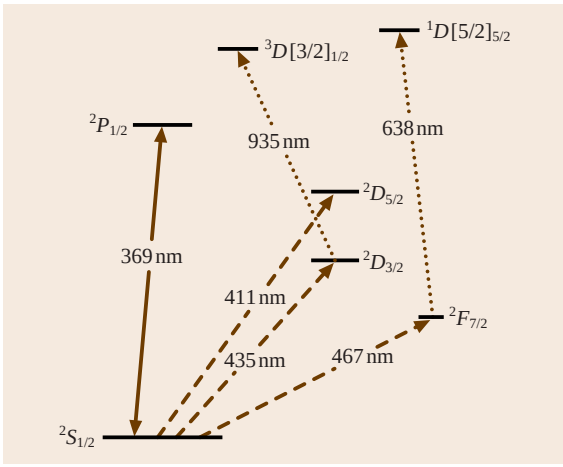

Fig. 11.298 Simplified energy-level diagram of ^{171}Yb

30 Hz (Fig. 11.299). In the meantime, this linewidth could be further reduced to 10 Hz [11.2478]. Utilizing this reference line a relative uncertainty of 1.1×10^{-15} was estimated recently [11.2479], demonstrating the great potential of optical frequency standards and optical clocks based on cold stored single ions.

A recent development based on quantum logic spectroscopy [11.2480] represents an extremely interesting alternative. Previously, quantum absorber candidates considered for optical clocks had to fulfill two criteria. First, a quantum transition is required with narrow natural linewidth which is highly immune to frequency shifts resulting from external fields and perturbations. Second, there has to be a suitable transition for laser cooling and detection. Using quantum logic spectroscopy, where a so-called *logic ion* that is entangled with the *clock ion*, i. e., the ion with the suitable clock transition is manipulated and interrogated. The entanglement assures that the external and internal states of both ions are intimately connected thereby allowing one to interact indirectly with the clock ion via the logic ion. With this technique the second criterion needs no longer be fulfilled. Due to its transitions in the UV, e.g., $^{27}Al^+$ ions were previously not accessible by lasers for cooling and interrogation even though $^{27}Al^+$ has a frequency of the clock transition which is extremely insensitive against external perturbations. With the quantum logic spectroscopy this ion can be utilized for the first time. An optical clock using the Al^+ ion as the clock ion and Be^+ or Mg^+ as the logic ion has been demonstrated with fractional uncertainties below 10^{-17} [11.2481].

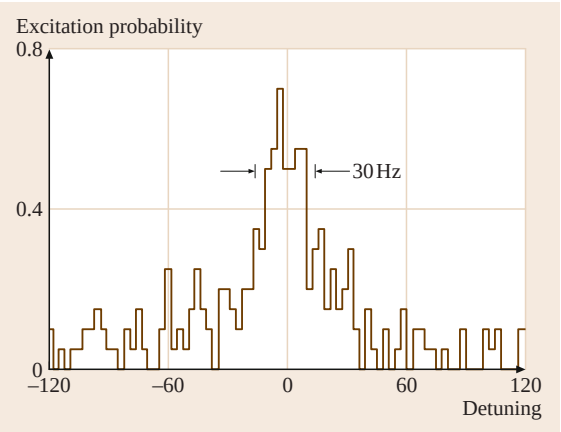

Fig. 11.299 Absorption signal of a single trapped and cooled $^{171}Yb^{+}$ ion (after [11.2476])

Frequency Standards Based on Cold Neutral Atoms. Neutral atoms can be cooled and trapped in a magneto-optical trap (MOT) [11.2482] if they have a suitable cooling transition. In contrast to ions, a large number of atoms in the range of 10^7 can be utilized to contribute to the stabilization, leading to an increased signal-to-noise ratio. However, to avoid unwanted frequency shifts, all trapping fields must be switched off when the reference transition is probed. Hence, the interaction time of the free atoms released from the trap is limited by their acceleration in the gravitational field.

Candidates for cold-atom optical frequency standards are silver [11.2483] and the alkali-earth atoms magnesium [11.2484, 2485], strontium [11.2486, 2487], and calcium [11.2456, 2461, 2483]. As a typical example, we describe a frequency-stabilized laser based on cold neutral calcium atoms.

Besides the narrow reference transition $^1S_0$–$^3P_1$ at $\lambda = 657\,\text{nm}$ (Fig. 11.300), ^{40}Ca has a strong cooling transition $^1S_0$–$^1P_1$ ($\lambda = 423\,\text{nm}$) that can be used to cool and trap Ca atoms in a MOT [11.2488]. On this transition, the Ca atoms can be cooled to approximately 3 mK. Further cooling to several microkelvin can then be achieved in a second step by means of the narrow inter-combination transition $^1S_0$–$^3P_1$ utilizing the method of *quench cooling* [11.2489].

In order to achieve high spectral resolution combined with a good signal-to-noise ratio (SNR), the method of separated field excitation in the time domain can be applied, similar to the spatially separated field excitation of an atomic beam. Short pulses of 1 µs duration are used to excite a significant part of the cold ensemble of atoms. The necessary high spectral resolution is then achieved by a sufficiently large time separation T between two consecutive pulses. If the lengths of the pulses are small compared to their separation, the width of the interference fringes $\delta\nu = 1/(4T)$ is inversely proportional to T.

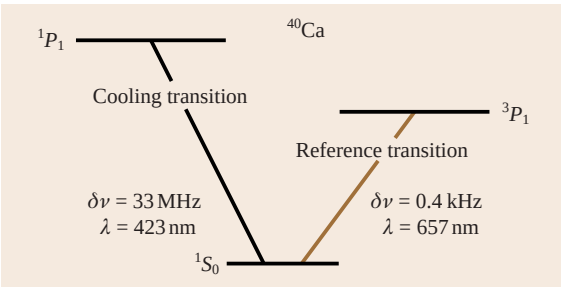

Fig. 11.300 Partial energy-level diagram of ^{40}Ca

Cooling and trapping of the atoms and probing of the clock transition are performed sequentially (Fig. 11.301). After the atoms have been trapped and cooled for about 15 ms in the first step, the trapping fields (laser beams and magnetic quadrupole field) are switched off, a small homogeneous magnetic quantization field (Helmholtz field) is turned on, and the clock transition is probed by two pulsed pairs of counter-propagating laser beams (Fig. 11.301). During this time, the cloud of cold, free Ca atoms expands according to the temperature of about 3 mK at a root-mean-square velocity of $v_{rms} \approx 80\,\text{cm/s}$. In the third step, the excitation to the $^3P_1$ state is detected by observing the fluorescence of its spontaneous decay to the $^1S_0$ ground state.

If the laser frequency is tuned across the atomic resonance, the fluorescence intensity contains a contribution that oscillates with the cosine of the laser detuning (Fig. 11.302). Similar to spatially separated field excitation, this oscillating behavior can be explained by an atom interference generated by the excitation with time-separated fields [11.2488].

The error signal for the stabilization is generated from the interference signal by modulating the laser

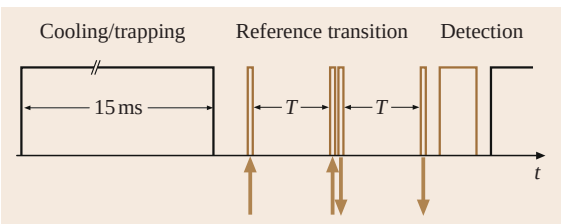

Fig. 11.301 Time sequence of atom cooling and trapping and probing of the reference transition

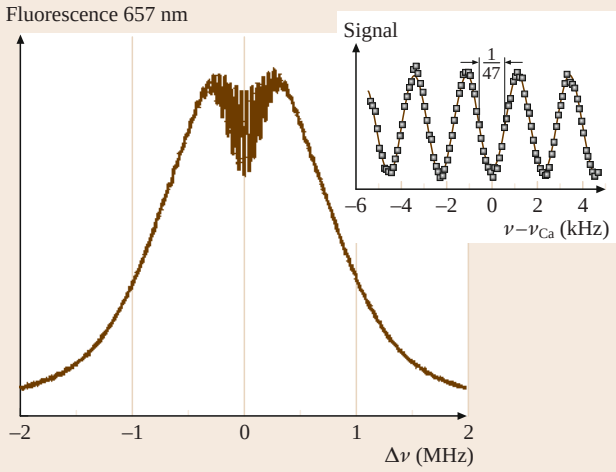

Fig. 11.302 Interference structure of cold, free Ca atoms generated by time-separated excitation

frequency and simultaneously measuring the fluorescence intensity. In the most straightforward approach, the frequency is square-wave modulated between two discrete values with the mean frequency tuned close to the center of the central fringe. The difference in the corresponding fluorescence intensities is used as the error signal. This method corresponds to a first-harmonic detection (1f method) of a servo control system using analog electronics and harmonic modulation. The maximum slope is obtained for a total modulation width of $\delta\nu_{\mathrm{mod}} = 1/4T$, i. e., if the frequency alternates between the points of maximum slope of the interference signal. After detection, the error signal is used to step the frequency of the laser spectrometer that corresponds to a digital integrating servo control. The linear drift of the eigenfrequency of the reference resonator can be determined by the servo control and compensated for by adding a corresponding feedforward signal to the signal controlling the laser frequency. Using Ca atoms, cooled on the $^1S_0$–$^1P_1$ transition to approximately 3 mK, a relative uncertainty of $\delta\nu/\nu \cong 2\times10^{-14}$ has been determined [11.2490]. The frequency stability of a laser stabilized to a ballistically expanding neutral atom cloud is ultimately limited by the interaction time of the atoms with the interrogating laser field. Considerable reduction of the interaction time broadening can be achieved if the neutral atoms are trapped in an optical lattice.

Frequency Standards Based on Atoms Stored in an Optical Lattice. Neutral atoms in an optical lattice experience a dipole force when the field polarizes the atom by separating the centers of the positive charge of the nucleus and the negative charge of the electronic shell. Such an optical lattice can be realized, e.g., by a standing laser field. The corresponding force on the atoms can readily be strong enough to confine the atoms in the nodes or antinodes of the standing light field. The atoms are then confined in a potential well corresponding to half a wavelength of the optical lattice field. Of course, this potential can shift the ground state and excited state connecting the clock transition by hundreds of kilohertz. However, if the lattice laser is operated at a so-called *magic wavelength* [11.2491], where the shifts of the ground and excited state are exactly the same, the net shift on the clock transition cancels. This cancelation is exact only for the states with the angular momentum zero, e.g., for the $^1S_0$–$^3P_0$ transition in the alkaline earth elements. In general, this transition would be totally forbidden for a transition with total electronic angular momentum $J = 0$ to $J = 0$. However, it can be excited for atoms with hyperfine interaction, e.g., for ^{87}Sr where the total angular momentum F (which also includes the nuclear spin) must be conserved. The $^1S_0$–$^3P_0$ transition can also be excited in the bosonic isotopes of Ca, Sr, and Yb if an additional magnetic field is employed that couples the $^3P_0$ with the $^3P_1$ state [11.2492]. Lasers stabilized by these methods have been operated using the $^1S_0$–$^3P_0$ transition of ^{87}Sr [11.2493–2495], ^{88}Sr [11.2496], and ^{171}Yb [11.2497] as optical clocks with fractional uncertainties below 10^{-15}.

During the past years several optical frequency standards have outperformed the best microwave clocks as the caesium atomic clock used to realize the definition of the second in the international system of units (SI). It is, therefore, likely that optical frequency standards will in the future lead to a new definition of the second in the SI. To prepare for this situation some of the optical frequency standards listed in Table 11.59 like the Hg^+-stabilized laser, the Yb^+-stabilized laser at 688 THz, or the ^{87}Sr-stabilized laser have been selected by the International Committee of Weights and Measures (CIPM) as so-called secondary representations of the second [11.2498] to investigate possible candidates for a new definition the second.

11.14.4 Measurement of Optical Frequencies

In many cases, the use of frequency-stabilized lasers requires precise knowledge of their frequencies. They have to be determined in relation to the primary standard of time and frequency, the Cs atomic clock. Earlier

concepts of optical frequency measurements used a harmonic frequency chain of several lasers [11.2499]. For example, measurements of the Ca inter-combination line with such a harmonic chain led to a fractional uncertainty of 2.5×10^{-13} [11.2500]. In the meantime alternative powerful methods have been developed to determine optical frequencies. An elegant and successful method is based on a mode-locked femtosecond laser [11.2501–2505]. Such lasers emit a continuous train of very short pulses covering a wide range of the optical spectrum of some 100 THz. This range can be further increased to more than one octave utilizing the phase modulation induced by the pulsed laser beam in an optical fiber of low dispersion [11.2506].

In the frequency domain, the continuous train of femtosecond pulses (Fig. 11.303a) corresponds to a comb of frequencies of which the inverse of the pulse separation is equal to the pulse repetition frequency f_{rep} (Fig. 11.303b). The value of an arbitrary comb frequency $\nu(m)$ is determined by

$$\nu(m) = \nu(0) + m\, f_{\mathrm{rep}}\,, \tag{11.274}$$

where m is an integer representing the respective order number of the comb frequency $\nu(m)$ and f_{rep} is the repetition frequency (Fig. 11.303b). Since the group velocity and the phase velocity of the short light pulses circulating in the laser cavity are slightly different an extrapolation to $m = 0$ leads to the frequency $\nu(0)$ which – in general – does not coincide with the zero frequency (Fig. 11.303b). According to (11.274), the determination of an arbitrary frequency $\nu(m)$ requires the knowledge of f_{rep}, the integer m, and $\nu(0)$. The pulse repetition frequency f_{rep} can be measured phase-coherently against the primary standard of time and frequency. If f_{rep} is larger than approximately 100 MHz, m can easily be identified by an interferometric wavelength measurement of moderate relative uncertainty ($\leq 10^{-7}$). In order to measure $\nu(0)$, we take advantage of the fact that the comb spans over a frequency range of more than one octave. This allows us to frequency double the low frequency part of the comb spectrum $\nu(0) + m\, f_{\mathrm{rep}}$ and beat it against the corresponding high-frequency part of the comb spectrum $2\nu(0) + 2n\, f_{\mathrm{rep}}$. This *self-referencing* of the frequency comb leads to a beat

$$\begin{aligned}\delta\nu &= 2\nu(0) + 2n\, f_{\mathrm{rep}} - \left[\nu(0) + m\, f_{\mathrm{rep}}\right] \\ &= \nu(0) + (2n - m)\, f_{\mathrm{rep}}\end{aligned} \tag{11.275}$$

that contains $\nu(0)$ plus integer multiples of the pulse repetition frequency f_{rep}. Since m, n, and f_{rep} are known, $\nu(0)$ can now be measured with very low uncertainty [11.2502, 2503]. Hence, any comb frequency $\nu(m)$ can now be connected phase-coherently to the frequency of the primary standard of time and frequency, the Cs atomic clock. Therefore, we can conclude that the frequency of any other laser emitting within the spectral range of the frequency comb can also be determined phase-coherently by measuring the beat between the laser frequency and a corresponding comb frequency $\nu(m)$. Femtosecond lasers have been applied for the first time to measure the frequency of 1S–2S two-photon transition in hydrogen, leading to the recommended values of the frequency given in Table 11.59 [11.2501].

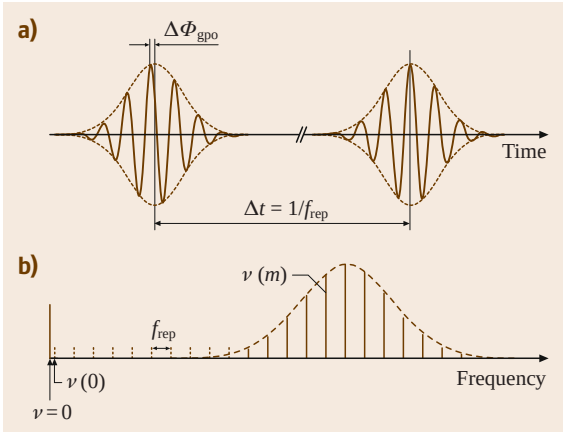

Fig. 11.303a,b Signal of a mode-locked fs laser, shown **(a)** in the time domain and **(b)** in the frequency domain

In the meantime femtosecond lasers are being widely used for optical frequency measurements in many laboratories worldwide. The first experiments applied titanium-sapphire femtosecond lasers as frequency comb generators. They will now be replaced by femtosecond fibre lasers in view of their high reliability, ease of operation, and accuracy [11.2507]. It has been shown that frequency comb generators based upon fs lasers are well suited for optical frequency measurements of the lowest possible uncertainty. Furthermore, it was demonstrated that frequency ratios could be determined with fs lasers with relative uncertainties as low as 10^{-18} [11.2508]. Basically, in their present state, frequency comb generators based on fs lasers allow the measurement of optical frequencies with uncertainties determined only by the uncertainty of the primary standard of time and frequency and the reproducibility of the stabilized laser, whereas the uncertainty of the comb generator itself can still be neglected.

A particularly interesting novel development is a frequency comb based on a microresonator [11.2509] where the mode spacing and offset frequency can be controlled, e.g., via the power and the frequency of the pump laser. This concept has distinct advantages in view of the compact size, low power, and large frequency separations of the comb lines. Octave spanning combs seem feasible [11.2509, 2510] thereby allowing for the application of the usual $1f$–$2f$ stabilization techniques [11.2505].

The frequency comb technique also allows one to transfer a very stable optical frequency to any arbitrary optical frequency. This technique has been applied, e.g., to transfer the frequency of optical frequency standards to a laser in the 1.55 μm regime. This frequency can be transferred via a fiber optical network to other locations and in turn locked to another frequency in the optical domain [11.2511]. This method allows for phase coherent dissemination of optical frequencies with arbitrarily good performance.

11.14.5 Conclusion and Outlook

The aim of this chapter was to review the foundations and methods of laser frequency stabilization including modern methods of optical frequency measurements. Regarding the wide field of lasers, laser spectroscopy, and frequency stabilization, and the fast development in these fields, this chapter could not be comprehensive within the limited space available. However, we hope that it presents a reasonable overview and gives some introduction to those scientists entering the fascinating field of laser frequency stabilization and laser spectroscopy.

The examples of stabilized lasers in Sect. 11.14.3 were discussed to illustrate the variety of methods applied in this field. The development of stabilized lasers is still progressing in various directions. One is the development of efficient, reliable and small lasers, e.g., diode lasers, diode-pumped solid-state lasers, or optical parametric oscillators (OPOs), which may be important to achieve efficient, reliable long-term operation. Another branch is the design of stable optical reference resonators to further decrease the laser linewidth close to the quantum limit. An important task is to isolate them from seismic influences and environmental disturbances. Here, alternative novel methods are being developed to compensate and reduce the seismic influence. A further reduction of the frequency uncertainty can be envisaged from the refinement of laser cooling. The introduction of optical frequency combs created by mode-locked fs lasers has provided us with a universal tool to determine optical frequencies and optical frequency ratios. This field will certainly be further explored by the development of frequency combs operating continuously over long periods and by increasing the total width of their emission ranges. It is expected that the combination of all these efforts will lead to optical frequency standards and clocks of unprecedented low uncertainty.
